A Teaching Guide to Flutemetamol F18 and Florbetapir F18, New Neuroimaging Agents for Evaluation of Dementia of the Alzheimer’s Type (DAT).

S Pamarthy¹, N Bohnen¹, K Frey², R Koepe², M Gross³, L Fig³
¹University of Michigan/Veterans Affairs Ann Arbor Healthcare System, Ann Arbor, MI,
²University of Michigan, Ann Arbor, MI, ³University of Michigan/Department of Veterans Affairs, Ann Arbor Healthcare System, Ann Arbor, MI

Purpose
Flutemetamol F18 is the latest PET brain imaging probe approved by the Food and Drug Administration (FDA) in October 2013 for evaluation of cognitive decline. It is the second agent for this indication; 18-F Florbetapir was approved in April 2012. High affinity binding of these probes to neuritic β-amyloid plaques estimates plaque localization and density, aiding the diagnosis of Dementia of the Alzheimer's type (DAT). An FDA-required, company-sponsored training program is mandatory for image interpretation. Imaging data sets require binary categorization of images as positive or negative. As an adjunct to clinical diagnosis, imaging results facilitate in vivo visualization of amyloid plaque held responsible for neuronal death and degeneration leading to symptoms of DAT. This educational exhibit reviews the latest approved PET probes in amyloid imaging, including methodology, interpretative guidelines and clinical case studies.

Materials and Methods
This educational poster will compare F-18 labeled Flutemetamol and Florbetapir under the following sections: 1. Technical aspects and probes used in PET amyloid imaging; 2. Interpretative criteria and clinical significance of imaging studies; 3. Advantages and pitfalls of amyloid imaging.

Results
¹¹C-Pittsburgh compound-B (¹¹C-PiB), a derivative of a fluorescent amyloid staining dye, Thioflavin T, is the gold standard among amyloid imaging probes. Its high affinity to β-amyloid plaques has been confirmed at autopsy in DAT cases. However, the longer half-life of newer fluorinated agents, 110 minutes (compared with 20 minutes for ¹¹C-PiB) make them ideal for clinical use. Flutemetamol F18, a fluorinated derivative of Thioflavin T, is structurally similar to ¹¹C-PiB; its cortical uptake/retention and β-amyloid plaque affinity also conforms with ¹¹C-PiB across the entire spectrum of DAT. The lower degree of nonspecific white matter uptake, color scale reading and slightly lower radiation dose are added advantages compared to the previous probe, 18-F Florbetapir, a stilbene derivative. A multi-society group recently has formulated appropriate use criteria to guide the clinical practitioner in optimal imaging indications. While a diagnosis of DAT can be made tentatively with positive results (greater than average cortical uptake) in conjunction with a strong clinical suspicion, a positive scan also may be observed with other neurologic conditions and normal aging. Negative imaging results decrease the likelihood
of dementia due to DAT. Although amyloid imaging at the present time is not approved to predict future dementia or monitor therapeutic response, this may be the greatest future potential of the amyloid-seeking agents.

**Conclusions**

PET amyloid imaging is gaining momentum with FDA approval of Flutemetamol F18 and similar agents. This poster seeks to disseminate the basic concepts of β-amyloid imaging to enable its clinical use in suitable patients and explore the diagnostic relevance of these agents. Further clinical trials will be needed to better understand the impact on patient outcome. Future availability of anti-amyloid disease modifying therapies is expected to significantly change the clinical utility of this new class of radiopharmaceuticals.

**Advanced Neuroimaging Tools for Planning/Guiding Occipital Lobe Surgery**

*E DeYoe¹, J Mathis², J Ulmer¹, W Mueller¹*

¹Medical College of Wisconsin, Wauwatosa, WI, ²Medical College of Wisconsin, Milwaukee, WI

**Purpose**

The complexity of evolving MR imaging (MRI) technologies and the wealth of new information they provide can make it difficult for clinicians to stay abreast of the latest developments and applications. This educational poster reviews clinically relevant aspects of functional MRI (fMRI) and diffusion tensor imaging (DTI) methods and their use in mapping the visual system to aid diagnosis of vision-related CNS pathology and to assist treatment planning, delivery and follow up. A unique focus is the use of novel methods to provide information that augments conventional brain image data. This permits better appreciation of the relationships among brain activation patterns, a site of operable pathology and the potential impact of invasive treatment on the patient's vision capacities/deficits.

**Materials and Methods**

A complete clinical workflow used at Froedtert Hospital/Medical College of Wisconsin and collaborating institutions for guiding surgical treatment of brain tumors, arteriovenous malformations and epilepsy is reviewed. Unique features of data acquisition, analysis and display are highlighted including the integration of neuroimaging and behavioral data into Functional Field Maps (FFMaps). FFMaps display brain activation patterns in the format of visual field maps highlighting the relationships between brain activation and visual sensation, and permitting presurgical estimation of potential postsurgical vision deficits. Case studies illustrating the advantages of this approach are reviewed.

**Results**

Functional MRI and DTI mapping of vision-related brain structures for clinical use requires interpretation of the imaging data in terms of the diagnostic/treatment goals and the patient's existing and post-treatment visual abilities, taking into account potential deficits that may be caused by the treatment procedures themselves. A substantial loss of portions of a patient's visual field may be acceptable in cases of life threatening illness though, even then, preserving critical foveal vision may be possible. However, when brain tissue is distorted due to tumor mass effects,
physical malformation or previous injury/surgery, then identification of eloquent tissue may be
difficult or impossible without fMRI mapping. Moreover, individual variation in the size of
primary and extrastriate visual areas and their positions relative to sulcal or gyral landmarks can
be considerable and avoidance of postoperative deficits may depend on careful surgical resection
to within millimeters of key structures. The occurrence of debilitating visual agnosias such as
prosopagnosia, alexia and akinetopsia are associated with lesions of specific extrastriate visual
areas whose locations or functionality are difficult to define for individual patients without
functional imaging. It also is becoming apparent that, without fMRI, it may not be possible to
fully diagnose/differentiate certain vision pathologies such as attention-related visual neglect
versus sensory field loss, and this can have important consequences for surgical planning and
outcomes.

Conclusions
Together, fMRI, DTI and behavioral tests can map visual system pathways and their 3-
dimensional configuration relative to a site of operable brain pathology. Yet, there is a significant
gap between the complexity and sophistication of the information that neuroimaging can provide
and its clinical use in comparably sophisticated ways. To maximally benefit patients, this
advanced knowledge must be conveyed to physicians at the forefront of daily medical practice.

Age-Based Approach to Pineal Region/Gland Lesions with Follow-Up Recommendations

D Durand\textsuperscript{1}, V Kalra\textsuperscript{1}, A Malhotra\textsuperscript{1}
\textsuperscript{1}Yale University School of Medicine, New Haven, CT

Purpose
Pineal gland lesions commonly are identified on brain imaging, with 25\% of normal human
subjects having an incidental pineal cyst and up to 40\% identified histologically at autopsy. The
diagnostic dilemma for the radiologist is to determine which patients need imaging of the entire
neuroaxis or continued follow up, with the purpose of avoiding unnecessary diagnostic imaging
and invasive testing. Pineal lesions are categorically presented by age of presentation, as specific
etiologies are clustered around different ages.

Materials and Methods
Malignant and benign lesions arising from the pineal region and gland are presented by patient
age, 0-10 years, 10-20 years, and greater than 20 years. Teaching points include key histological,
pathological, and imaging differences and similarities between the lesions. Information is
presented in pictorial format with lesions discussed individually, separated by age and
characteristics. Comparisons then are made between lesions to reinforce similarities and
differences to help the clinician narrow their differential diagnosis. The etiology,
pathophysiology, key characteristics and imaging findings, and clinical management are
included. Special emphasis is placed on management of benign pineal cysts by summarizing
recently published long-term epidemiological studies.

Results
The broad spectrum of pineal lesions will be presented by age and tissue of origin, with CT
and/or MR imaging (MRI) case examples. Lesions presenting in the 0-10 age group include pineoblastoma, trilateral retinoblastoma, germ cell tumors (germinoma, choriocarcinoma, teratoma, embryonal, and yolk sac), vein of Galen aneurysm/AVM, papillary tumor, pineal parenchymal tumor of intermediate differentiation (PPTID), lipoma, tectal glioma, and dermoid. Lesions presenting in the 10-20 age group include pineal cyst, germ cell tumors, papillary tumor, PPTID, lipoma and dermoid cyst (congenital). Lesions presenting in the 20 year old and beyond group include pineal cyst, meningioma, pineocytoma, papillary tumor, PPTID, metastatic disease, lipoma and epidermoid (congenital).

Conclusions
Pineal region and gland lesions represent a challenging group of lesions for the diagnostic radiologist. Understanding the key histologic differences and imaging characteristics is invaluable for differentiating benign from malignant lesions. Increasing the specificity of the differential diagnosis and providing the referring provider appropriate management recommendations is of utmost importance. Accurate identification of pineal lesions allows for entire imaging of the neuroaxis to be recommended for or against. Awareness of results of long-term robust studies can allow for radiologists to justify recommending against follow up for pineal cystic lesions up to 2 cm in size.

Pineal Germinoma

![Image](TCT_EdE-22_PinealGerminoma.jpg)

Heterogeneously enhancing 3.7 cm lobulated mass projects into the left lateral ventricle and 3rd ventricle with cerebellar mass effect. TIWI pre (left) and post contrast (right).

- **Etiology**
  - Male >>> Female. 90% in the first 2 decades of life. Majority in pineal region vs. suprasellar (3rd ventricle).
  - Derive from ectopic rests, transformation of nascent germ cells, or late migration.
- **Pathophysiology - MALIGNANT**
  - Histology resembles ovarian dysgerminoma & testicular seminoma. Large pleomorphic nuclei.
  - Well circumscribed. Solid ± cystic components.
  - No capsule- can be locally invasive! CSF dissemination is possible – evaluate entire neuroaxis!
  - ± syncytiotrophoblastic cells (14%) - more likely to secrete hCG.
- **Imaging characteristics**
  - CT: Hyperattenuation due to hypercellularity. Engulfs pineal calcifications. 100% calcified.
  - T1WI: iso- to hyperintense to gray matter
  - T2WI: iso- to hyperintense to gray matter
  - Enhancement on post contrast images
  - DWI: restricted diffusion due to hypercellularity
- **Management**
  - Biopsy with immunostaining. Sensitive to chemotherapy and radiation.
  - Prognosis 75-95% 5-10 year survival. Syncytiotrophoblastic types have poorer prognosis.

6:30AM - 9:00PM

**Cerebral Venous Thrombosis: State of the Art Diagnosis and Management**

A Dmytriw¹, C Poon², E Yu³, R Forghani⁴

¹University Health Network, Toronto, Ontario, Canada, ²Yale Medical School, New Haven, CT, ³University of Toronto, Toronto, Ontario, Canada, ⁴Jewish General Hospital & McGill University, Montreal, Quebec, Canada

**Purpose**

The purpose of this educational exhibit is to review the pathophysiology, clinical presentation, and neuroimaging of cerebral venous thrombosis (CVT). Different approaches for diagnosis of CVT including CT, MRI, US, and DSA will be discussed and the reader will become acquainted with imaging findings as well as limitations of each modality. Lastly, this exhibit will review the standard of care for CVT treatment including the use of neurorventional procedures.
Materials and Methods
The exhibit will consist of a basic overview of cerebral venous anatomy and pathophysiology, clinical presentation of CVT, and imaging findings suggestive of CVT on nonenhanced head CT (NECT). Thereafter, advanced imaging of CVT with CT venography as well as MRI/MRV will be discussed providing a comparative discussion of strengths and pitfalls of each modality. The use of US in the pediatric population will be discussed briefly. This will be followed by an overview of treatment options for CVT, including neurointerventional techniques, with cases illustrating reversibility of brain abnormalities after successful treatment.

Results
The presentation of CVT is often nonspecific, and requires a high index of clinical suspicion. The radiologist plays a key role by recognizing potential signs and patterns suggestive of CVT on NECT and confirming the diagnosis using more advanced neuroimaging techniques. Signs of CVT on NECT can be divided into indirect signs (edema, parenchymal hemorrhage in certain patterns and locations, subarachnoid hemorrhage, and rarely subdural hematomas) and less commonly direct signs (visualization of dense thrombus within a vein or cord sign, or within the cerebral venous sinuses such as dense triangle sign in the superior sagittal sinus). Confirmation is performed with CTV, directly demonstrating the thrombus as a filling defect, or MRI/MRV, which also provides superior characterization of parenchymal abnormalities. However, one must be familiar with pitfalls of each technique (e.g., variable density of thrombus on CT depending on thrombus age) and ancillary MRI sequences helpful for detection and confirmation of thrombi which will be discussed using case examples. General pitfalls and anatomical variants including hypoplastic sinus, bifid sinus, and arachnoid granulations as well as MR artifacts mimicking thrombus also will be discussed. Lastly, treatment algorithms including indications for the use of catheter-directed thrombolysis or thrombectomy in select cases will be reviewed.

Conclusions
Cerebral venous thrombosis (CVT) is a relatively uncommon phenomenon, and frequently overlooked at initial presentation. Familiarity with imaging features and diagnostic workup of CVT will help in providing timely diagnosis and therapy which can significantly improve outcome and diminish the risk of acute and long-term complications, optimizing patient care.

Classification of Glial Tumors in the Deep White Matter and Corpus Callosum

P Wangaryattawanich\textsuperscript{1}, Z Mahmood\textsuperscript{1}, L Chavali\textsuperscript{1}, A Kumar\textsuperscript{1}, L Ketonen\textsuperscript{1}, L Hayman\textsuperscript{2}
\textsuperscript{1}The University of Texas MD Anderson Cancer Center, Houston, TX, \textsuperscript{2}Anatom-e Information Systems, Ltd., Houston, TX

Purpose
To match the contrast enhancement pattern of gliomas of corpus callosum and deep white matter with the deep medullary vein territories defined by venous susceptibility maps.

Materials and Methods
One thousand untreated gliomas of the cerebral hemispheres were reviewed retrospectively. This sample contained seven primary enhancing gliomas in the corpus callosum and 50 deep white matter enhancing gliomas which touched to the lateral ventricular walls. The latter group included four un-operated cases with serial imaging of the enhancement pattern. The tumors were sorted into seven deep medullary venous territories each of which eventually drains into vein of Galen. These territories were defined by using previously published postmortem venography and ten normal venous susceptibility maps as the gold standard.

Results
Contrast-enhanced MR imaging of gliomas of the deep white matter and corpus callosum demonstrated pathognomonic intratumoral venous thrombosis and dilation of the normally invisible deep medullary veins due to intratumoral capillary shunting. Shape and location of enhancing gliomas in the deep white matter and corpus callosum matched seven deep venous territories: 1. the septal which drains the corpus callosum and frontal pole (BA 10), 2. the thalamostriate (terminal) vein which drains the upper part of the basal ganglia and the white matter of the posterior frontal and the anterior parietal lobes, 3. the anterior cerebral vein drains the undersurface of the rostrum of the corpus callosum and the adjacent orbitofrontal gyri (BA11), 4. the dorsal callosal vein drains the splenium and adjacent cingulate gyrus, 5. the basal vein of Rosenthal drains the medial and inferior parts of the occipital and temporal lobe and the insula, 6. the inferior ventricular vein of temporal horn drains the lateral part of the anterior temporal lobe and 7. the veins of occipital horn drain the lateral part of the posterior temporal lobe and the occipital lobe). In addition, there were three cases of internal radial patterns consistent with classic appearance of the deep white matter venous convergence arcs as defined by postmortem venography. The enhancement pattern in the corpus callosum included the adjacent cingulate cortex which was consistent with the territory of the paired septal veins which drain the corpus callosum through the roofs of the lateral ventricles. The previously documented dilatation of the valveless medullary veins in the normal white matter surrounding gliomas was seen in tumors. Case 1: Glioblastoma in septal venous territory. Sagittal and companion coronal postcontrast T1-weighted imaging demonstrates enhancement in the corpus callosum and adjoining left medial cerebral hemisphere. Capillary shunting within the tumor enlarges the deep medullary veins.

Conclusions
Contrast enhancement of gliomas in the corpus callosum and deep white matter can be used to
assign tumors to one of seven venous territories thereby providing a much needed classification which can stratify patients for clinical trials and genetic mapping.

Clinical Applications of Dynamic Contrast-Enhanced Magnetic Resonance Imaging Permeability in Brain Tumors

J Ramalho¹, S Bazyar², Y Lee³, M Castillo³

¹University of North Carolina, Chapel Hill, NC, ²University of North Carolina, Raleigh, NC, ³University of North Carolina Chapel Hill, Chapel Hill, NC

Purpose
Permeability of blood vessels in brain tumors provides valuable information about blood-brain barrier (BBB) integrity, vascular morphology, nature of neovascularization, and tumor pathophysiology, and prognosis. Here we discuss the clinical applications of T1-weighted dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) permeability in brain tumors.

Materials and Methods
The most widely applied and accepted MR technique for permeability evaluation is DCE-MRI. During T1-weighted DCE-MRI, contrast agent accumulation results in T1-shortening and positive enhancement. Through pharmacokinetic modeling of contrast agent accumulation into the extravascular-extracellular space (EES), a number of parameters can be determined including: transfer constant (Ktrans or vascular permeability) that is a combination of capillary wall permeability surface area product per unit volume of tissue (PS) and capillary blood flow.
volume of the EES (Ve) and fractional blood-plasma volume (Vp). We use a dedicated T1-weighted DCE sequence as part of our standard protocol for assessment of intracranial mass lesions. All studies were performed on 1.5T and 3.0T MR systems and automated postprocessing was performed on a Versavue server® (iCad, Nashua, NH). Regions of interest (ROIs) were manually delineated avoiding areas of necrosis or hemorrhage and the higher values of Ktrans, Ve and Vp were considered for our study.

Results
Ktrans in metastases was higher than in glioblastoma (GB), however higher Ve was found in GB probably related to a higher degree of neovascularization. In contrast to GB, neovascularization was absent in primary central nervous system lymphoma which tended to have relatively low perfusion and permeability compared with GB. We found that permeability Ktrans was able to discriminate low- from high-grade gliomas, probably related to presence of immature and permeable vessels in high-grade gliomas. Differentiation between GB and abscess was also possible. In our study GB had higher perfusion and lower Ktrans compared to abscess. Radiation necrosis showed decreased perfusion and Ktrans with a very slow rate of enhancement whereas tumor recurrence resulted in high perfusion and permeability. Patients on antiangiogenic therapeutic such as thalidomide and bevacizumab demonstrated decrease in the enhancing volume, perfusion, and vascular permeability as a response to treatment.

Conclusions
Current clinical applications of DCE-MRI microvascular permeability in brain tumors include differential diagnosis, tumor grading, and therapeutic monitoring.

Common and Uncommon Encephalitis Syndromes: Imaging Findings and Differential Diagnosis

R Forghani1, M Cortes2, M Levental1, N Wilson2, J Chankowsky4, L Rosenbloom1, C Torres4, R Del Carpio-O'Donovan5, D Tampieri2
1Jewish General Hospital & McGill University, Montreal, Quebec, Canada, 2Montreal Neurological Hospital and Institute, Montreal, Quebec, Canada, 3McGill University Health Centre, Montreal, Quebec, Canada, 4Montreal General Hospital, McGill University Health Centre, Montreal, Quebec, Canada, 5McGill University, Montreal General Hospital, Montreal, Quebec, Canada

Purpose
Imaging evaluation of patients presenting with encephalopathy syndromes can be challenging because of variable clinical presentation, patient's inability to provide a reliable history, and wide range of potential abnormalities seen on neuroimaging. However, there are key features and patterns on imaging that can help suggest and in certain cases diagnose the specific entity. As such, the radiologist plays an essential role in appropriate diagnosis and management of these patients. The objective of this pictorial essay is to provide an overview of imaging features and patterns encountered in the more common and uncommon but important encephalitis syndromes and differential diagnoses.
Materials and Methods
To provide an overview of (1) general imaging findings and patterns suggesting an encephalopathy syndrome with particular focus on MRI, and (2) to review specific examples of relatively common and uncommon infectious, metabolic, toxic and miscellaneous encephalitis syndromes with case-based differential diagnoses. The exhibit will include infectious etiologies: herpes simplex encephalitis, acute necrotizing encephalitis, acute disseminated encephalomyelitis, progressive multifocal leukoencephalopathy; Prion disease: Creutzfeldt-Jacob disease; metabolic and toxic syndromes: posterior reversible encephalopathy syndrome, osmotic myelinolysis syndrome, Wernicke's encephalopathy, hypoglycemic encephalopathy, drug-induced toxic leukoencephalopathy, metronidazole-induced encephalopathy; and miscellaneous and rare entities such as Cree encephalitis. Important variants of same disease (for example, hemorrhagic herpes encephalitis mimicking subarachnoid hemorrhage), and differential diagnoses (for example for herpes simplex encephalitis: PCA territory infarct, limbic encephalitis, astrocytoma involving the medial temporal lobe) will be illustrated and discussed.

Results
MR imaging (MRI) is the mainstay modality for characterization and diagnosis of encephalopathy syndromes. On MR imaging, T2/FLAIR, diffusion-weighted images (DWI), and occasionally contrast-enhanced images are the key sequences used for characterization and diagnosis. Encephalitis syndromes are characterized by different patterns of abnormal hyperintensity on T2 and FLAIR images depending on the specific pathology. Diffusion-weighted imaging (DWI) is important for distinction of vasogenic edema from cytotoxic edema and occasionally the abnormalities may be more evident on DWI than T2 or FLAIR images. The first step in recognition of an encephalitis syndrome is to distinguish the abnormalities from incidental nonspecific white matter changes and large or small vessel ischemic infarction. Some clues for distinction from the latter are (1) abnormality may not correspond to a typical vascular distribution, (2) mixed diffusion characteristics within a small area or between the cortex and subcortical white matter, (3) mass effect, earlier than would be expected with an acute stroke, (4) abnormalities may be partially reversible, (5) presence of normal or increased perfusion, and (6) occasionally gyral or leptomeningeal enhancement earlier than would be expected for an acute infarct. If focal, these must be distinguished from intracranial masses and venous thrombosis. As is often the case, a concise and proper clinical evaluation often can help narrow and focus the differential diagnosis. Specific examples of encephalitis syndromes, as outlined above, important variants, and their differential diagnoses will be illustrated and discussed.

Conclusions
Encephalitis syndromes can have complex and variable presentations. This exhibit will provide an overview of the more common and uncommon encephalitis syndromes and their differential diagnoses and mimics. Familiarity with the imaging patterns of these syndromes will help early recognition of these important entities and optimize patient management.

EdE-04

Demystifying the Subcortical U-Fibers: Spectrum of their Neuroimaging Findings with Reference to Underlying Mechanisms of White Matter Disease
T Matys, D Scoffings, K Allinson, T Massoud

Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom,
Stanford University School of Medicine, Stanford, CA

Purpose
U-fibers are white matter short association fibers connecting cerebral cortex of a particular region with that of adjacent gyri, thus forming discrete U-shaped bands immediately below the sixth (multiform) cortical layer. In neuroradiologic interpretation, the involvement of subcortical U-fibers by white matter pathologic processes, or their sparing, is an important feature in the imaging differential diagnosis of both inherited leukencephalopathies and acquired white matter diseases. In the current neuroradiologic literature there is, however, scant explanation of potential mechanisms of this differential involvement. It would be highly pertinent and useful for neuroradiologists to be familiar with these theories for better understanding of imaging findings and their significance when encountering U-fiber abnormalities.

Materials and Methods
We review the available data on mechanisms that underpin the involvement of U-fibers in pathologic processes in adjacent white matter, or their relative resistance to these perturbations. We present neuroimaging patterns of diseases typically involving or sparing the U-fibers, with neuropathologic microscopic correlation.

Results
There is evidence that U-fibers are the slowest myelinating fibers in the central nervous systems with myelination extending well into adulthood. Therefore, diseases that affect myelin degradation and recycling (turnover) rather than myelin synthesis tend to spare the U-fibers in which myelin turnover is very slow. Inherited metabolic defects of this kind include metachromatic leukodystrophy (MLD), globoid cell leukodystrophy (Krabbe's disease), and X-linked adrenoleukodystrophy. In contrast, in diseases affecting myelin synthesis or in which there is toxic damage to myelin, U-fibers are equally vulnerable as the remaining white matter (for example in Canavan, Alexander, van Der Knapp, or Pelizaeus-Merzbacher diseases). Mechanisms of toxic damage to myelin also probably apply to acquired demyelinating disorders such as multiple sclerosis, some cases of acute disseminated encephalomyelitis (ADEM) or progressive multifocal leukoencephalopathy (PML). Similarly, U-fibers are affected in cerebral amyloid inflammatory vasculopathy (CAIV) in which there is a combination of vasculopathy and inflammation, in keeping with the observation of their involvement in other inflammatory processes. Conversely, sparing of U-fibers by most arterial diseases may be explained by the microvascular architecture of the cortico-medullary junction. In addition to long penetrating medullary vessels, short pial vessels supply the interface of the white matter and the adjacent cortex. Thus, U-fibers are typically spared by white matter lesions caused by small vessel disease, CADASIL, and cerebral amyloid angiopathy (CAA). This double vascular supply may also explain U-fiber sparing in carbon monoxide poisoning and delayed hypoxic encephalopathy (Grinker myelinopathy), as well as their preservation in venous infarction due to dural sinus occlusion.

Conclusions
Resistance of U-fibers to pathological process in adjacent white matter may depend on different myelination rates and the vascular microarchitecture of the gray-white matter interface. U-fibers are, however, equally vulnerable to processes affecting myelin directly. This pictorial and
educational display will clarify the several possible underlying mechanisms of involvement of U-fibers in white matter diseases and the resulting neuroimaging findings.

EdE-23

From Baseball to the OR

A Klein¹, J Ulmer¹, W Mueller¹, L Mark¹, M Agarwal¹, A Ceranske¹, D Baruah¹
¹Medical College of Wisconsin, Wauwatosa, WI

Purpose
To explore the implications of a commonly encountered phenomenon in presurgical mapping of brain tumors using advanced imaging, mainly diffusion tensor imaging (DTI).

Materials and Methods
The "ball-in-glove" configuration of brain tumor and white matter fibers is presented using illustrations as well as images from clinical presurgical brain mapping studies. Discussion of presurgical DTI interpretation in the setting of clinical cases introduces and reinforces concepts of common yet critical functional systems. Implications of the "ball-in-glove" configuration and presurgical DTI for the neurosurgeon then are explored through examination of preoperative considerations, intraoperative techniques and assessments, and postoperative outcomes. Intraoperative photographs and postoperative imaging from clinical cases are used.

Results
The recently described "ball-in-glove" configuration in presurgical brain mapping commonly is encountered. The majority of presurgical brain mapping cases are performed for gliomas, white matter-based lesions. Because gliomas often are round, they tend to displace tracts about their periphery. The configuration is similar to a baseball within a glove, with the lesion mimicking the ball and the white matter tracts mimicking the palm and finger extensions of a baseball glove. This visualization can help the neurosurgeon, especially if specific tract border designations are described. An accurate description and visualization of high risk lesion borders will impact surgical planning as well as intraoperative assessments, allowing the neurosurgeon to test specific functions as the tumor is dissected along specific borders. This approach results in improved postoperative outcomes, maximized tumor resection and minimized postsurgical deficits.

Conclusions
Presurgical brain mapping for tumors has had a profound impact on patients. Diffusion tensor imaging has been critical in this process as it allows the neurosurgeon a better understanding of surgical risks and also how to avoid postoperative deficits. It is vital for the neuroradiologist to understand the commonly encountered "ball-in-glove" configuration and how to approach it during DTI interpretation.

6:30AM - 9:00PM
From Bench to Bedside: Inclusion of Magnetization-Transfer-Imaging into Routine MR Imaging in Multiple Sclerosis: Can Patient Management Benefit from Consecutive Monitoring of the Magnetization-Transfer-Ratio?

K Krueger¹, P Krueger²
¹Neurologische Gemeinschaftspraxis Hennef, Hennef, Germany, ²University of Geneva, Geneva 4, Switzerland

Purpose
When judging longitudinal MR imaging in multiple sclerosis (MS) beyond counting lesions and gadolinium enhancement, markers of myelin integrity are of additional value. As all applicable methods are considered costly in terms of scan time and postprocessing facilities, our aim was to test whether or not a routine approach in everyday conditions is at all feasible and beneficial for practical disease monitoring.

Materials and Methods
Based upon a neurological out-patient practice with a 1.5 T "workhorse" (Philips Intera-Achieva) we took an old-fashioned approach using Magnetization Transfer (MT): A PDW SE sequence before and after an off-resonance MT pulse (TR = 1710 ms, TE = 30 ms, NSA = 1, scan time 3:09 min) was added to our standard MS protocol, thus routinely providing both additional PDW image information and the opportunity for gathering data on myelin integrity in all patients and disease stages. We used the FDA approved software package nordicICE® for image segmentation, calculation of the Magnetization-Transfer-Ratio (MTR) and consecutive MTR histograms of the whole brain as well as FLAIR and gadolinium enhancing lesions. Statistical analysis was performed with STATA 12 using tests for (i) differences in mean MTR (ANOVA) and (ii) equality of distributions (Kolmogorov-Smirnov and Mann-Whitney tests).

Results
Our still ongoing (by its nature retrospective) study covers approximately 1200 patient years, and the longitudinal MTR registration proves to be valuable in monitoring disease activity of MS. We present as a "pars pro toto" three examples with the specific results of consecutive MTR monitoring and the corresponding MR images in (i) early failure of first line and following success of escalation therapy in aggressive tumefactive MS, (ii) development and course of Natalizumab associated progressive multifocal leukoencephalopathy in relapsing-remitting MS (RRMS), and (iii) patient surveillance in RRMS after therapy discontinuation on patient's request facing bothersome side effects of interferon treatment. During the monitoring period over up to 4 years, all presented cases showed gradual and significant (p<0.0001) changes in mean MTR and shifts of MTR histograms respectively. These always did precede the relevant clinical events - both to the worse and the better, and in our Natalizumab associated PML case even several months!

Conclusions
Longitudinal databases for consecutive monitoring of the MTR can be created for individual MS patients with reasonable effort, and the technique seems suitable for routine MR imaging procedures. Concerning scan time, addition of a PDW sequence before and after an off-resonance MT pulse (3:09 min @ 1.5 T) should be feasible in any clinical environment. The method itself is robust and reliable, and it seems valuable in predicting both lurking danger and trends to the better during the course of the disease. It thus can contribute to an improved clinical surveillance of MS patients and risk assessment of MS therapy. Limitations definitely arise from
the retrospective character of our still ongoing study and from restricted manpower for
postprocessing in a routine clinical setting without research funds. Vendors should make efforts
to incorporate "push-button" MTR procedures in their user interfaces; national societies should
develop and negotiate reimbursement schemes.

Half-a-Dozen Reasons to Map the Motor Cortex Presurgically

J Ulmer1, E DeYoe1, W Gaggl2, W Mueller1, A Klein1, L Mark1
1Medical College of Wisconsin, Wauwatosa, WI, 2University of Wisconsin, Madison, Madison, WI

Purpose
To demonstrate vital applications of presurgical fMRI localization of motor cortex, beyond that
afforded by anatomical landmarks.

Materials and Methods
Six distinct applications of presurgical fMRI localization of motor cortex are presented, and
illustrated with clinical cases. Critical clinical questions answered by presurgical fMRI as well as
postsurgical outcomes are reported. Functional MRI paradigms and strategies to localize the
motor cortex in a variety of clinical settings where anatomical landmarks alone are insufficient
are discussed. Adverse consequences associated with failure to map the motor cortex are
demonstrated and discussed as well.

Results
The precentral gyrus and motor cortex can be localized with sulcal and gyral landmarks in the
vast majority of patients without the need for presurgical mapping. Some practitioners believe
that motor fMRI is altogether unnecessary. However, there are critical circumstances requiring
presurgical mapping of the motor cortex, where anatomical landmarks are insufficient to answer
clinical questions that may impact surgical decision-making. Applications include multiplanar
localization, lesion-induced distortion of anatomical landmarks, homunculus localization,
congenital brain anomalies, informing DTI interpretations, and localization of nonvisible targets.
Preoperative and intraoperative surgical decision-making can be impacted by presurgical motor
mapping. This includes resectability, surgical trajectory, establishing functional resection
boundaries, and surgical target localization.

Conclusions
Presurgical mapping of the motor cortex is a vital service in institutions where perirolandic
surgeries are performed. Neuroradiologists should be versed in motor mapping to support
neurosurgical services and minimize postoperative motor deficits.

High Resolution Black Blood Imaging of Atherosclerotic Disease in the Carotid Bulb
M Trelles de Belaunde¹, T Saam²
¹UTMB Health, Galveston, TX, ²Ludvik Maximillian Universitat, Munich, AZ

Purpose
Atherosclerotic disease of the carotid bulb is a major cause of morbidity and mortality in the form of stroke. Current treatment guidelines are based on NASCET type carotid bulb stenosis. Black blood imaging has developed into a major tool in the characterization of diseases that affect the vessel wall. This exhibit will describe the imaging characteristics of carotid bulb atherosclerotic disease as depicted by black blood MRI.

Materials and Methods

Results
Black blood imaging is able to detect complicated atherosclerotic plaques of the carotid bulb which have an increased risk of stroke. This may be used in the future as a surrogate marker to decide for more aggressive medical or even surgical management.

Conclusions
The objective of this exhibit is to depict how atherosclerotic plaques of the carotid bulb can be characterized using high resolution black blood MRI.

KEYWORDS: Atherosclerosis, Black-Blood Technique, Black-Blood Vessel Wall

Hypertrophic Olivary Degeneration: Anatomy and Imaging

M Igra¹, I Djoukhadar¹, I Craven¹, D Warren¹
¹Leeds Teaching Hospitals, Leeds, UK

Purpose
The aim of this presentation is to provide a comprehensive review of hypertrophic olivary degeneration (HOD) through correlation of the normal anatomy with imaging abnormalities detected on MR imaging.

Materials and Methods
We describe, explain and illustrate the spectrum of imaging abnormalities encountered in HOD.

Results
Hypertrophic olivary degeneration is a rare entity and a form of trans-synaptic degeneration resulting from an insult to the triangle of Guillain and Mollaret. This pathway connects the dentate nucleus of the cerebellum, the red nucleus of the midbrain and the inferior olivary nucleus of the medulla. Using different diagrammatic illustrations and MR images (MRI), we will explain the relationship between the primary lesion and the resulting radiological appearances. We also include the three distinct MRI stages encountered in HOD.

Conclusions
It is important for radiology residents to recognize the imaging features and patterns of HOD.
This exhibit provides a detailed review of the imaging features with emphasis on the normal anatomy of the Guillian and Mollaret triangle.

KEYWORDS: Adult Brain, Degenerative, Olivary Degeneration

Imaging of Penetrating Traumatic Brain Injuries - Providing Added Value in Emergency Evaluation

J Johnson1, B Millard-Hasting2, G Punch3, S Stalcup4, M Huang3, J Romero4, J Talbott3
1University of California San Francisco/Joint Base McGuire-Dix-Lakehurst, San Francisco, CA, 2David Grant Medical Center, Travis Air Force Base, CA, 3University of California San Francisco, San Francisco, CA, 4Massachusetts General Hospital, Harvard Medical School, Boston, MA

Purpose
Penetrating wounds of the brain represent a small but significant segment of traumatic brain injuries seen in both civilian and in military settings. Both clinical treatment and imaging paradigms require unique considerations beyond algorithms used in blunt traumatic brain injuries. Purpose: 1. To review types of penetrating traumatic brain injuries along with pathophysiological considerations. 2. To illustrate the imaging findings in a variety of penetrating head injury mechanisms. 3. To discuss imaging and interpretation strategies focused on optimizing clinical decision making in the emergency and sub-acute setting.

Materials and Methods
Subcategories of penetrating head trauma will be reviewed using selected cases along with original medical illustrations. Imaging anatomy of the various pathophysiology of injury will be reviewed. Illustrated cases of the various patterns of injury will be reviewed using different imaging algorithms to demonstrate goal-oriented imaging evaluation.

Results
Penetrating head trauma represents a small proportion of the overall traumatic brain injury population; however, it is a unique clinical population with potential for high morbidity and mortality and requires unique considerations compared to the more common blunt head injury. This exhibit reviews the types of penetrating head injury using various imaging strategies focused on goal-oriented interpretation schemes.

Conclusions
After reviewing this exhibit, the reader will be familiar with the subtypes of penetrating head wounds and pathophysiologic considerations for these types of traumatic brain injuries. The imaging features and strategies for a broad spectrum of penetrating wounds are reviewed and discussed in the context of optimizing imaging strategies to assist in optimal clinical decision making.

Intracranial Contrast Extravasation during CT Angiography in Acute Trauma Settings: A Pictorial Presentation

A Eran¹, R Shreter¹, G Sviri¹
¹Rambam Health Care Campus, Haifa, Israel

Purpose
Recent reports have indicated that intracranial contrast extravasation during CT angiography (CTA) predict poor outcome and prognosis. The purpose of this presentation is to demonstrate different types of intracranial contrast extravasations.

Materials and Methods
From our clinical data we identified trauma patients with intracranial contrast extravasation on CTA. We present cases that demonstrate different type of hematomas in which contrast extravasation was present with technical and practical tips.

Results
We present intracranial contrast extravasation into epidural hematoma, subdural hematoma, hemorrhagic contusion and parenchymal hematoma. Setting an appropriate window level and scrutiny of the hematoma site are essential for correct identification of intracranial contrast extravasation. In some cases, hematoma growth can be depicted between noncontrast head CT and CTA.

Conclusions
Intracranial contrast extravasation can be detected during CTA in acute trauma settings. This imaging finding has significant clinical implications for patient care and Neuroradiologists should be familiar with it.

KEYWORDS: Contrast Extravasation, CT Angiogram, Traumatic Brain Injury

Intracranial Findings in Patients with IgG4-Related Disease

C Tiegs-Heiden¹, L Eckel¹, F Diehn¹, K Schwartz¹, C Hunt¹
¹Mayo Clinic, Rochester, MN

Purpose
Manifestations of IgG4-related disease have been reported in nearly every organ system. The purpose of this education exhibit is to describe imaging features seen in several patients with intracranial manifestations of IgG4-related disease.

Materials and Methods
In this series, we identified four patients with biopsy proven IgG4-related disease of the head and neck and intracranial involvement by imaging. Patient 1 is a 66-year-old female who presented to our Neurology department for further evaluation after an abnormal MRI of the head, performed elsewhere, for left-sided facial and ear pain. The patient has since been treated with steroids and rituximab, with resolution of her symptoms. Patient 2 is a 42-year-old female who presented to our Hematology department for "orbital pseudotumor." Her initial workup began secondary to a right-sided headache, intermittent right orbital swelling, and diplopia. The patient
was treated initially with steroids, and now has been transitioned to rituximab. Her symptoms have resolved. Patient 3 is an 82-year-old male who presented to our Endocrinology department for evaluation of proptosis. He was treated with steroids for several years, and then transitioned to rituximab. His proptosis has resolved. Patient 4 presented to our Hematology department in 1998 with proptosis. Steroids, rituximab, and radiation provided no symptom relief. He passed away in 2013 at the age of 52 secondary to end stage liver disease.

Results
Patient 1's initial MRI demonstrated dural thickening and enhancement centered at the left tentorium. The most recent MRI examination demonstrated moderate decrease in these findings. Patient 2's initial MRI demonstrated an enhancing mass in the right cavernous sinus. This had resolved on the most recent MRI. Patient 3's initial CT and MRI examinations demonstrated enhancing masses involving the bilateral cavernous sinuses and anterior Meckel's caves. Intracranial disease had resolved on the most recent CT. Patient 4's initial MRI demonstrated an enhancing mass involving the anterior right cavernous sinus. This lesion progressed after several years. A new enhancing mass was seen in the left cavernous sinus on subsequent examinations.

Conclusions
Intracranial involvement in IgG4-related disease can present in varying locations. In this small series, three of four patients presented with masses in the cavernous sinus, one of which extended to Meckel's caves. One of four patients presented with dural thickening and enhancement. The neuroradiologist should be aware of intracranial IgG4-disease, and include it in the differential diagnosis for these findings when appropriate.

KEYWORDS: IgG4 Related Disease
Magnetic Resonance Spectroscopy Patterns in Adult Intra-Axial Brain Tumors

N Sgarbi¹, O Telis¹, T Wozniak¹
¹Hospital de Clínicas, Montevideo, Uruguay

Purpose
Magnetic resonance imaging (MRI) is the best diagnostic tool in patients with central nervous system tumors with an excellent yield and cost/benefits ratio being consider as the gold standard for diagnosis and follow up. Conventional sequences (T1, T2 and FLAIR) and the use of paramagnetic contrast agents allow a precise diagnosis and detailed analysis in most cases, with
great anatomical resolution and real impact in initial therapeutic approach. In the last years we face various technologic advances in tumor diagnosis and treatment and it is a necessary multidisciplinary approach of the affected patient, where the radiologist plays a key role. At the present time MRI allows morphologic study and functional analysis of tumors using different techniques like diffusion, perfusion and magnetic resonance spectroscopy (MRS). MR spectroscopy is an imaging technique that allows to obtain noninvasive metabolic mapping of brain lesions with an excellent performance in patients with brain tumors. MR spectroscopy allows not only to mainly establish a more precise diagnosis of tumor kind, but in addition to evaluate regional extension, discard alternative diagnoses and a complete post-therapeutic evaluation and follow up. Our goal was to evaluate the contributions of MRS in central nervous system tumors and the main metabolic patterns in most frequent primary and secondary tumors in adult population.

Materials and Methods
To achieve our goal we analyzed the magnetic resonance images obtain in 300 patients over five years (2008-2013), with initial diagnosis of tumor, in which conventional MRI and MRS were acquired. MR spectroscopy were obtained in a closed field 1.5 T MRI unit, using PRESS technique, with both monovoxel lecture, TE 35 ms, and 2D or 3D multivoxel acquisition, TE 144 ms. In multivoxel acquisition tumoral and peritumoral areas were included. The authors performed a spectrum analysis with special attention to levels of n-acetyl-aspartate (NAA), choline (Ch), creatine (Cr), myo-inositol (mI) and lipids/lactate (Lip/Lac) in comparison with the same levels in the normal parenchyma contralateral to the lesion in each particular patient. Metabolic ratios of Ch/NAA, Ch/Cr, mI/Cr and Cr/NAA obtained in the lesion were analyzed and compared with the values of contralateral normal parenchyma and peritumoral areas. The MR images and radiologic initial diagnosis were compared with histological findings and definitive diagnosis. From the analysis we found five metabolic patterns in the most frequent adult brain tumors including primary and secondary lesions. We describe these patterns finding in each different tumor kind trying to establish the global MRS contributions to brain tumor diagnosis and initial therapeutic approach.

Results
From the analysis of the metabolic patterns obtained we found an excellent correlation with definitive histological diagnosis in nearly 98% of the patients, suggesting tumor histology and grade. Those metabolic patterns were divided into five main groups: nontumoral lesions, low grade glioma, high grade glioma, primary central nervous system lymphoma and brain metastasis with characteristic peaks and metabolite ratios in comparison with normal brain parenchyma and lesions from other group. Nontumoral lesions show normal NAA and Ch peaks, with normal ratios or under tumoral values, without Lip/Lac in almost all cases. Low grade gliomas show two patterns: pseudonormal with normal NAA and Ch peaks, and tumoral pattern with mI in those from astrocytic origin, and normal or high mI/Cr ratios. High grade gliomas showed a typical pattern: high levels of Ch, low NAA with ratios very high and Lip/Lac in those lesions with necrosis and lower mI/Cr ratio. A very suggestive finding was the presence of a definite tumoral pattern in the peritumoral area. Primary central nervous system lymphoma was a diagnostic dilemma with a typical tumoral pattern, with high levels of lipids and lactate in a solid tumor. All last secondary brain tumors show a typical tumoral spectra with normal appearance metabolic pattern in the peritumoral area. All of these patterns show an excellent correlation with definitive diagnosis with high levels of sensitivity and specificity, 90-95% varying with each group. MR spectroscopy is a MRI technique which provides semiquantitative information of metabolic
composition as a different area of normal and abnormal brain tissue. In most cases measurement of pathological area allows to differentiate between tumoral and nontumoral lesions, evaluate tumor grade in different nature and different areas of the same lesion, metabolic composition of adjacent normal appearing brain and evaluate the evolution of lesions and normal brain.

Conclusions
The use of MRS in brain tumors has been clearly proved, showing a great metabolic heterogeneity among different tumors. It allows characterization of tumors with high sensitivity and good rates of specificity being consider an excellent noninvasive preoperative diagnostic tool in predicting tumor histology and grade.

EdE-03

Molecular Neuroimaging of Brain Tumors Using Nanoparticles: A Pictorial and Educational Review of Basic Principles and Current Applications

J Ananta¹, R Paulmurugan¹, T Massoud²
¹Stanford University School of Medicine, Palo Alto, CA, ²Stanford University School of Medicine, Stanford, CA

Purpose
Despite advancements in surgery, radiotherapy, and chemotherapy, the survival rate for patients with glioblastoma remains poor. Difficulty in identifying tumor margins and tumor dissemination remain major obstacles for successful treatment of these brain tumors. Contrast agents that could improve anatomical, functional, and molecular neuroimaging are critical for better pre-operative tumor delineation and postoperative therapy monitoring. In this exhibit, we present an overview of the basic principles of nanoparticles as source of image contrast and discuss various platforms that show promise in brain tumor imaging.

Materials and Methods
Nanoparticles with their characteristic size, shape and surface functionality offer a new paradigm for enhancing the selectivity and sensitivity of imaging modalities. Though there is no universal definition for nanoparticles, optimal brain tumor imaging favors particles <200 nm in size. Nanoparticles are classified as organic (liposomes, polymers, dendrimers, etc.) or inorganic (metallic nanoparticles, etc.) based on the chemical nature of their core structure. We will highlight features of currently available nanoparticles in this exhibit.

Results
The inherent optical, magnetic and electrical properties of inorganic nanoparticles make them attractive candidates for imaging brain tumors. Iron oxide nanoparticles are under clinical investigation as T2-weighted MR imaging (MRI) contrast agents for brain imaging. However, systemic delivery of imaging and therapeutic agents to the brain is markedly hindered by the blood-brain barrier (BBB), which prevents nonregulated brain entry of blood-borne chemicals and imaging agents. Surface modification of iron oxide particles with targeting peptides enables significant accumulation in tumor resulting in better contrast enhancement. Recently, gadolinium (Gd) and manganese-based nanoparticles have emerged as T1-contrast agents for brain tumor imaging. These contrast agents exhibit higher efficacy of contrast enhancement than clinically
used Gd-based agents. When surface functionalized with targeting molecules they show enhanced selectivity towards brain tumors. Conversely, use of diagnostic optical imaging generally suffers from significant barriers such as tissue auto-fluorescence, attenuation by skull, and tissue absorption. That said, metallic nanoparticles show promise as optical imaging agents for intraoperative tumor resection. Quantum dots and gold nanoshells emit in the near infrared region where there is less biological attenuation. Thus, peptide targeted quantum dots have been used for imaging tumor vasculature. Similarly, RGD targeted gold nanospheres accumulate significantly in glioma tumor models and show promise in imaging tumor margins. Polymeric nanoparticles encapsulating small-molecule optical imaging agents also have been used for imaging tumor margins. Iron oxide nanoparticles functionalized on the surface with fluorescent molecules have shown promise as dual (MRI-optical) imaging probes. Similarly, 64Cu-DOTA has been conjugated on the surface of iron oxide nanoparticles for combined MRI-PET imaging.

Conclusions
Many of these nanoparticle applications have been evaluated in vitro or in animal models, suggesting the need for further optimization prior to clinical translation. Despite some advancements in targeted delivery, crossing the BBB is still a significant obstacle for many of the above-mentioned platforms when injected systemically. With the advent of multivalent targeting and better strategies for theranostic administration (convection-enhanced delivery (CED), intra-arterial delivery, etc.) to the brain, nanoparticle-based platforms will continue to show enormous promise in the field of glioma imaging.

Neuroimaging Findings of Encephalitis

C McKnight1, B Foerster1, A Nidecker2, S Gebarski1
1University of Michigan, Ann Arbor, MI 2University of California Davis, Sacramento, CA

Purpose
Encephalitis affects approximately seven in 100,000 people per year. Occurrence often is fatal, resulting in over 100,000 deaths annually. There are several different types of encephalitis including herpes simplex encephalitis, Epstein-Barr encephalitis, West Nile encephalitis and Rasmussen encephalitis. Herpes simplex encephalitis can be treated if diagnosed early enough; untreated herpes simplex encephalitis has a 70% mortality rate. Therefore as a radiologist, it is important to recognize the imaging features of encephalitis in order to raise the possibility of the diagnosis at the earliest possible stage. The aim of this study is to present radiological findings and complications associated with the different types of encephalitis in order to provide an educational background for physician trainees.

Materials and Methods
After IRB approval was attained, a search of our institutional imaging database was conducted to generate a list of adult and pediatric patients who presented between 1/1/1995 and 10/10/13 for imaging to evaluate possible cases of encephalitis. Radiology imaging including CT and MRI was reviewed. Pertinent medical records including clinical notes, surgical and pathology reports were reviewed and correlated with imaging.
Results
Search of our institutional imaging database demonstrated numerous cases of encephalitis. Salient imaging features and other ancillary findings characteristic of distinct etiologies are reviewed. Several cases of herpes encephalitis at various clinical and imaging stages both before and following treatment are described. Illustrative cases of encephalitis resulting from various other etiologies are also detailed, including examples of Epstein-Barr encephalitis, Rasmussen encephalitis, rhomboencephalitis, rabies encephalitis and West Nile encephalitis. Finally, various complications related to encephalitis are reviewed such as hemorrhage, ischemia, necrosis and shunt malfunction.

Conclusions
Early recognition of encephalitis is critical, but can be quite complex due to diverse pathologies and overlapping features. Familiarity with the salient imaging features for some of the entities as well as ancillary findings presented in this exhibit provides a basic framework for correct and early diagnosis.

Paradoxical worsening of symptoms following Type D carotid-cavernous fistula embolization: A case report

S Chaudhary¹, S Dalal²
¹Geisinger Health System, Danville, PA, ²Geisinger Medical Center, Danville, PA

Purpose
Syndrome of paradoxical worsening of ophthalmic symptoms following carotid-cavernous fistula embolization is an unusual phenomenon which usually results from thrombosis of superior ophthalmic vein (SOV)/cavernous sinus. Given its rare occurrence, it remains an under-recognized entity. We report serial imaging findings of a patient presenting with this syndrome.

Materials and Methods
Serial imaging studies on an 83-year-old male presenting with right ophthalmoplegia and tinnitus are reported, including pre- and postembolization CT/CTA, initially and following catheter arteriogram and fundoscopy findings.

Results
An 83-year-old male initially presented with gradual onset right ophthalmoplegia, proptosis and tinnitus. He was diagnosed with carotid-cavernous fistula on CTA and underwent a catheter arteriogram along with particulate embolization. This was followed by near complete resolution of symptoms. However, two months later he presented to the ER with severe right proptosis and ophthalmoplegia. Follow-up arteriogram demonstrated no residual AV shunting. However, CT orbits with contrast showed cavernous sinus thrombosis. The patient was managed conservatively with subsequent improvement without additional intervention. Such clinical deterioration has been attributed traditionally to increased blood flow through the malformations into the superior ophthalmic vein. However, in this case there was thrombosis of the cavernous sinus. The patient subsequently underwent spontaneous, complete resolution of symptoms. The alternation of clinical and angiographic findings in this case help to understand the etiology of paradoxical worsening of cavernous sinus DAVF and emphasize role of conservative management.

Conclusions
Syndrome of paradoxical worsening of ophthalmic symptoms following carotid-cavernous fistula embolization is an unusual phenomenon. Flow dynamics observed on follow-up imaging highlight the alternative explanation of clinical deterioration emphasizing conservative management of this rare condition.

Pictorial Review of Diffusion Tensor Imaging and Tractography

K Hsieh¹, H Neitzschman¹, J Nguyen¹, E Palacios¹, M Weidenhaft¹
¹Tulane University, New Orleans, LA

Purpose
1. Describe the physical principle and mathematics of diffusion tensor imaging (DTI).
2. Describe the utilization of the DTI data.
3. Describe the principle of tractography.
4. Review of normal anatomy of the fiber tracts of the brain in correlation with tractography of the white matter.
5. Illustrate the clinical applications of DTI to characterize disease processes in the brain.
including stroke, neoplasm, neurodegenerative disorders, congenital anomalies, traumatic brain injury, and demyelinating disease.

**Materials and Methods**

Illustrations will be provided to ease the understanding of tensor theory as applicable to diffusion imaging. MR images of the brain based on diffusion data and fiber tracts will be displayed.

**Results**

Diffusion tensor imaging is an advanced form of diffusion imaging in magnetic resonance imaging (MRI), which has shown useful applications in clinical imaging. However, understanding DTI is no easy task, since it involves highly complex mathematics and physics of tensor analysis. Diffusion imaging is based on the inherently random motion of the molecules known as Brownian motion. Diffusion tensor imaging exploits this characteristic motion of water molecules in tissues allowing full characterization of molecular diffusion in the three dimensions of space. Diffusion anisotropy effects can be extracted fully, characterized, and utilized, thus providing even more exquisite details on tissue microstructure. The two most common scalar metrics are fractional anisotropy (FA) and mean diffusivity (MD), which are used to generate images of the diffusion data. Tractography also can be performed using data from diffusion tensor imaging to allow the mapping of the white matter tracts in the brain.

**Conclusions**

Diffusion tensor imaging is a useful tool in mapping tractography of the white matter. Clinical applications of DTI include characterizing disease processes in the brain such as stroke, neoplasm, neurodegenerative disorders, congenital anomalies, traumatic brain injury, and demyelinating disease.

**KEYWORDS:** Brain, DTI Tractography, White Matter Tracts

**Postictal Encephalopathy: Role of Functional Imaging**

**M Bajaj**, T Moritani, A Capizzano, M Graham

**University of Iowa Hospitals and Clinics, Iowa City, IA**

**Purpose**

1. To illustrate MR imaging findings associated with postictal encephalopathy, with emphasis on diffusion-weighted imaging (DWI). 2. To describe pertinent findings in cases of postictal encephalopathy on perfusion studies and PET imaging. 3. To review seizure-related pathology with discussion of the differential diagnoses and imaging pitfalls.

**Materials and Methods**

We evaluated patients presenting with diagnosis of status epilepticus to Radiology and Nuclear Medicine departments of our hospital over a period of five years (2008-2013). Findings on different MR sequences, perfusion studies and positron emission tomography (PET) imaging were evaluated thoroughly and utilized to frame an educational exhibit describing underlying pathophysiology, imaging pearls, potential pitfalls to be avoided and imaging differentials to be considered thus formulating a systematic approach to diagnosis of postictal encephalopathy.

**Results**

1. Characteristic findings of postictal encephalopathy are increased T2/FLAIR signal and
diffusion-weighted imaging (DWI) abnormalities in the hippocampi, pulvinar/medial aspect of the thalami and within the neocortex and underlying white matter. FLAIR and T2 sequences are relatively sensitive in detecting edema related to status epilepticus, but lack specificity with regard to vasogenic versus cytotoxic etiology. Diffusion-weighted imaging increases this specificity. 2. Prolonged seizure activity leads to profound glucose hypermetabolism with only mild increase in blood flow during status in areas of MR signal abnormality. These findings can be appreciated with combined MR perfusion studies and FDG PET. Postictal follow up reveals hypometabolism/hypoperfusion in these areas. 3. Important imaging differentials of postictal encephalopathy include mesial temporal sclerosis, herpetic and nonherpetic limbic encephalitis, Hashimoto encephalopathy, anti-NMDA encephalopathy, hypoxic ischemic encephalopathy, PRES, central nervous system (CNS) vasculitis, extrapontine myelinolysis, mitochondrial encephalopathy, gliomatosis, Langerhans cell histiocytosis, neurofibromatosis type 1 and Creutzfeldt-Jakob disease.

Conclusions
A knowledge of underlying pathophysiology and functional correlation on advanced imaging may help diagnose postictal encephalopathy with certainty and exclude imaging differentials such as infarction, neoplastic conditions, encephalitis or other encephalopathy. This may help in preventing unnecessary or invasive management such as conventional angiography, biopsy, or inappropriate therapies.

Practical Approach to Analyzing Brain Stem Lesions in Daily Practice

H Nakamura¹, S Takuya¹, Y Nakajima¹
¹St. Marianna University of Medicine, Kawasaki, Kanagawa, Japan

Purpose
The poster is to list the wide spectrum of diseases affecting the brainstem and to show the characteristic radiological findings including clinical tips and secondary effect referring the anatomy of major white matter pathways.

Materials and Methods
The brain stem is the posterior part of the brain, adjoining and structurally continuous with the spinal cord. Because 10 pairs of the 12 cranial nerves come from the brain stem and the nerve connections of the motor and sensory systems from the main part of the brain to the rest of the body pass through the brain stem, it is an extremely important part. Because the very important part of the brain stem must not be damaged, the biopsy usually is not performed. So, a noninvasive technique is very meaningful to diagnose the disease. In the radiological field, magnetic resonance imaging (MRI) is the most sensitive and specific technique, because computed tomography (CT) is not very useful due to the bone hardening artifact. Magnetic resonance spectroscopy (MRS) is also useful especially in judging whether the lesion is a tumor or not. The knowledge about clinical profile (patient age, past illness, characteristic symptom, clinical course, laboratory data, etc.) is also important. We retrospectively reviewed one thousand MRI examinations in daily practice per year from 2009 to 2013.
Results
First of all, the normal anatomy of the brainstem nuclei and fiber tracts will be reviewed through anatomical diagrams and corresponding MRI in order to understand the reason why such radiological finding or symptom is produced. Second, radiological findings of the lesions affecting the midbrain, pons, and medulla will be presented and also clinical tips. The subtle or unclear CT findings are not omitted for education. These diseases include dilated Virchow-Robin space, infarction (according to the affected artery), specific cause (systemic lupus erythematosus, dissection), vascular malformation (dural AVF, cavernous hemangioma), demyelinating disease [neuromyelitis optica (NMO)], multiple sclerosis, osmotic myelinolysis, Wernicke encephalopathy, Bechet disease, posterior reversible leukoencephalopathy syndrome, tumor [glioma (high grade, low grade)], chronic lymphocytic inflammation with pontine perivascular enhancement responsive to steroids, degenerative disease (multiple system atrophy, progressive supranuclear palsy). Clinical tips are the characteristic symptom (e.g., NMO is hiccup), patient age (e.g., the peak age of the glioma is child), and specific laboratory findings (e.g., Wernicke encephalopathy is vitamin B1 deficiency). Finally, based on the anatomical knowledge, secondary effect (Wallerian degeneration, hypertrophic olivary degeneration ) will be presented.

Conclusions
The lesions affecting brain stem are diverse. Being unable to obtain the pathological diagnosis easily, the radiological findings may be the key factor to diagnose it.

Radiation-Associated Neoplasm: What Radiologists Should Know

A Sakata¹, T Okada¹, A Yamamoto¹, M Kanagaki¹, Y Fushimi¹, T Okada¹, T Dodo¹, K Togashi¹

¹Kyoto University Graduate School of Medicine, Kyoto, Japan
Purpose
Therapeutic advances in the treatment of malignant neoplasms including brain tumors have improved the prognosis but also have increased the risk of developing rare secondary tumors, which are often radiation-associated (i.e., secondary to radiation therapy). Our goal is to provide comprehensive review of clinical and imaging characteristics of various types of radiation-associated tumors.

Materials and Methods
Several cases of radiation-associated tumors, especially those affecting the brain, head and neck, at our tertiary care academic institution over the last several years will be selected for presentation. This educational exhibit will discuss the pathogenic background, the clinical presentation, and the imaging characteristics of radiation-associated tumors.

Results
Secondary radiation-associated neoplasms are usually associated with pediatric neoplasms including lymphoma, leukemia, retinoblastoma and pediatric brain tumor, but some of them occurred in adult patients with a history of postoperative irradiation for residual brain tumors such as pituitary adenoma or schwannoma. Secondary meningiomas, the most common second malignancy in the cranium, are characterized by a younger age, multiplicity and/or more aggressive clinical behavior than primary ones. High grade gliomas and other sarcomas occurred in the irradiation field may mimic tumor recurrence or other long-term toxicity such as radiation necrosis. Even in the situation with very limited clinical information, knowledge of imaging characteristics of not only secondary malignancy but treatment-related changes will give us a chance to diagnose correctly or suggest the possibility of secondary malignancy. Therefore, changes after radiation therapy also are summarized, and their relationships with secondary tumors will be discussed.

Conclusions
Radiation-associated neoplasm is a rare but dramatic late event that affects patients. Radiologist should be familiar with the long-term consequences of antineoplastic therapy to facilitate diagnosis and anticipate adverse outcome. Through this exhibition we hope to broaden our reader's knowledge regarding radiation-associated tumors.

EdE-17

Review of Bilateral Inferior Petrosal Sinus Sampling: Technique, Outcomes, and Utility in the Management of Hypercortisolemia

E. Lowther, P Morris, C Geer, M Baker
Wake Forest School of Medicine, Winston Salem, NC

Purpose
The aim of this exhibit is to review the technical aspects, procedural outcomes, and utility of bilateral inferior petrosal sinus sampling (BIPSS) in preoperative localization of hypercortisolemia in patients with Cushing's syndrome (CS). Cushing's syndrome carries a high morbidity and a five-year mortality approaching 50 percent in untreated cases. Therefore, it is of the utmost importance to localize the source of the hypercortisolemia for treatment planning.
purposes. However, the high dose dexamethasone suppression test, the standard noninvasive test utilized clinically to localize the culprit lesion, is only 60-80 percent specific for localization. Moreover, the presence of a demonstrable pituitary lesion on high resolution, dynamic contrast-enhanced magnetic resonance imaging (MRI) cannot solely be relied upon for localization, as up to 10 percent of the normal population has an incidental pituitary lesion by imaging. This exhibit demonstrates the power of BIPSS to definitively localize the source of hypercortisolemia.

Materials and Methods
We performed a retrospective case analysis with institutional review board approval of the 18 patients who underwent BIPSS for CS at our institution from 2000 to 2013. Simultaneous bilateral venous sampling with corticotrophin releasing hormone (CRH) augmentation was performed in all cases. Using a coaxial delivery system via a common femoral vein approach, microcatheters were advanced into each inferior petrosal sinus or as close to the sinus as was technically feasible. Peripheral venous access was established to allow sampling of peripheral venous blood as well. Venous samples were obtained from each source at baseline and then at specific time intervals following the intravenous administration of CRH. Central to peripheral ratios of the concentration of ACTH were calculated at each time interval. A central to peripheral ratio of greater than 2 at baseline and greater than 3 following the administration of CRH was considered positive for localization of hypercortisolemia to the pituitary.

Results
Bilateral inferior petrosal sinus sampling was successful in localizing the source of hypercortisolemia in all of the cases performed. Due to difficulty in accessing the inferior petrosal sinuses in two patients, it was necessary to place the microcatheters in the internal jugular veins approximating the inferior petrosal sinuses. A single patient experienced intense episodic muscle contractions immediately following administration of CRH, a rare, previously described reaction that subsided with time and supportive care and did not preclude successful completion of the procedure. There were no postprocedural complications.

Conclusions
Hypercortisolemia may present as a diagnostic quandary for clinicians in localizing the origin of abnormal cortisol secretion. This diagnostic uncertainty can be virtually eliminated with bilateral inferior petrosal sinus sampling (BIPSS), an invasive procedure that allows highly accurate localization of hypercortisolemia to the pituitary. Moreover, BIPSS has a high success rate and very low complication rate in the hands of an experienced operator. The exhibit demonstrates the significant diagnostic utility and viable clinical impact of BIPSS in the management of CS.

Sellar Masses: The Snowman Myth

A Namini¹, K Kazmi²
¹Hahnemann University Hospital, Cherry Hill, NJ, ²Hahnemann University Hospital, Philadelphia, PA

Purpose
Snowman morphology of sellar masses has been classically described with pituitary
macroadenomas. This configuration is caused by suprasellar extension of a pituitary adenoma with indentation at the level of diaphragma sellae. The purpose of this investigation was to evaluate reliability of this sign for diagnosis of pituitary macroadenomas and whether other sellar lesions could manifest with this morphology.

Materials and Methods
A search of the picture archiving and communications system (PACS) at our institution and affiliated hospitals was used as the primary tool for identification of sellar masses with the desired snowman morphology. Pathology and/or historical data were obtained to establish final diagnosis.

Results
Numerous sellar masses with the desired Snowman morphology were identified. These included pituitary macroadenoma, craniopharyngioma, optic nerve glioma, aneurysm, meningioma, Langerhans cell histiocytosis, abscess, nasopharyngeal tumors and metastasis.

Conclusions
Although the Snowman configuration of a sellar mass has been described as a classic feature of the pituitary macroadenomas, our study demonstrated that a variety of entities, both benign and malignant, could create this specific shape. Therefore, final diagnosis of these masses should be performed with attention to their overall imaging characteristics, clinical information and if necessary, pathologic correlation.

Spectrum of Calvarial Lesions: An algorithmic approach for formulating a differential diagnosis.

S Garla	extsuperscript{1}, R Rojas	extsuperscript{2}, R Bhadelia	extsuperscript{2}
	extsuperscript{1}Beth Israel Deaconess Medical Center, Brookline, MA, 	extsuperscript{2}Beth Israel Deaconess Medical Center, Boston, MA

Purpose
To illustrate the CT and MR imaging (MRI) findings of various calvarial lesions and how imaging can help with the differential diagnosis and guide further management.

Materials and Methods
CT and MRI studies of patients with calvarial lesions encountered at Beth Israel Deaconess Hospital will be presented in this exhibit. When possible pathologic correlation also will be provided.

Results
Skull/calvarial lesions frequently are encountered on both CT and MRI. The reported incidence of these lesions on radiography is approximately 7%, with benign etiologies more common than malignant ones. The appropriate differential diagnosis is important in determining further management such as biopsy, surgery or follow up. In this education exhibit the spectrum of calvarial lesions and their imaging findings on CT and MRI will be presented. Also, will describe an algorithm for formulating an appropriate differential based on patient demographics,
clinical history and imaging characteristics. When possible pathologic correlation will be provided.

Conclusions
Calvarial lesions are commonly encountered in everyday practice and imaging findings can help determine an appropriate differential that can further guide management.

KEYWORDS: Calvarial

Stroke Mimics, Pearls and Pitfalls: A Pictorial Essay

S Kamalian1, S Kamalian2, D Boulter3, M Lev2, R Gonzalez2, P Schaefer2

1Department of neuroradiology, MGH hospital, Boston, MA, 2Massachusetts General Hospital, Boston, MA, 3Massachusetts General Hospital / Harvard Medical School, Boston, MA

Purpose
Various vascular and nonvascular diseases can present with symptoms similar to ischemic stroke. These stroke mimics are commonly encountered in the emergency room, and it is estimated that between 9-31% of patients suspected of having an acute ischemic stroke have one of these mimics. Appropriate imaging studies, most importantly diffusion weighted imaging, usually facilitate diagnosis. Nevertheless, several diseases can present with diffusion abnormality adding to confusion. Our purpose is to discuss different mechanisms causing diffusion abnormality in various diseases and the patterns of involvement, to help narrow the differential diagnosis.

Materials and Methods
1. Multiple cases of known stroke mimics with diffusion abnormality who presented to our tertiary care academic institution over the last several years were selected. 2. We performed a review of the literature to guide discussion of radiologic findings and pearls and pitfalls in differentiating stroke mimics from acute ischemic stroke. Pathophysiologic mechanisms resulting in decreased diffusion also are discussed. 3. Various disorders are categorized based on the patterns of diffusion abnormality to help narrow the differential diagnosis. Typical case examples of these stroke mimics are illustrated and discussed with respect to those patterns. An algorithm for differential diagnosis based on DWI pattern in combination with vascular imaging and MR perfusion findings is presented.

Results
Diffusion abnormality with decreased ADC can be seen with cytotoxic edema related to energy failure of the membrane-bound Na/K-ATPase pump due to ischemia and/or excitotoxic injury; tissue vacuolization or spongiform change; high protein concentration and increased viscosity; or dense cell packing. Diverse etiologies can mimic ischemic stroke including vascular, metabolic, medication-related, infectious, inflammatory, neoplastic and traumatic etiologies. The pattern of diffusion abnormality in combination with vascular imaging and MR perfusion findings can help narrow the differential diagnosis.

Conclusions
Knowledge of the most important stroke mimics and their imaging findings is essential for timely diagnosis of acute ischemic stroke and its differentiation from those mimics. Although a
few recent studies have demonstrated that thrombolysis may be a safe option in case of stroke mimics, it is important to correctly diagnose the etiology of the stroke mimic so that the patient is treated appropriately.

KEYWORDS: Differential Diagnosis, Ischemia, Stroke

EdE-31

6:30AM - 9:00PM

J Rozell¹, S Li²
¹Baystate Medical Center, Springfield, MA, ²Baystate Medical Center, Longmeadow, MA

Purpose
The aim of this exhibit is to review and explore the different pathologies and imaging characteristics affecting the ventricular system of the brain. The disease entities discussed include but are not limited to intraventricular masses, pseudotumor, infectious or inflammatory diseases, etc. We will discuss how the various steps leading to their proper diagnosis can dramatically affect clinical outcome.

Materials and Methods
Related cases will be provided with initial presenting clinical signs and symptoms. The presentation will include but is not limited to the following: infectious and noninfectious diseases, non-neoplastic lesions, ventricular associated neoplasms, and choroid plexus neoplasms. Associated secondary conditions will be identified. Different imaging modalities from initial workup to advanced techniques will be illustrated for each case. Additionally included will be pertinent examples of peri-operative findings, virtual histology, and post-treatment clinical course.

Results
1. Discuss causes of ventricular pathologies and clinical presentations. Pictorial examples will be provided. 2. Case-based demonstration of characteristic imaging findings for diagnosis. Emphasis will be on advantages and disadvantages of various imaging modalities/techniques, which may include CT, MRI, or US. 3. Discuss complications including intracerebral and intraventricular hemorrhage, obstructive hydrocephalus, and mass effect. 4. Discuss differential diagnoses and their clinical courses.

Conclusions
Pathologies affecting the ventricular system are rare and often difficult for radiologists to appropriately evaluate. Because proper diagnosis and treatment can dramatically improve outcome, an understanding of a large number of clinical correlating conditions and imaging diagnoses are equally critical. At the end of the presentation, the viewer will become familiar with causes, clinical presentations, diagnostic imaging features, and differential diagnoses.

Under Disguise: A Pictorial Review of Tumor Mimickers

L Nakamura¹, E McCrum¹, M Nicolas-Jilwan¹

¹University of Virginia, Charlottesville, VA
Purpose
Multiple inflammatory, infectious, and structural brain disorders frequently are misdiagnosed as brain tumors on imaging studies. The purpose of this exhibit is to highlight the characteristic imaging features of a wide variety of brain tumor mimickers in an effort to minimize unnecessary brain biopsies and craniotomies.

Materials and Methods
We present examples of a variety of infectious, inflammatory, and congenital brain disorders that are frequently misdiagnosed as brain tumors on imaging. Emphasis will be made on the key differentiating features.

Results
We will first present a case of tumefactive demyelination: a teenage girl referred to our institution for brain tumor resection. Next is an unusual case of chronic calcified stage neurocysticercosis which exhibited enhancement on preoperative imaging and went on for resection as a presumed brain tumor. Additional infectious disorders with characteristic differentiating features including tuberculoma and toxoplasmosis are presented. Finally, we discuss a few cases of cortical dysplasia and emphasize some differentiating features from low grade glioneuronal tumors.

Conclusions
Knowledge of the patient's age, sex, background, and clinical history is crucial to keep a high level of suspicion for a non-neoplastic process in face of a mass-like brain lesion. Identification of the key imaging features of these disorders helps to make the appropriate diagnosis and minimize unnecessary brain biopsies and craniotomies.

KEYWORDS: Cortical Dysplasia, Toxoplasmosis, Tumefactive Demyelinating Lesion

Underreported yet Important Mastoid Emissary Vein

G Gong¹
¹Johns Hopkins University School of Medicine, Baltimore, MD

Purpose
The mastoid emissary vein is one of the posterior fossa emissary veins that traverse through skull base cranial apertures resulting in extracranial venous drainage of the posterior fossa dural sinuses. They can cause clinical symptoms such as tinnitus, spread infections, causes perfuse bleed, or can serve as a pathway for intracranial vascular intervention. This exhibit illustrates their anatomy through case presentation and reviews embryology and anatomy based on high-resolution CT, CT angiography, and MR venography images.

Materials and Methods
This exhibit reviews protocol optimization and multidetector CT (MDCT) findings of mastoid emissary vein with high resolution skull base CT, CT angiography, and MR venography images with 2D and 3D rendering.

Results
This emissary vein is usually small and asymptomatic in healthy population, connecting between the sigmoid sinus and posterior auricular or occipital vein by crossing the mastoid foramen, with
further drainage into the suboccipital venous plexus or external jugular vein. They can protect the brain from increases in intracranial pressure in patients with lesions of the skull base or neck and obstructed internal jugular veins. It can enlarge in patient with high-flow vascular malformations, hypoplasia or aplasia of the jugular veins. It has been reported that mastoid emissary vein can be used to access an isolated or inaccessible transverse or sigmoid sinus system. This vein also is a potential source of life-threatening bleeding during surgical procedures or trauma. Furthermore, surgical materials or air, such as bone wax, may predispose one to complications through this pathway. It also can be a source of sinus thrombosis after middle ear surgery. Knowing this vein pre-operatively would allow one to modify the surgical procedure to reduce complications. This vein also may constitute a potential risk for spreading infectious processes from extracranial to intracranial compartments. Thrombosis of this vein causes edema and tenderness of the postauricular soft tissue overlying the mastoid process, Griesinger's sign.

Conclusions
Mastoid emissary vein should be recognized and reported by neuroradiologist. After reviewing this exhibit, the radiologist will gain an understanding of the myriad of pathology that could be related to the mastoid emissary vein. The importance of noncontrast-enhanced CT to recognize the mastoid foramen also is emphasized, and through case review, those MR and CT findings are illustrated.

KEYWORDS: Venous Drainage
Vascular Anomalies and their Initial Presentation to the Emergency Department

S Lee¹, E Libfeld¹
¹Beth Israel Medical Center, New York, NY

Purpose
To review the initial emergency room presentations of various vascular anomalies and the pitfalls of diagnosing hemorrhage on nonenhanced computed tomography (CT). In cases where CT was the initial study, multiplanar reconstruction and subsequent magnetic resonance imaging (MRI) are crucial for clarifying the disease process and in some instances, altering diagnosis completely.

Materials and Methods
The clinical history and initial radiographic images obtained in the emergency room will be
presented, with identification of the abnormal imaging findings. Correlation will be made with multiplanar reconstructions and follow-up MR imaging, with discussion of the typical imaging and clinical features of different vascular anomalies.

Results
Clinical histories given by the emergency department for initial imaging scans include symptoms of stroke, headache, or a recent history of trauma. Initial nonenhanced CT is a quick way to evaluate for the presence of intracranial hemorrhage; however, a vascular anomaly without active hemorrhage may be mistaken for acute intracranial hemorrhage on initial CT. MR imaging can better evaluate vascular malformations. The cases we will present include a middle cerebral artery aneurysm found on nonenhanced CT; the initial diagnosis of questionable intracranial hemorrhage in a patient with reported trauma, later found on gadolinium-enhanced MR to be a capillary telangiectasia with a closely associated developmental venous anomaly; and a venous sinus thrombosis presenting to the emergency department with headache, among others.

Conclusions
While initial nonenhanced CT in an emergent setting provides valuable information, particularly in the setting of hemorrhage, or identification of an aneurysm, there are many times when additional imaging using MRI is needed. Particularly with vascular anomalies, MRI is useful for confirmation or further characterization. Otherwise, a vascular anomaly may be mistaken for hemorrhage, particularly when accompanied by clinical history of trauma.

Why is Balo Concentric Sclerosis Still a Surgical Disease?

J Anderson1, J Ulmer1, A Klein1, M Agarwal1, L Mark1, P Kochar1, C Lath1
1Medical College of Wisconsin, Wauwatosa, WI

Purpose
To elucidate the reasons and rationale for surgical biopsy of Balo concentric sclerosis, despite typical MR imaging (MRI) characteristics known preoperatively. To emphasize the pathognomonic imaging features of Balo concentric sclerosis and foster a correct diagnosis at presentation, thus minimizing the likelihood of a surgical biopsy.

Materials and Methods
Clinical and MR imaging features of three patients with histologically confirmed Balo concentric sclerosis are presented to illustrate the pathognomonic characteristics of the disease. Known classic imaging features and new physiologic imaging characteristics are presented and discussed. The perspectives of neurosurgeons and patients in proceeding with biopsy despite classic MR imaging features are analyzed through detailed electronic health record review.

Results
Balo concentric sclerosis is a rare demyelinating disorder characterized by alternating concentric layers of demyelination and relative myelin preservation, yielding a characteristic target appearance on T2-weighted images. The disease typically presents with acute onset of neurological symptoms and rapid clinical progression. On imaging, the lesion can enlarge over time, exhibit an MRS profile similar to that of tumor, and may not respond to typical doses of
glucocorticoids. Often, the lesion is initially misdiagnosed as neoplasm or neoplasm is considered in the differential diagnosis prior to entry into a tertiary center, though a misdiagnosis may be subsequently over-ridden by a trained neuroradiologist. This can result in contradictory interpretations in the setting of rapid clinical progression of neurological deficits. The anxiety associated with this scenario may engender an unnecessary surgical biopsy, which is more likely the longer the initial misinterpretation stands. Recognition of pathognomonic imaging features at presentation is essential to avoid a biopsy and its potential complications. An understanding of neurosurgical and patient perspectives as well as prompt contact between the neuroradiologist and neurosurgeon may influence surgical decision making.

Conclusions
Despite the best efforts of neuroradiology, Balo concentric sclerosis still may be misdiagnosed initially as neoplasm. Despite subsequent corrective interpretations, contradictory opinions in the medical record and psychological factors can prompt a biopsy. Identification of the pathognomonic imaging features at presentation and prompt communication with referring physicians should minimize the likelihood of a biopsy and its potential complications.

A Case-Based Review of Lesions Affecting the Lower Brainstem in the Adult and Pediatric Population

A Neymotin\textsuperscript{1}, R Hang\textsuperscript{1}, D Meltzer\textsuperscript{1}, D Lefton\textsuperscript{1}
\textsuperscript{1}St. Luke’s-Roosevelt Hospital Center, New York, NY

Purpose
The purpose of this educational review is to discuss and illustrate the broad spectrum of pathology that affects the lower brainstem, defined as the pons and medulla. Common pathologies as well as rare findings will be reviewed and the differential diagnosis for both the adult and pediatric population will be discussed. Clinical manifestation and radiological features will be examined for each entity with focus on MR imaging (MRI) findings. This review will aid the radiologist in the interpretation and characterization of lower brainstem lesions.

Materials and Methods
An illustrative review of the broad differential of etiologies including vascular lesions, infections, neoplastic processes, postradiation therapy lesions, ischemic and hemorrhagic lesions, and demyelinating disease will be presented. Additionally, various congenital and mitochondrial disorders, with focus on the radiological manifestations in the lower brainstem, will be presented. Examples include Leighs syndrome, Mobius syndrome, and mitochondrial leukodystrophy.

Results
The lower brainstem is a common site for various neoplastic processes. In the pediatric
population, neoplasms including pilocytic astrocytomas and medulloblastomas are commonly encountered, while postradiation gliomas also may be seen occasionally. Vascular malformations, including capillary telangiectasias and cavernomas, may be identified and differentiated from other neoplastic lesions based on their MRI features, providing an important diagnostic measure in determining possible therapeutic intervention. Manifestations of demyelinating disorders and infectious processes demonstrate varying patterns and are recognizable on MRI, including multiple sclerosis, influenza and abscesses. A variety of congenital and metabolic disorders may manifest with lesions in the lower brainstem. Knowledge of imaging features and clinical history is crucial to recognize and narrow down the vast differential diagnosis of lesions found in the lower brainstem.

Conclusions
Review of the broad differential of pathology affecting the lower brainstem in the adult and pediatric populations, with illustrative discussion of cases encountered at our institution.

An Image-Based Review of Intracranial Calcifications

A Militana\textsuperscript{1}, C Buckingham\textsuperscript{1}
\textsuperscript{1}Vanderbilt University, Nashville, TN

Purpose
Intracranial calcifications are encountered daily in clinical practice and can represent a broad spectrum of physiologic and pathologic conditions. The purpose of this educational exhibit is to provide an image-based review of common, uncommon, and rare cases in which intracranial calcifications may suggest a specific diagnosis or narrow a differential allowing the interpreting radiologist to facilitate patient management and care.

Materials and Methods
We present a collection of cases archived by neuroradiologists at our institution as a pictorial review of intracranial calcification.

Results
Intracranial calcifications can be classified broadly as physiologic, congenital, metabolic, infectious, inflammatory, dystrophic, vascular, and neoplastic. It is often possible to suggest a specific diagnosis based on the calcification pattern and location of the lesion as well as the patient's age and presentation. For example, a cystic mass with a calcified mural nodule within the temporal lobe of a young patient presenting with medically refractory epilepsy is most likely a ganglioglioma. When a specific diagnosis is not possible, the differential often can be narrowed with a familiarity of pathologic conditions in which calcification occurs. For example, periventricular calcifications in an infant are likely secondary to in utero infection such as cytomegalovirus, toxoplasmosis, human immunodeficiency syndrome, and herpes simplex virus. In some situations, calcifications may be the only finding to suggest an underlying abnormality. For example, a seemingly innocuous frontal lobe calcification encountered on unenhanced CT may represent an underlying vascular malformation or neoplasm requiring further workup.
Conclusions
Intracranial calcifications can be seen in a variety of conditions and are encountered frequently in clinical practice. Knowledge of the potential etiologies as well as typical imaging characteristics can help facilitate clinical management. It is for this reason that we find this image-based review of intracranial calcifications useful for both the training and practicing radiologist.

Angiographic Anatomy of the Neck Vasculature and the Major Anastomotic Connections

R Brandt¹, C Eskey¹
¹Dartmouth Hitchcock Medical Center, Lebanon, NH

Purpose
To demonstrate the arterial vasculature of the neck from the subclavian artery to the level of the
mandible anteriorly and the occiput posteriorly using CT and digital subtraction angiograms. Emphasis will be placed on the arteries not commonly studied with routine cerebral angiography.

Materials and Methods
The arterial vasculature of the neck will be demonstrated with labeled angiographic images. Major branches, vascular territory and important anastomotic connections will be described. Cases will be used to further illustrate the arterial anatomy.

Results
The arterial vasculature of the neck supplies many vital structures including the larynx, trachea, thyroid gland, spinal cord and brachial plexus. The vessels of the neck also have several important anastomotic connections to arteries that may supply the brain and spinal cord. The major arteries supplying the neck arise from the subclavian and external carotid arteries; they include the vertebral arteries, costocervical trunk, thyrocervical trunk, dorsal scapular artery, and superior thyroid artery. Knowledge of these arteries is important in the targeted embolization of head and neck tumors and vascular malformations. There are important anatomical variants of the vascular structures of the neck, chief among them the origin of the radiocolommedullary artery, which can originate from either the vertebral artery, deep cervical artery and less commonly, the supreme intercostal artery. Knowing the anatomy of these variants and being able to recognize them on angiographic studies is important to avoid cerebral or spinal cord infarction during embolization procedures. Further, there are clinically relevant anastomoses between the deep cervical artery, ascending cervical and vertebral arteries. These anastomoses allow for reconstitution of flow to occluded vertebral or carotid arteries.

Conclusions
It is important for the neuroradiologist and the neurointerventional radiologist to be familiar with the vascular branches that supply the osseous and soft tissue structures of the neck. Knowledge of the clinically relevant anastomoses of neck vasculature as well as anatomical variants can be helpful for delineating disease and for planning interventional procedures.

EdE-53

As Hard As the Rock: Imaging of the Petrous Apex

R Al-Sharhan¹, J Nair¹, C Torres¹, J Chankowsky¹, R del carpio¹
¹Montreal General Hospital, McGill University Health Centre, Montreal, Quebec, Canada

Purpose
To revisit the complex structural anatomy of the petrous apex, the adjoining cranial nerves and neurovascular bundles. To highlight the imaging features and salient differentiating characteristics of various petrous apex pathologies.

Materials and Methods
We archived 75 cases from the PACS with petrous apex lesions and then retrospectively analyzed each lesion based on location and characteristic imaging findings to reach a definitive conclusion.

Results
Based on the underlying cause, petrous apex lesions are classified into developmental,
inflammatory, infectious, neoplastic, vascular and osseous. We shall discuss some classical cases under each category having distinctive imaging features. The exhibit will include but is not limited to characteristic imaging features of the following petrous apex lesions on cross-sectional imaging: Petrous effusion, Pneumatization, Pseudo fractures, Mucocele, Cephalocele, Petrous Apicitis, Osteomyelitis, Cholesterol granuloma, Cholesteatoma, Meningioma, Schwannoma, Paraganglioma, Petrous Carotid Aneurysm, Endolymphatic sac tumor, Osteoblastoma, Giant cell tumors; Fibrous Dysplasia, Paget disease, Plasmacytoma, Chondroma, Chondroblastoma and Metastasis.

Conclusions
Lesions related to petrous apex cause diverse clinical sequelae ranging from mass effect to direct invasion of the neurovascular bundles. Due to its inert location, cross-sectional imaging plays an important role in recognizing, characterizing and also aids in treatment planning of the lesions. Understanding the anatomical units and their relations can lead to accurate and early diagnosis of petrous apex lesions.

KEYWORDS: Masses, Petrous, Petrous Apex
**CASE 1**

1: Axial CT section in Bone window showing a lytic lesion in the right petrous apex in a patient known with primary breast cancer

2: Axial MRI of the brain showing a Heterogeneously enhancing soft tissue lesion in the right petrous apex involving the carotid canal.

Clearing the air: Incidental foci of air observed on cross-sectional imaging

H Rama¹, A Iyer², E Libfeld¹

¹Beth Israel Medical Center, New York, NY, ²Mount Sinai Beth Israel, New York, NY
Purpose
On-call residents, as well as attendings, often are confronted with foci of air in abnormal places on CT scans of the head and sometimes even the spine. In some cases, this may be related to contrast injection or represent the sequela of routine vascular access obtained by a nurse or physician prior to scanning. This can be particularly troubling in the setting of trauma when small foci of venous air may raise alarm for skull base fracture. Similarly, in the setting of altered mental status, small collections of venous air may simulate infection. The purpose of this exhibit is to illustrate the typical regions in which air emboli may be found within the central nervous system (CNS) so as to help stratify suspicion for more ominous underlying injury.

Materials and Methods
We will use CT images focused on the head and spine to illustrate examples of air emboli and correlate these images with illustrations of corresponding venous anatomy.

Results
Blank

Conclusions
This exhibit will help on-call radiologists recognize the typical locations for venous air emboli within the CNS, in contradistinction to foci of air resulting from trauma or infection.

KEYWORDS: Iatrogenic, Venous Anatomy

EdE-51

Cortical Substrates of Cranial Nerve Functions

M Agarwal¹, J Ulmer¹, L Mark¹, A Klein¹, K McCollister¹, E DeYoe¹, D Baruah¹, C Lath¹
¹Medical College of Wisconsin, Wauwatosa, WI

Purpose
To elucidate the cortical networks subserving cranial nerve functions, using diagrammatic and MR imaging illustrations.

Materials and Methods
Color-coded cortical networks subserving cranial nerve functions are presented diagrammatically. Corresponding functional color-coded cortical regions and networks are illustrated on multiplanar high resolution MR images and on 3D brain illustrations for intuitive reference. Cranial nerve deficits associated with cortical lesions and network disruptions are discussed and localized. The impact of the functional laterality and recoverability on clinical outcomes are discussed as well.

Results
The functional realm of the cranial nerves extends far beyond postganglionic innervation of the head and neck. In addition to critical sensory and motor functions, cranial nerves are involved in complex neuronal functions including memory, circadian rhythm and sexual stimulation. Most of these functions are directly or indirectly controlled by the cortex. Lesions of cortex affecting cranial nerve functions may manifest a confusing clinical picture. Clinical symptomatology and natural history depends on the extent of functional bilaterality, functional recoverability, and disease process. Thus, unilateral lesions may cause permanent or transient deficits, but the period of recovery may vary depending on the involved network. Bilateral lesions due to etiologies such
as stroke, trauma, and demyelinating disease may cause permanent and debilitating deficits, some of which may be lethal. Bilateral lesions may be separated temporally, thus appearing as unexplained and atypical unilateral syndromes. Cranial nerve dysfunction associated with neurodegenerative diseases may not be apparent on imaging, but an understanding of the same will facilitate an accurate diagnosis. An intuitive understanding of cranial nerve cortical functional networks empowers clinical neuroradiology.

Conclusions
Cranial nerve functions are varied and complex. Cortical representations often are not emphasized in clinical neuroradiology practice. A conscious appreciation of cranial nerve cortical functional networks will foster accurate imaging diagnoses of cranial nerve disorders.

EdE-48

Diffusion-Weighted Imaging: Beyond Acute Stroke

AD mytriw1, V Sawlani2, J Shankar3
1University Health Network, Toronto, Ontario, Canada, 2New Queen Elizabeth, Birmingham University Hospitals, Worcester, Worcestershire, UK, 3QE II Hospital, Halifax, Nova Scotia

Purpose
Diffusion-weighted imaging (DWI) provides image contrast that is different from that provided by conventional magnetic resonance imaging (MRI) techniques. It is highly sensitive for detection of cytotoxic edema useful in the detection of acute infarcts. However, DWI is under-represented in the characterization of many other disease processes. The objective of this paper is to differentiate diseases that manifest with various neurological disorders, based on diffusion contrast and apparent diffusion coefficient (ADC) values and review hyper and hypo-intense lesions on DWI.

Materials and Methods
Content will be organized to first show how DWI is produced with a simple overview of spin echo and gradient pulse concepts, followed by a discussion of how patterns of diffusion reflect pathological processes. After reviewing the DWI/ADC characteristics in arterial and venous infarcts to consolidate the concepts of cytotoxic and vasogenic edema, we present cases of other neurological diseases for which there is good evidence for the utility of DWI. For each, DWI and ADC characteristics are explained pathophysiologically and compared with T1 or T2 MR findings. Lastly, a differential for diffusion-bright lesions is provided.

Results
We propose a differential diagnosis for diffusion-bright lesions, separated into the categories: Acute Ischemia, Infections, Tumors, Demyelination/Dysmyelination, Artifacts, Hemorrhage, Injury, and Metabolic Conditions. Since DWI is sensitive to early changes of cytotoxic edema, the sequence may show restriction in the descending white matter tracts that precedes Wallerian degeneration. In the acute stage of hypoxic ischemic injury, we usually see restricted diffusion in a pattern dependent upon the age of the patient and severity of the insult. In the chronic stage, there is free diffusion in the same distribution. Diffusion-weighted imaging is valuable in diffuse axonal injury because it identifies additional shearing injuries not visible on T2/FLAIR or T2
sequences. In brains that appear normal in the setting of CNS vasculitis, abnormalities may be demonstrated on DWI with lower ADC values in the anterior white matter, central white matter, thalami, and internal capsules. Abscesses appear hyperintense on DWI, with very low ADC values. Therefore, DWI is useful in the differential diagnosis of "ring-enhancing" cerebral masses. Diffusion-weighted imaging is more sensitive than conventional MR imaging in detecting early temporal lobe and limbic system cytotoxic edema of herpes encephalitis. In the setting of Japanese Encephalitis, DWI can reveal early involvement of the thalami. Apparent diffusion coefficient and index of diffusion anisotropy determinations have proven useful in the identification of arachnoid cyst, epidermoid cyst, meningioma, lymphoma and metastasis. Adrenoleukodystrophy changes on DWI are demonstrated often in the occipital lobes, with low ADC values. Lastly, the increased diffusivity of multiple sclerosis plaques, compared to that of normal white matter, appears to be more pronounced than corresponding T2 signal intensity changes.

Conclusions
Image contrast on DWI is dependent on the molecular motion of water, which is substantially altered by disease. A review of hyperintense and hypointense lesions on DWI with emphasis on the concept of cytotoxic and vasogenic edema may help in differentiating various neurological disorders.

Ecchordosis Physaliphora: A Report of Four Cases and a Review of the Literature

K Anton¹, S Dalal², J Smith³
¹Geisinger Medical Center, Danville, PA, ²Geisinger Medical Ctr, Danville, PA, ³Geisinger Health System, Danville, PA

Purpose
Ecchordosis physaliphora (EP) is a rare congenital hamartomatous remnant of the primitive notochord located in the midline along the craniospinal axis (1). Classically, they are asymptomatic and found incidentally on imaging or during an autopsy. Only few reported symptomatic cases are described in the literature. The purpose of this case series is to describe variations in imaging findings of this rare entity.

Materials and Methods
Four cases of retroclival ecchordosis physaliphora documented in imaging reports were identified by retrospective review of clinical charts. The reported cases were reviewed again by a neuroradiologist focusing on the imaging characteristics of EP. We present a case-based review of the imaging spectrum and a review of the EP literature.

Results
All four cases demonstrated classic findings reported in the literature including retroclival location, T2 hyperintensity, T1 hypointensity and nonenhancement, an important feature differentiating EP from chordoma (2). Irregularity and signal changes in the adjacent clivus were seen to varying degrees in all cases. Mild mass effect on the pons and basilar artery was identified in two. One of the cases was identified on workup for trigeminal neuralgia; however, no anatomical relationship of EP to the trigeminal nerve was noted on imaging. Although typically asymptomatic, cases of symptomatic patients have been reported when EP compresses adjacent structures (3). Few cases have been reported in the literature describing an association between EP and trigeminal neuralgia (4).

Conclusions
Ecchordosis physaliphora is a rare, benign lesion representing ectopic notochordal remnant, most commonly found incidentally on imaging. Precise knowledge of imaging characteristics, notably lack of enhancement, is vital in distinguishing EP from an enhancing chordoma (5). Patients with EP are managed nonoperatively, unlike those with chordomas who receive aggressive radiation therapy and surgery (6).

KEYWORDS: Chordoma, Ecchordosis Physaliphora
Focal Fluid Signal Change in the Cervical Spine: Anterior Median Fissure or Central Canal - Anatomical and Clinical Considerations

L Wang1, T Tomsick2
1University of Cincinnati Medical Center, Cincinnati, OH, 2University Hospital/University College Of Medicine, Cincinnati, OH

Purpose
Evaluation of fluid signal changes affecting the cervical spinal cord may impact further clinical patient management. Specific linear T2 hyperintense signal, variable in not only craniocaudal extent but also in position in the antero-posterior direction frequently are encountered. Corresponding axial cross-section sequences show these signal changes relatively anterior, in the midline, with variable appearance of linear or rounded T2 hyperintensity, or a combination giving the appearance of a key hole. The differential diagnosis for this finding includes the anterior median fissure, a normal anatomical structure not requiring any medical interventions or follow up, or hydromyelia which is the sequela to variable pathological processes, with the possibility of progressing and requiring surgical and/or medical interventions. Anatomical sections or depictions place the base of the fissure and the central canal separated by 1 mm or less, with variable width and diameter of the 2 structures. This exhibit aims to emphasize distinguishing features of the anterior median fissure versus hydromyelia in patient with dilated CSF channels in the spinal cord (as might be seen with Chiari malformation, hydromyelia, syringomyelia, multiple sclerosis). In doing so, these features may help to not only distinguish fissure from canal, but also to elucidate pathogenesis, pathophysiology of syrinx formation.

Materials and Methods
Prospective review of 1.5 T and 3.0 T magnetic resonance imaging (MRI) cervical spine cases encountered in a clinical practice with a busy neurosurgical unit is underway. The exhibit includes a series of interesting cases from ongoing review that will illustrate the purpose and issues at hand. Imaging features hypothesized to be useful in distinguishing the differential diagnoses will be presented. Temporal changes of focal fluid signal changes, when available, also will be reviewed.

Results
Focal fluid signal change is not an infrequent finding. Anterior median fissures can have a variable appearance. It also can change in size with time. Syrinx and a prominent anterior fissure can co-exist in the same patient. There may be a relationship between a prominent anterior fissure and syrinx formation.

Conclusions
Focal fluid signal change may pose diagnostic conundrum in some patients. Correlation of findings on multiple planes is essential to distinguish fissure from canal. Increased awareness of potential differential diagnoses and imaging features to distinguish normal variant from pathology will help to eliminate the need for additional or follow-up spine imaging.

KEYWORDS: Spinal Cord, Spinal Imaging, Syringohydromyelia
**Purpose**

To illustrate the relationships between critical brain functions and CNS vascular supply, thus producing an intuitive "functional vascular anatomy" atlas.

**Materials and Methods**

The arterial vasculature supplying functional brain networks are presented on color-coded reconstructed CTA and MRA images. Corresponding color-coded functional cortical and subcortical brain regions are illustrated on high-resolution magnetic resonance imaging (MRI), to provide an intuitive understanding of anatomical-functional-vascular relationships. Functional deficits associated with specific vascular lesions are discussed.

**Results**

Advanced imaging technologies including fMRI and DTI can provide localization of functional brain networks prior to neurosurgical intervention, and have led to improved outcomes and reduced postoperative deficits. While such information has allowed neurosurgeons to avoid direct injury to elegant networks, vascular risks also must be considered to optimize surgical outcomes. Functional networks remote from a resected lesion may be compromised by vascular injury. Functional vascular supply is a central consideration in endovascular surgical plans as well. The relationship to, or involvement of, eloquent vasculature by brain lesions should be elucidated prior to surgical intervention. While larger arterial vessels may be readily identifiable preoperatively and intraoperatively, small perforators supplying vital neurological functions may not. Some functional vascular distributions are shared or variable. For example, motor cortex and white matter pathways are supplied by spatially distinct subdistributions in the MCA, ACA, and PCA territories. Likewise, speech and language functions may be compromised by lesions of MCA, ACA, and PCA subdivisions. Perforating arteries arising from anterior, communicating, and posterior circulations supply various elements of the visual pathways. These also may supply structures vital to memory functions, including the fornix, mammillary bodies, and portions of the thalamus and mamillothalamic tracts. The rostral third of the hippocampus is supplied by the anterior choroidal artery arising from the ICA, while the posterior two-thirds is supplied by middle and posterior hippocampal arteries arising from the PCA. The exhibit intuitively illustrates motor, visual, memory, and language functional vascular anatomy using standard clinical imaging techniques, required to estimate surgical or endovascular risks and to promote safe therapeutic plans.

**Conclusions**

Presurgical functional brain mapping has proved its value in surgical decision-making. Functional vascular anatomy has been less emphasized among neuroradiologists, but is equally as important. A thorough understanding of functional vascular anatomy is within the domain of Neuroradiology and can enhance presurgical consultations, surgical decision-making, and the assessments of vascular diseases.
Imaging of Intracranial Germ Cell Tumors: A Pictorial Essay

J Nair¹, S Jaggi², C Saint-Martin¹, J Chankowsky¹, C Torres¹, I Talwar², R del carpio¹
¹McGill University Health Centre, Montreal, Quebec, Canada, ²Bombay Hospital, Mumbai, Maharashtra, India

Purpose
1) To revisit the WHO classification of types of intracranial germ cell tumors. 2) To review the location and general characteristic CT and MR imaging (MRI) findings of intracranial germ cell tumors with histopathologic correlation in some cases. 3) To discuss the differentiation diagnosis based on location.

Materials and Methods
A PACS search of CT and MRI examination was undertaken to identify and select cases representing germ cell tumors. An attempt was made to classify them based on location, CT and MRI findings. Note was made of clinical features and associated complications as mentioned in the history.

Results

Conclusions
Imaging findings of CNS germ cell tumors are nonspecific and correlation with clinical findings, oncproteins in CSF and serum with histopathological confirmation are required to arrive at the diagnosis.

Keywords: Germinoma, Teratoma

Imaging Review of Basal Ganglia and Thalamic Lesions

R Hang¹, D Lefton¹, D Melzter¹, A Neymotin¹
¹St. Luke’s-Roosevelt Hospital Center, New York, NY

Purpose
Assessment of disease of the basal ganglia and thalami can be complex, and often requires a combination of thorough clinical exam with history, serology workup, urinalysis, and imaging. The purpose of this educational exhibit is to categorically demonstrate a wide array of cross-sectional imaging findings of basal ganglia and thalamic lesions. Familiarity with these imaging findings will enable the radiologist to offer valuable information to the clinicians faced with diagnosing and treating these conditions.

Materials and Methods
This exhibit will provide a retrospective illustrative review of CT and MR imaging findings of various pathologic conditions which affect the basal ganglia and thalami. Categories of
underlying etiology will include metabolic, congenital, inflammatory, vascular, neoplastic, infectious, and neurodegenerative causes. The images are drawn from cases ranging back over 15 years. Some of the disease entities covered have characteristic findings on CT or MR, with a limited differential diagnosis. These findings will be emphasized, to aid the radiologist in improved detection and diagnosis. Other examples emphasize the importance of correlation with available clinical information and intracranial imaging findings outside the deep gray structures, or from imaging of other parts of the body.

Results
The basal ganglia and thalami are highly metabolically active, and various forms of metabolic derangement can result in a symmetric distribution of imaging findings. Metallic deposition, such as copper in Wilson's disease, or manganese in the setting of chronic hepatic encephalopathy, manifest as symmetric, bilateral imaging abnormalities. In addition, compromise of arteries or veins may present with symmetric findings, sometimes related to anatomical variation. However, as there is a vast differential of lesions involving the basal ganglia or thalami, many with nonspecific imaging findings, correlation with concurrent intracranial imaging findings outside the basal ganglia, supplemented with pertinent clinical information, can greatly aid in diagnosis. For example, in the setting of an asymmetric basal ganglia lesion, the history of immunocompromise could prompt the radiologist to recommend a thallium-201 brain SPECT examination to differentiate lymphoma from toxoplasmosis, or diffuse basal ganglia calcifications may suggest Fahr's disease in the presence of subcortical calcifications. Increased awareness of imaging patterns and corresponding histories will enable radiologists' to better recognize specific diseases of the basal ganglia and thalami.

Conclusions
Awareness of the common imaging patterns of various categories of disease is crucial for the radiologist's evaluation of lesions of the basal ganglia and thalami. Correlation with additional intracranial findings and with clinical history is also invaluable for deriving a limited and useful differential diagnosis for the referring physician.

Limbic System in and beyond the Border Zone: Functional Concepts and Clinical Correlation

A Elgendy¹, A El Nekidy¹, H Hamda²
¹University of Alexandria Faculty of Medicine /Egypt, Brookfield, WI, ²Medical College of Wisconsin, Brookfield, WI

Purpose
Limbic system is an ambiguous term used to describe a heterogeneous set of brain structures that drives from the diencephalon, mesencephalon and telencephalon. Despite of the diversity of these related structures they are connecting to form a neural circuitry that control visceral, olfactory, memory and learning functions. The expanding and crucial role of the limbic system has been the focus of the researchers. Detailed knowledge of the limbic pathway is essential for
the interpretation of the diffusion tensor imaging (DTI), functional MR imaging (fMRI) and routine clinical MR imaging (MRI).

**Materials and Methods**

The exhibit will describe the fiber pathways connecting the hippocampus to the basal ganglia, thalamus, amygdala, certain related cortical areas, and hypothalamus neural loops/circuitry. The morphology and location of these pathways will be related to readily visible anatomical landmarks and the functional significance of these connections will be illustrated.

**Results**

The key anatomical components of the intrinsic circuitry of the hippocampal formation are arranged transversely to the long axis of hippocampal formation. It is a trisynaptic circuit that projects from the entrohinal cortex. The entrohinal hippocampal intrinsic pathways are related to memory functions and learning. The afferent fibers that project to this intrinsic pathway are derived from cerebral cortex, the amygdala, the medial septal nucleus and the nucleus of the diagonal band mainly through the fornix, the anterior and midline nuclei of the thalamus via cingulate bundles and noradrenergic and serotoninergic fibers arising from the locus coeruleus and mesencephalic raphe nuclei projecting mainly through the fornix. The main efferent fibers of the hippocampal formation are mainly through the fornix. These projection fibers form the alveus and the fimbria.

**Conclusions**

The hippocampus contributes to several important functional pathways that affect memory function. Together with the amygdala participate in the elaboration of emotional behavior. Knowledge of these neural networks will not only improve the interpretation of routine MR imaging of the brain, DTI and fMRI but also will influence the application of those techniques.

**EdE-46**

**Neuroimaging of Cribriform Plate Lesions: A Comprehensive Pictorial and Educational Review**

F Zaccagna¹, E Raz², L Saba³, T Massoud⁴

¹University of Rome - Sapienza, Rome, Italy, ²New York University Medical Center, New York, NY, ³University of Cagliari, Monserrato, Italy, ⁴Stanford University School of Medicine, Stanford, CA

**Purpose**

The cribriform plate (CP) is a part of the ethmoid bone, and is also known as the horizontal lamina or lamina cribrosa ossis ethmoidali. Cribriform is indeed derived from the Latin word "cribrum" owing to its sieve-like perforations that transmit the olfactory nerves. Anatomically it straddles two cavities, forming part of the floor of the anterior cranial fossa, where it articulates with the ethmoidal notch of the frontal bone, and it also forms the roof of the nasal cavity. It therefore divides the intracranial cavity and brain from the nasal cavity and supports the olfactory bulb. Accordingly, the CP is at an anatomical crossroads for a great variety of important structures and a consequent wide range of diseases that can affect this anatomical region. Scant attention has been paid to comprehensive classification of the neuroimaging
manifestations of CP abnormalities. In this educational exhibit we review the neuroimaging findings of lesions involving the CP and classify them according to their etiology.

Materials and Methods
We review and present the imaging manifestations of a wide spectrum of pathologies originating from or involving the CP, and we classify these entities according to their etiology.

Results
We describe the imaging anatomy of the CP and the ethmoid bone. We comprehensively display a pictorial review and discussion of the imaging findings of lesions originating from the CP itself or invading it from adjacent structures. First we review congenital lesions (e.g., nasal meningocele, meningoencephalocele, nasal glioma and nasal dermal sinus cysts); then we discuss acquired benign pathologies such as mucoceles and fractures consequent to trauma. We review neoplastic lesions, both benign and malignant. Benign lesions include olfactory groove menigioma, olfactory Schwannoma, inverted papilloma, juvenile angiofibroma and dermoid or epidermoid, either within or outside nasal dermal sinus cysts. Malignant lesions include esthesioneuroblastoma, squamous cell carcinoma, sinonasal undifferentiated carcinoma, melanoma, olfactory neuroblastoma, rhabdomyosarcoma, sinonasal teratocarcinosarcoma, chordoma of the skull base and lymphoma. Bone lesions also may be divided into benign (e.g., fibrous dysplasia, ossifying fibroma, osteoma), or malignant, such as osteoblastoma, osteosarcoma, chondrosarcoma and metastases. Several infective and inflammatory diseases also affect the CP, namely: sinusitis, tuberculosis, and sarcoidosis. Rare findings include vascular lesions (e.g., dural arteriovenous fistulas and anterior ethmoidal artery aneurysms, or iatrogenic lesions) resulting in CSF leakage after anterior craniofacial surgery, or very rare cases of CP perforation during medical procedures within the nasal cavity.

Conclusions
Management strategies for lesions involving the CP vary substantially, depending on the abnormalities revealed on neuroimaging. We comprehensively review the wide spectrum of pathologies encountered in this often neglected area in neuroimaging. This presentation will aid in differentiating the many imaging appearances of lesions in this region.

Radiologic Anatomy of the Larynx

S Hauck¹, L Palińska¹, B Gosselin¹, J Paydarfar¹, C Belden¹, D Pastel¹
¹Dartmouth-Hitchcock Medical Center, Lebanon, NH

Purpose
The purpose of this exhibit is to provide a radiologic overview of laryngeal anatomy with CT and MR imaging (MRI), along with correlative laryngoscopically-obtained pictures and histologic sections. Understanding the radiologic anatomy of the larynx is critical for understanding patterns of disease spread along natural anatomical planes. It is also important for staging disease and treatment planning. For these reasons, both radiologists and clinicians should have a good understanding of normal laryngeal structures and their appearances on various imaging modalities.
Materials and Methods
Using CT and MR images, clinical and endoscopic photos, and histologic sections, this exhibit will review important anatomical structures of the larynx.

Results
The larynx is defined superiorly by the glossoepiglottic and pharyngoepiglottic folds superiorly and inferiorly by the lower margin of the cricoid cartilage. The cartilaginous scaffolding consists of the thyroid, cricoid and arytenoid cartilages. The larynx is divided into the supraglottic, glottic, and subglottic regions. Within the supraglottic larynx are five anatomical subsites: the suprahypoid epiglottis, infrahyoid epiglottis, laryngeal surface of the aryepiglottic folds, arytenoids, and false vocal cords. The glottis contains the true vocal cords and the anterior and posterior commissures. The subglottis extends from the inferior surface of the vocal fold and is difficult to visualize clinically. The mucosal surface of the subglottis is applied closely to the cricoid cartilage and should have a smooth surface. Laryngoscopy is very sensitive for mucosal pathology and laryngeal function. However, direct visualization of the deep structures of the larynx is solely the realm of radiologic imaging. With current CT and MRI resolution, structures of the larynx can be evaluated in great detail. Thus, a wide array of diverse pathology in addition to normal anatomy can be visualized.

Conclusions
Having a working knowledge of the complex anatomy and relationships within the larynx is critical to understanding the pathology of this region.

So You Think You Know Sensori-Motor Brain Anatomy

J Ulmer¹, A Klein², M Franczak², L Mark²
¹University Lake School, Hartland, WI, ²Medical College of Wisconsin, Wauwatosa, WI

Purpose
To foster a deeper understanding among neuroradiologists of sensori-motor functional anatomy and deficits associated with brain injury.

Materials and Methods
Cadaver brain images and overlaid illustrations foster a 3-dimensional (3-D) understanding of cortical functional anatomy and deficit localization. Correlative normal brain MR imaging (MRI) and functional brain mapping promote a 2-D understanding of sensori-motor brain anatomy. Sensori-motor cortico-cortical integration is discussed. Imaging of selected brain lesions illustrates applications in clinical practice. A stepwise approach focuses specifically on primary sensori-motor, pre-motor, and higher order sensory functional anatomy and deficits.

Results
The key to understanding functional anatomy of the sensori-motor system on cross-sectional imaging is an understanding of sulcal and gyral landmarks. Identifying these landmarks can localize functional anatomy of primary sensori-motor, pre-motor, supplementary motor, and secondary somato-sensory systems. In addition to obvious functional deficits such as contralateral weakness or basic sensory dysfunctions, neuroradiologists need to be able to
localize higher order deficits such as apraxia, mutism, acquired stuttering, alien hand syndrome, impaired discriminative sensations, and tactile agnosia, among others. An understanding of deficits and functional localization at standard cross-sectional imaging can impact diagnostic search patterns, imaging diagnoses, and imaging recommendations in patients with stroke, tumor, and other conditions. Sulcal and gyral landmarks are critical in interpreting brain mapping activation in normal as well as pathologic brains.

Conclusions
Sensori-motor functional anatomy and deficit locations can be identified readily by neuroradiologists using sulcal and gyral landmarks. An understanding of the sensori-motor system can improve diagnostic accuracy at cross-sectional imaging and functional brain mapping. A thorough understanding of sensori-motor anatomy and dysfunction is critical for the practicing neuroradiologists.

Spinal CSF Leak: Current Status, Imaging Techniques and Treatment

J Nair¹, J Chankowsky¹, A Maram¹, Y Wang¹, M Bagheri¹, C Torres¹, R del carpio¹
¹McGill University Health Centre, Montreal, Quebec, Canada

Purpose
1. To enumerate causes of spinal CSF leak. 2. To review the relationship between spinal CSF leak and spontaneous intracranial hypotension. 3. To analyze the various imaging modalities for detection of spinal CSF leak including their advantages and disadvantages. 4. To discuss possible treatment options.

Materials and Methods
1. Understand the pathophysiology of spinal CSF leaks, their clinical presentation and complications including spontaneous intracranial hypotension. 2. Discuss imaging findings of conventional brain and spinal MRI, CT/MRI myelography and radionuclear studies. 3. To showcase illustrative cases and discuss their findings. 4. Discuss treatment options including conventional conservative treatment, blood patch and surgical Intervention.

Results
1. MRI findings include: A) brain: i) Bilateral subdural collection with diffuse pachymeningeal enhancement. ii) Sagging of the brainstem with tonsillar herniation, crowding and effacement of the suprasellar cisterns and reduction in the mammillo-pontine distance. B) Spine (postintrathecal injection of gadolinium): i) Spinal extradural fluid collection. ii) Dilated perineural root sleeves, thought to be potential site of CSF leakage. 2. Radionuclide study: For delayed leaks. 3. CSF opening pressure following lumbar puncture: less than 12 cm of H2O at level of the right atrium.

Conclusions
This exhibit aims to reinforce the role of the neuroradiologist in diagnosis and treatment of spinal CSF leaks and associated complications, including spontaneous intracranial hypotension (SIH).

Subcortical Substrates of Cranial Nerve Functions

M Agarwal¹, J Ulmer¹, L Mark¹, A Klein¹, K McCollister¹, E DeYoe¹, T Chandra², P Kochar¹
¹Medical College of Wisconsin, Wauwatosa, WI, ²Medical College of Wisconsin, Milwaukee, WI

Purpose
To elucidate the subcortical networks subserving cranial nerve functions, using diagrammatic and MR imaging illustrations.

Materials and Methods
Color-coded subcortical nuclei and neural tracts subserving cranial nerve functions are presented diagrammatically. Corresponding color-coded nuclei within the thalami, basal ganglia, and brainstem and associated white matter networks are illustrated on multiplanar high resolution MR images and on 3D brain illustrations for intuitive reference. Various cranial nerve functional deficits are localized and recoverability is discussed.
Results
The importance of functional and anatomical knowledge of subcortical cranial nerve networks cannot be overemphasized. Despite awareness of these networks in the anatomical literature, their locations on imaging studies are not directly discernible and therefore may not be emphasized in imaging diagnoses. The literature is replete with cases of unexplained neurological symptoms without corresponding imaging findings, attributed to isolated involvement of cranial nerve tracts or nuclei by lacunar infarcts, small demyelinating plaques, or injury. Knowledge of cranial nerve network functions and locations is of clear importance in such instances. For example, pure sensory symptoms that can be explained by subtle lesions in subcortical nuclei of the thalami may be ignored or even attributed to psychiatric illness. In some cases, cranial nerve functions may be disrupted by unilateral subcortical lesions, but may show considerable recoverability due to bilateral representations or alternate pathways. In other cases, bilateral lesions associated with conditions such as stroke, demyelinating disease, or trauma may be required to produce deficits. Debilitating sensory or motor modulatory symptoms may be manifest by disruption of bilateral subcortical substrates, but may be temporally separated. Cranial nerve dysfunction associated with neurodegenerative diseases may not be apparent on imaging, but an understanding of the same will facilitate an accurate diagnosis. Poor understanding of the functions and locations of subcortical cranial nerve networks engenders apathy toward correlative diagnoses in these areas. An intuitive understanding of cranial nerve subcortical functional networks empowers clinical neuroradiology.

Conclusions
Small subcortical lesions may produce debilitating deficits in cranial nerve functions. Tracts and subcortical nuclei of the thalami, basal ganglia, and brainstem form the basis of important cranial nerve circuitry. A conscious appreciation of subcortical cranial nerve network functions and anatomical locations will foster the proper diagnoses of cranial nerve disorders.

KEYWORDS: Anatomy, Cranial Nerves

EdE-56

Temporal Run: A Pictorial Essay of CNS Lesions with Predilection to the Temporal Lobes.

J Rozell1, S Li2
1Baystate Medical Center, Tufts University School of Medicine, Springfield, MA, 2Baystate Medical Center, Longmeadow, MA

Purpose
The aim of this exhibit is to review different pathologies and etiologies of lesions which have predilections for the temporal lobes, including but not limited to herpes simplex encephalitis, ganglioglioma, mesial temporal sclerosis, CADASIL (Cerebral Autosomal-Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy), and trauma, and to review each of their characteristic imaging findings. Their clinical presentations, course and treatment also are discussed.

Materials and Methods
Noteworthy cases are divided into different categories such as infection or inflammation, tumor, trauma, ... ... They include herpes encephalitis, ganglioglioma, mesial temporal sclerosis,
contusion/hemorrhage, CADISIL disease, etc. Initial discussion focuses on presenting clinical signs and symptoms and diagnostic planning. Different imaging modalities from initial studies to advanced techniques, including CT, MR, and CTA, PET, nuclear medicine study, then will be illustrated for each case. Post-treatment clinical course and available follow-up imaging also will be included.

Results
1. Discuss etiologies and mechanisms behind each of the provided examples of temporal lobe lesions. 2. Focused characteristic imaging findings for each of the provided diagnosis with emphasis on advantages and disadvantages of various imaging modalities/techniques. 3. Discuss differential diagnoses and the consequences of misinterpretation. 4. Discuss importance of treatment, plans of intervention, and characteristic imaging findings during post-treatment and resolution phase.

Conclusions
There are a number of interesting cerebral lesions which have a predilection for the temporal lobes. Due to the redundant nature of the function of the temporal lobes, clinical signs and symptoms often can be subjective, leading to either delayed or missed diagnoses. At the end of the presentation, the viewer will become familiar with causes, clinical findings, diagnostic imaging features, consequences of interpretations, and plans of treatment.

What Stems from the Brainstem?

S Lam\textsuperscript{1}, P Hanagandi\textsuperscript{2}, F Goncalves\textsuperscript{3}, L do Amaral\textsuperscript{4}, C Torres\textsuperscript{5}, J Chankowsky\textsuperscript{5}, R del carpio\textsuperscript{5}  
\textsuperscript{1}McGill University, Montreal, Quebec, Canada, \textsuperscript{2}The Ottawa Hospital, University of Ottawa, Ottawa, Ontario, Canada, \textsuperscript{3}Brasilia Children's Hospital, Brazilia, Distrito Federal, Brazil, \textsuperscript{4}Medimagem- Hospital Beneficencia Portuguesa and Hospital São José - São Paulo - Brazil,
Purpose
Pathologies affecting the brainstem are diverse and occasionally can be challenging to differentiate on imaging because of their nonspecific appearance. The purpose of this exhibit is to categorize brainstem lesions and to describe their epidemiology, presentation, key imaging findings and differential diagnoses.

Materials and Methods
Brainstem lesions can be classified as focal or diffuse, with further subdivisions based on etiology. A search of our PACS will be undertaken to identify patients with brainstem lesions. The cases that best illustrate the typical imaging findings of lesions in each category will be retained and used as examples in this exhibit.

Results
Brainstem lesions can be classified as focal or diffuse. Focal lesions are generally well defined and confined to a single brainstem segment, whereas diffuse lesions are larger, with ill defined borders, occupying more than half of a brainstem segment, or extending across more than one segment. Focal and diffuse brainstem lesions can be further subdivided into tumor, ischemic, infectious, demyelinating, degenerative, metabolic, traumatic, and vascular. Some of these entities can present both as focal and as diffuse lesions. Examples of each category will be illustrated with cases from our institutions, and their characteristics and imaging findings will be highlighted.

Conclusions
Because brainstem pathologies can be so diverse, it is useful to divide them into categories to facilitate conceptualization. Placing brainstem lesions into categories, presenting different examples in each category, and reviewing their characteristics will enable better differentiation and identification of such lesions on imaging.

KEYWORDS: Brainstem, Classification, Masses
“Stop and Smell the Roses”: Olfactory Dysfunction from Lesions along the Olfactory Pathway

S Vagvala¹, E McComb¹
¹Northwestern Memorial Hospital, Chicago, IL

Purpose
Review the olfactory pathway and imaging features of lesions that can cause decreased olfaction.

Materials and Methods
The anatomy of the olfactory system and the radiologic findings of different pathologic processes along the olfactory pathway will be discussed. These include sinonasal infections, neoplasms such as esthesioneuroblastoma and olfactory groove meningioma, traumatic
intracranial injury, neurodegenerative diseases such as Alzheimer disease, and congenital disorders such as CHARGE syndrome (ocular Coloboma, heart defects, choanal atresia, retarded growth/development, genital anomalies, and characteristic ear anomalies) and Kallmann syndrome.

Results
Anosmia/hyposmia is the loss of smell or diminished sense of smell, and can be caused by lesions that affect the olfactory pathway. Knowledge of the olfactory anatomy therefore aids in the imaging evaluation of disorders affecting the sense of smell. Olfaction is induced by the stimulation of olfactory receptors, located in the roof of the nasal vault. This information is transmitted by the olfactory nerves to the olfactory bulbs through the cribriform plate. The olfactory bulbs then give rise to the olfactory tracts, which project to areas of the brain including the olfactory nucleus, piriform cortex (uncus and anterior parahippocampal gyrus), amygdala, and entorhinal cortex. There also are connections with the dorsomedial thalamus, insula, hippocampus, and orbitofrontal cortex. Sinonasal infections, both acute and chronic, are a common cause of olfactory disturbance. This is felt to be secondary to olfactory mucosal edema and nasal airflow obstruction to the olfactory receptors. Neoplasms, such as esthesioneuroblastoma and olfactory groove meningioma, also can affect olfaction. Esthesioneuroblastoma arises from the olfactory epithelium in the nasal vault and directly involves the olfactory receptors. An anterior skull base mass such as a meningioma can cause secondary compression of the olfactory bulbs and tracts, thereby affecting olfaction. Traumatic injury can injure or shear the olfactory fibers at the cribriform plate via a coup or contra-coup mechanism. Trauma affecting the orbitofrontal regions or temporal lobes also can affect olfaction. Decreased olfaction has been documented in neurodegenerative disorders such as Alzheimer disease. This is felt to be due to disproportionate volume loss of central olfactory structures such as the temporal lobes and hippocampus. Congenital disorders such as CHARGE and Kallmann syndromes are associated with anomalies of the olfactory sulci, bulbs, and tracts, which can be hypoplastic or aplastic.

Conclusions
Decreased olfaction traditionally has been overlooked compared to other cranial nerve dysfunction. Although there is a broad differential for olfactory deficits, knowledge of the anatomy of the olfactory system facilitates the imaging evaluation of patients presenting with anosmia or hyposmia.

Clinical and Radiological Assessment for Staging of Laryngeal Cancer

L Palifka1, S Hauck1, D Pastel1, B Gosselin1, J Paydarfar1, C Belden1
1Dartmouth-Hitchcock Medical Center, Lebanon, NH
Purpose
Radiological imaging and clinical and endoscopic information have critical complementary roles in the staging and treatment planning for laryngeal cancer; over 90% of which is squamous cell carcinoma. While endoscopy is superior in assessing disease of the mucosal surface, imaging with CT and MRI best assesses deep extension. Accurate pretreatment staging will ensure appropriate treatment and lend toward a more favorable prognosis. It is therefore essential that the radiologist be familiar with anatomy of the laryngeal spaces and regional architecture in order to fully characterize spread of disease, and thereby, tumor stage.

Materials and Methods
Using CT and MR images, clinical and endoscopic photos and pathologic specimens, this exhibit will review important imaging features and regional subsites of laryngeal cancer spread.

Results
Tumors arising in the larynx can be divided into three types by region: supraglottic, glottic, or subglottic tumors. For the purposes of staging, the supraglottis is divided into five subsites: suprathyoid epiglottis, infrahyoid epiglottis, laryngeal surface of the aryepiglottic folds, arytenoid cartilages, and false vocal cords. For the glottis, the important components to evaluate are the vocal folds and anterior and posterior commissures as well as evidence for invasion of the thyroid cartilage. Although involvement of the anterior or posterior commissures does not alter tumor stage, it often can alter surgical approach and this observation is important to report. The subglottis extends from the inferior aspect of the vocal cords to the inferior margin of the cricoid and is bounded laterally by the conus elasticus. Imaging of the subglottic region is particularly important as endoscopic evaluation is limited to the mucosa. Involvement of cricoid cartilage mandates total laryngectomy. For each laryngeal region, tumor bulk beyond the subsite of origin will alter staging with multiple subsite involvement or transglottic spread of tumor classified as T2. Additionally, vocal cord fixation, paralaryngeal or pre-epiglottic tumor extension or partial cartilaginous invasion will further upstage a laryngeal tumor to T3. Extralaryngeal or transcartilaginous invasion will upstage to T4a while invasion into the prevertebral space, mediastinum, or carotid artery adventitia to T4b indicating unresectability. Initial assessment of possible cartilaginous invasion is done by imaging alone, and although specificity and sensitivity of CT and MR are variable and particularly low for early invasion, the presence of invasion alters treatment; favoring extensive surgical resection over nonsurgical organ preservation therapies such as radiation or chemoradiation therapy. Evaluation of nodal status and distant metastatic disease conclude the T-N-M staging.

Conclusions
Knowledge of laryngeal regional subsite involvement and accurately reporting tumor extension will aid in accurate assessment of pretreatment staging and treatment options; thereby optimizing patient prognosis.

Deep Soft Tissue Venous Malformations of the Neck: Imaging Pitfalls to Avoid in the Adult

B Chandrasekaran¹, G Berberian¹, D Kowal¹
Purpose
Venous malformations are slow-flow vascular malformations, the most common vascular malformation and occurring in approximately 1% of the population. However, venous malformations are uncommonly seen in the neck of the adult, where if present may be mistaken for more aggressive neoplastic lesions, leading to unnecessary and invasive testing. Our purpose is to comprehensively review the characteristic CT, MRI, ultrasound and scintigraphic imaging findings of these lesions through case presentation, highlighting techniques to avoid pitfalls and misdiagnosis.

Materials and Methods
We review the imaging findings in three patients with soft-tissue venous malformations, describing the specific imaging features using a multimodality approach. Patients with venous malformations in the posterior cervical triangle, submandibular space, and masticator space will be presented. Comparison to common neck malignancies such as adenoid cystic carcinoma will be performed for contrasting purposes.

Results
Vascular anomalies of the head and neck can be divided into vascular neoplasms (such as infantile hemangioma) and vascular malformations. Hemangiomas and other benign vascular neoplasms are characterized by proliferation of endothelial cells, are typically present at birth, and often spontaneously involute. Vascular malformations result from abnormal morphogenesis of blood and lymphatic blood vessels and can present at any age including adulthood. Vascular malformations are divided into low-flow and high-flow lesions, with low-flow lesions further divided into venous, lymphatic, and venolymphatic malformations. Depending on their location, venous malformations can be confused with malignant neoplasms if their characteristic imaging appearance is not realized. On noncontrast CT, venous malformations typically are well circumscribed lobulated masses containing characteristic calcified phleboliths. A variable but predominantly avid enhancement pattern on contrast-enhanced studies typically is seen. The excellent contrast resolution of MRI allows for detailed evaluation of the extent of the lesion and its relationship to adjacent structures, including the preservation of surrounding fat planes. On T2-weighted imaging, venous malformations classically appear as multiple high-signal-intensity lobules. Areas of fibrosis, calcification, phleboliths and thrombus appear as low signal intensity with blooming present on gradient echo sequences. Avid postcontrast enhancement usually is present. Red blood cell scintigraphy can be a powerful problem-solving tool showing specific intense, slow filling and persistent late-phase uptake.

Conclusions
In summary, we present three cases of neck soft tissue venous malformations in adult patients illustrating the specific multimodality imaging features of these benign lesions. Awareness of these features can prevent unnecessary invasive testing, and guide the patient toward more appropriate testing such as red blood cell scintigraphy.

Dental Disease: A Frequently Misdiagnosed Source of Head and Neck Pathology

V Zohrabian¹, J. Abrahams¹
¹Yale-New Haven Hospital, New Haven, CT

Purpose
Dental disease often is overlooked as a potential source of head and neck pathology, frequently resulting in misdiagnosis. A familiarity with the various imaging manifestations of dental disease will help prevent this. This exhibit will illustrate examples of dental pathology that has potential to be confused with other head and neck disease processes.

Materials and Methods
A retrospective review of our teaching files has yielded a number of clinical cases demonstrating dental disease that was misdiagnosed initially or had the potential to be confused with other head and neck pathologies.

Results
A few examples of the cases that will be presented in this exhibit that were misdiagnosed initially or had the potential for misdiagnosis are as follows: 1. Endodontal infection initially
misdiagnosed as infected submandibular gland with cutaneous fistula. 2. Endodontal infection initially misdiagnosed as calculus with associated inflammation in parotid gland duct near 2nd maxillary molar. 3. Oroantral fistula following tooth extraction initially misdiagnosed as maxillary sinusitis, unresponsive to treatment. 4. Osteitis condensens (sclerosis of bone surrounding chronic dental infection) initially misdiagnosed as an osteoblastic malignancy. 5. Endodontal infection initially misdiagnosed for a soft tissue tumor.

Conclusions
Dental disease is a common source of head and neck pathology that often is overlooked. A working knowledge of dental disease and its imaging manifestations will aid in preventing potential misdiagnoses. Endodontal disease, periodontal disease, and dental anatomy is reviewed in a separate submission entitled "Endodontal and Periodontal Disease Made Ridiculously Simple: A Radiologist's Guide."

Ears Looking at You: A Pictorial Essay of Middle Ear Pathology Correlating Temporal Bone CT with Archived Otoscopic Photographs

Q Fender¹, J Lane¹, M Carlson¹, B Neff¹, C Beatty¹, C Driscoll¹, L Eckel¹, K Koeller¹, J Morris¹, C Wood¹, F Diehn¹, C Hunt¹, K Schwartz¹, R Witte¹

¹Mayo Clinic, Rochester, MN

Purpose
To demonstrate the utility of correlating temporal bone CT with archived otoscopic images to refine the differential diagnosis of common middle ear pathologies.

Materials and Methods
The medical image archive at our institution recently has been expanded to include otoscopic photographs taken by the ENT specialist during the physical examination. The availability of these images at the time of CT interpretation significantly impacts the neuroradiologist's ability to narrow the differential diagnosis of middle ear disease.

Results
The temporal bone CT and correlative otoscopic appearance of common inflammatory, vascular, neoplastic, traumatic and congenital conditions of the middle ear are presented. The impact of the otoscopic appearance on CT interpretation is discussed.

Conclusions
The radiographic differential diagnosis of middle ear disease can be refined using otoscopic images uploaded to a common institutional image archive leading to a more concise interpretation of temporal bone CT findings.

EdE-78

Endodontal and Periodontal Disease Made Ridiculously Simple: A Radiologist’s Guide.
V Zohrabian¹, J Abrahams¹
¹Yale-New Haven Hospital, New Haven, CT

Purpose
Endodontal and periodontal disease are frequent causes of Head and Neck pathology, including facial swelling, sinus tracts, fistulas, masses, abscesses, sinus disease, etc. Unfortunately, radiologists traditionally have had little understanding of dental disease, thus causing endodontal and periodontal lesions to be confused with other pathologies. This exhibit reviews the pertinent dental anatomy and elucidates the radiographic manifestations of endodontic and periodontal disease and its treatment.

Materials and Methods
Retrospective review of our teaching files has yielded clinical cases that will be used to demonstrate the imaging appearances of endodontic and periodontal disease.

Results
Endodontal disease: The vital structure of the tooth, the neurovascular bundle, enters from the apical foramen at the root apex and travels up the radiolucent root canal to access the radiolucent pulp chamber within the crown. Dental caries (cavity) refers to bacteria that cause demineralization of the tooth. Caries may erode through enamel and dentin to access the pulp chamber, resulting in pulpitis. The infection then may travel down the root canal forming an abscess or granuloma at the root apex. This infection causes resorption of bone around the root apex creating periapical radiolucency. Treatment: Endodontal disease is treated with a root canal procedure in which the dentist gains access to the pulp chamber by drilling through the crown. He next uses special endodontic files to remove the infection and shape the root canals. The root canals then are sealed with gutta percha, a radioopaque latex material. A crown, which sometimes requires posts for more support, will therefore be used to restore the tooth.

Periodontal disease: The teeth are held in the bony socket by the periodontal ligament, which attaches to the cementum of the root and the lamina dura of the socket. Bacteria-laden plaque on the teeth may lead to inflammation of the gums (gingivitis). The hyperemia from this inflammation often results in bleeding gums. The infection then can extend into the periodontal ligament (periodontitis) along the lateral surface of the root, eroding bone and creating a space, or periodontal pocket. Radiographically, these lesions appear as lucencies associated with bone loss at the lateral surface of the tooth. Treatment: The periodontal pocket is curettaged to remove the infection and necrotic tissue. The remaining defect then is packed with bone graft material and allowed to heal. Tissue stimulating proteins also may be used to enhance bone growth.

Conclusions
A working knowledge in combination with a systematic approach to endodontal and periodontal disease will aid radiologists in understanding the role these lesions play in Head & Neck pathology. These dental related pathologies will be addressed in a separate submission entitled "Dental Disease: A Frequently Misdiagnosed Source of Head & Neck Pathology."

R Al Hazmi¹, D Tampieri¹, D Melancon¹, M Cortes¹
¹Montreal Neurological Hospital and Institute, Montreal, Quebec, Canada

Purpose
Horner's syndrome is a classic neurologic syndrome characterized by the triad of ptosis, miosis and anhydrosis. It results from an interruption of the oculosympathetic pathway. It is classified into three types (central, preganglionic and postganglionic) depending on the location of the lesion. We present a brief review of the anatomy of the oculosympathetic pathway, describe the clinical features of the three types of Horner's syndrome and neuroimaging strategies.

Materials and Methods
Reviewing the literatures on PubMed about imaging in Horner's syndrome in the last 30 years. We also reviewed the anatomy of the oculosympathetic pathway and database of Horner's syndrome in our institute.

Results
Horner's syndrome results from an interruption of the oculosympathetic nerve supply to the eye and is characterized by the classic triad of ptosis, miosis and anhydrosis. It is classified into central, preganglionic and postganglionic types according to the location of the lesion in the first, second and third-order neurons; respectively. The neural pathway affected in Horner's syndrome is complex, it extends from the hypothalamus, brainstem, spinal cord, upper thorax, neck, skull base to the eye. The associated clinical presentation varies in every location. The differential diagnosis is broad and the pathology ranges from a benign to a life-threatening condition. It needs clear combined clinical, pharmacological and imaging guide to establish the diagnosis and the underlying cause.

Conclusions
The various clinical presentations of Horner's syndrome have to be known in order to tailor the appropriate imaging at the correct anatomical site in order to provide the diagnosis. This presentation provides an imaging teaching tool to review the anatomy and clinical correlations of the complex pathway that may be affected in Horner's syndrome and offers examples of several pathologies that lead to this clinical presentation.

How to Use Lymphotropic Superparamagnetic Iron Oxide Nanoparticles to Improve Accuracy of Malignancy Detection in Cervical Lymph Nodes on Magnetic Resonance Imaging

S Novak¹
¹Mount Auburn Hospital, Cambridge, MA

Purpose
Detection of malignant cells in lymph nodes is critically important for staging and treatment planning. Undetected malignant cells can serve as a cancer reservoir, predisposing the patient to recurrence, and making it difficult or impossible to cure the disease. The crucial pretreatment
knowledge of whether each cervical lymph node harbors malignancy currently primarily depends on anatomical characteristics such as size and morphology. The accuracy of these indicators is suboptimal because metastatic disease can be present in small nodes, whereas infections and other benign causes can enlarge nodes beyond the size criteria. While other technologies such as positron emission tomography can be useful, they too suffer accuracy limitations particularly in small nodes. There is a need for a better method to evaluate lymph nodes for malignant disease, and the relatively new technology of superparamagnetic iron oxide nanoparticles (SPIONs) as contrast agents for magnetic resonance (MR) imaging has been shown to be useful for this purpose.

Materials and Methods

The SPION-containing agent currently commercially available in the United States is ferumoxytol, although its use for MR contrast is an off-label indication. Ferumoxytol is an intravenous iron replacement product which was approved by the Food and Drug Administration (FDA) in 2009 for the treatment of iron deficiency anemia in adults with chronic kidney disease (1). The drug contains superparamagnetic iron oxide magnetite (Fe3O4) particles coated with polyglucosan sorbitol carboxymethyl ether, with a colloidal particle size of 17-31 nm diameter. The carbohydrate shell shields the iron oxide from plasma, until the particles are taken up by macrophages of the reticuloendothelial system. Ferumoxtran 10, an alternative SPION-containing agent, has been used for many of the early studies of this technique, but is not currently approved by the FDA. MR scanning is first performed prior to administration of the agent utilizing standard sequences. The SPION agent is administered, and then the patient returns approximately 48 hours afterwards for post-SPION imaging. The timeframe is chosen to optimize relocation of the particles to the reticuloendothelial system, in particular within lymph nodes. SPIONs are useful as contrast agents for MR imaging due to physiologic localization to normal lymph nodes, and magnetic susceptibility properties enabling visualization on MR images. Superparamagnetism of these particles causes T2* dephasing, resulting in hypointense signal on gradient-recalled echo (GRE) T2*-weighted sequences.

Results

On the MR images post-SPION administration, lymph nodes are evaluated primarily on T2*-weighted sequences. In benign lymphatic tissue, the SPIONs within macrophages cause local magnetic susceptibility and thus decreased T2* signal. In foci of tumor infiltration, the macrophages and particles are not present and therefore the signal remains unchanged from precontrast images. The fatty hilum is also unchanged, but can be differentiated based on signal characteristics on other sequences included in the exam. One of the largest studies performed evaluating this technique was a phase III study of SPIONs for evaluation of neck and body lymph node metastases (2). The study found sensitivity, specificity, and accuracy of 54%, 82%, and 68%, respectively based on size; 83%, 77%, and 80% after administration of a SPION agent; and 96%, 87%, 93% in the subgroup of head and neck cancers. These results reveal that SPION-enhanced imaging is superior to traditional size-based criteria, and works specifically for head and neck cancers. This technique can be used on existing MR scanners with an FDA-approved medication (although off-label). Ferumoxytol is relatively safe and well tolerated. In clinical trials, anaphylaxis was reported in 0.2% of subjects, and other hypersensitivity type reactions in 3.7% (1). An additional benefit of ferumoxytol is that it is safe in patients with renal insufficiency, as its primary indication is in adults with chronic kidney disease, in contradistinction to gadolinium-based contrast agents which are typically avoided in these patients.
Conclusions
SPIONs are useful as contrast agents in MR imaging through localization to macrophages in normal lymph nodes and inducing magnetic susceptibility. Benign nodes become hypointense on T2*-weighted sequences after SPION administration, whereas foci of malignant cells do not change signal. SPION agents have been shown to improve sensitivity, specificity, and accuracy in head and neck lymph node evaluation for malignancy. A SPION-containing agent is commercially available, and the technique can be used on existing MR scanners. While further advances will continue to improve this technology and increase the body of evidence demonstrating its accuracy, SPION technology has arrived in the clinical realm and can benefit patients.

Imaging Hemifacial Spasm

A Reynolds¹, M Hughes¹, B Branstetter¹, A Frederickson¹, J Oskin¹, U Yankevich¹, R Sekula¹
¹University of Pittsburgh Medical Center, Pittsburgh, PA

Purpose
Hemifacial spasm (HFS) is a severe and disabling condition characterized by unilateral facial nerve hyperactive dysfunction. Vascular compression of the facial nerve is the most common etiology of HFS; however, not all segments of the facial nerve are equally susceptible to compression. The purpose of this exhibit is to discuss the anatomy and vulnerable portions of the facial nerve and to demonstrate the imaging appearances of those patients who were successfully treated with microvascular decompression.

Materials and Methods
Following a review of the pertinent facial nerve anatomy, the imaging appearances of vascular compression in patients with HFS who were treated successfully with microvascular decompression will be reviewed. The pertinent imaging protocols also will be presented.

Results
Pulsatile vascular compression is the most common cause of HFS. The facial nerve emerges from the brainstem within the pontomedullary sulcus and then adheres to the undersurface of the pons for 8-10 mm, referred to as the adherent segment. It then separates from the pons at the root detachment point. The transition zone extends laterally from the root detachment point for approximately 4 mm and is the area where the central glial myelin transitions into the peripheral myelin created by Schwann cells. Lateral to the transition zone is the cisternal segment of the facial nerve. The vulnerable segment of the facial nerve begins at the pontomedullary sulcus and extends to the lateral aspect of the transition zone. Many neuroradiologists are unaware of the fact that the facial nerve is adherent to and vulnerable to arterial compression along the undersurface of the pons. Furthermore the majority of cases of vascular compression causing hemifacial spasm occur along this adherent segment. Dedicated thin section multiplanar steady-state free precession MR images and anatomical knowledge of the vulnerable regions of the facial nerve allow for identification of the offending vessels and delineation of compression points that would be amenable to microvascular decompression.
Conclusions
Hemifacial spasm is a rare but debilitating disorder, most commonly caused by vascular compression of the facial nerve proximal to its cisternal segment. Knowledge of the anatomy and vulnerable portions of the facial nerve and utilization of specific MR imaging protocols is critical to correctly identify patients who are candidates for microvascular decompression, to locate the culprit arterial vessel, and to guide surgical management. Failure to identify vascular compression of the proximal facial nerve can delay or prevent neurosurgical referral and potential cure.

Imaging of the External Auditory Canal

J Moon¹, M Hughes¹, A McCall², B Hirsch², B Branstetter¹, N Milanovich²
¹University of Pittsburgh Medical Center, Pittsburgh, PA, ²University of Pittsburgh, Pittsburgh, PA

Purpose
Lesions of the external auditory canal (EAC) can present a diagnostic dilemma to both clinicians and radiologists. The purpose of this exhibit is to present a simplified approach to evaluating acquired EAC lesions in adults. The imaging appearance of common lesions which occur in the EAC will be reviewed.

Materials and Methods
From an imaging standpoint, lesions of the EAC may be categorized into erosive and nonerosive etiologies, which will be the focus of this education exhibit.

Results
The walls of the EAC comprise a medial osseous and a lateral cartilaginous component. Erosion of the osseous segment of the canal suggests an infectious, inflammatory or malignant etiology. Abnormal osseous erosion may be a result of a cholesteatoma, infections such as malignant otitis externa, or malignancy. The most common malignancy to involve the EAC is squamous cell carcinoma. Less common malignancies include adenoid cystic carcinoma, melanoma, sarcoma, metastasis and lymphoma with variable associated erosive changes. Intracranial extension or perineural spread are important findings to convey to the referring surgeon. Nonerosive EAC lesions are more likely benign. Considerations include osteoma, exostosis, keratosis obturans, and benign neoplasms such as a pleomorphic adenoma. Several of these lesions have a characteristic imaging appearance that may allow for a specific radiologic diagnosis.

Conclusions
External auditory canal lesions can be categorized into erosive and nonerosive lesions. Within these categories many lesions have a characteristic imaging appearance that suggest specific diagnoses.

Imaging of the Glaucoma Drainage Implants

B Salehi1, A Sepahdari2, T Wood1, K Tong1
1Loma Linda University Medical Center, Loma Linda, CA, 2University of California Los Angeles, Los Angeles, CA

Purpose
1. Pictorial review of the most commonly used glaucoma drainage implants. 2. Discuss the CT and MR appearance of glaucoma drainage implants. 3. Identify the normal postsurgical changes, and differentiate it from possible pathologies. 4. Delineate the role of imaging in diagnosis of postsurgical complications associated with glaucoma drainage implants in a case-based review. 5. Explore the possible pitfalls in imaging interpretation of these implants.

Materials and Methods
The structure and functional mechanism of each type of glaucoma drainage implant will be discussed briefly using several photographs and graphics. Intra-operative images will be used to illustrate the surgical technique and anatomical concept of these implants. CT and MR images of a series of glaucoma drainage devices will be reviewed, with pearls to help identify the normal in vivo appearance of these devices, expected postsurgical changes, and associated pathologies. The Ahmed glaucoma valve, the most commonly used glaucoma drainage device, will be emphasized. Imaging findings associated with different surgical techniques, including scleral flap versus scleral or pericardial graft, will be discussed using a case-based review.

Results
A glaucoma valve consists of a small plate with a valve that regulates the intra-ocular pressure (IOP), and a tube that drains aqueous humor. A scleral flap or graft covers the implant. Glaucoma drainage devices are designed to divert aqueous humor from the anterior chamber to an external reservoir, where a fibrous capsule forms about 4-6 weeks after surgery and regulates flow. The plate of the glaucoma valve is made of radiopaque material, in curvilinear configuration conforming the curvature of the globe. On CT images, the plate is seen as convex density along the superotemporal aspect of the globe. Fluid and low density fibrotic tissue is seen around the reservoir within the scleral pocket in the majority of the late postsurgical imaging. This finding is a pitfall for misinterpretation as an abscess or abnormal fluid collection. Edematous periocular tissue adjacent to the glaucoma valve is another important postsurgical change caused by drainage of the aqueous humor to the reservoir, commonly appreciated on CT images. On MR images, low signal plate and nonenhancing bleb in the superotemporal quadrant of the globe delineate the presence and position of the glaucoma valve. Infection of the implant and endophthalmitis are rare complications of glaucoma valve implantation. The infection-related imaging findings include periorbital soft tissue and uveoscleral thickening, edema, and abnormal enhancement on CT and MR images. Giant reservoir formation is another rare postsurgical complication manifested on cross-sectional imaging. Detailed image review is essential to differentiate the abnormal findings from expected postsurgical changes.

Conclusions
This pictorial exhibit will provide practical information for the radiologist to accurately and comprehensively diagnose and interpret the imaging findings in the presence of glaucoma drainage implants.
Non vascular Neck Imaging with MRI and CT: When to Use and Which to Pick

C Buckle

University Radiology Group, Chicago, IL

Purpose
The neck is an anatomically complex region affected by a variety of complex disease processes well visualized by advanced neuroimaging modalities like CT and MR imaging (MRI). The purpose of this educational exhibit is to review the clinical indications for nonvascular head and neck imaging using CT and MRI, to identify their relative strengths and weaknesses and to compare their performance across a variety of indications for head and neck imaging.

Materials and Methods
Literature review of guidelines for head and neck imaging with MRI and CT including ACR appropriateness criteria, National Guidelines Clearinghouse, National Comprehensive Cancer Network (NCCN) and European/International sources, Literature review using Pubmed for studies comparing the performance of CT/MRI in the neck.

Results
Review common indications for nonvascular CT neck with contrast, without contrast. Review common indications for nonvascular MRI neck. Review benefits and drawbacks of CT and MRI. Review benefits /drawbacks of CT and MRI for the following regions orbits: temporal bones, suprahypoid neck, Infrahypoid neck including thyroid.

Conclusions
Both MR and CT are powerful imaging modalities for visualization of nonvascular neck pathology in appropriately selected patients. While MR or CT may be clearly superior for specific clinical indications (for example evaluation of perineural spread or marrow abnormalities with MRI), in many cases the decision to use one modality over the other may be determined more by the patient than by the indication.

KEYWORDS: Neck Infections, Neck Lesions, Neck Masses

Occlusion of the Internal Auditory Canal Alters Cochlear Fluid Homeostasis: A New Mechanism Explaining Hearing Loss Due to Vestibular Schwannomas

J Butman, H Kim, A Asthagiri

National Institutes of Health, Bethesda, MD, University of Virginia, Charlotesville, VA

Purpose
To present the imaging findings that support the new hypothesis that occlusion of the internal auditory canal (IAC) alters cochlear fluid homeostasis eventually resulting in SNHL.
Materials and Methods
Representative MR imaging (MRI) findings from neurofibromatosis 2 (NF2) patients enrolled in a natural history study, using high-resolution FLAIR imaging to suppress signal from normal endolymph and perilymph to reveal subtle alterations in the protein content of these intralabyrinthine fluids were reviewed.

Results
Cases with SNHL demonstrated abnormal signal from the labyrinth. Cases with normal intralabyrinthine fluid signal demonstrated normal hearing. Cases with an occluded IAC (no CSF communication from the CPA to the modiolus) typically had an abnormal labyrinth signal. Cases with no occlusion invariably had normal signal. Particularly instructive were (1) cases of very small tumors with profound SNHL and (2) cases of large tumors with normal hearing. Examples of (1) show that these small tumors were situated at the fundus of the IAC, occluding the cribriform area that normally permits communication between the CSF and the cochlea. In congruence with the hypothesis, elevated protein in the cochlea was demonstrated in these cases. Examples of (2) revealed that the IAC has remodeled around these large tumors such that a pathway of CSF from the cerebellopontine angle cistern can be demonstrated. In these cases with normal hearing, FLAIR signal in the inner ear was normal.

Conclusions
Because vestibular schwannomas of the internal auditory canal impinge upon the cochlear nerve, the mechanisms postulated for the associated SNHL typically focus more on the nerve than on the sensory end organ. However, two common observations cannot be explained by a nerve centered mechanism. First, is the dissociation of SNHL and tumor size. Many patients with small tumors suffer from a profound SNHL, and, conversely, many patients with large tumors have preserved hearing. Second, significant facial nerve dysfunction is almost never found even for large tumors, even though there is no a priori reason why the facial nerve and the cochlear nerve should respond differently to pressure exerted from a vestibular schwannoma. The detection of abnormal signal in the labyrinth in those patients with SNHL indicates that pathology in the sensory end organ is a necessary condition for SNHL. But, if the tumor is not in the labyrinth, what accounts for this biochemical degradation? Because there is a normal communication of CSF with the perilymph, these observations can be explained by the following cascade of events: (1) tumor growth leads to (2) occlusion of the IAC which results in (3) alteration of normal cochlear homeostasis (accumulation of protein in the cochlea) (4) which eventually leads to hearing loss. Occlusion of the IAC is proposed as the inciting event that leads to audiovestibular dysfunction in NF2 patients with vestibular schwannoma. Hyperintense signal in the labyrinth on FLAIR MRI demonstrates the accumulation of protein within inner ear fluids representing the alteration of cochlear homeostasis which is an intermediate stage in this process.

Ophthalmic Artery: Angiographic Anatomy, Anatomical Variants and Collaterals

S Mohiuddin\textsuperscript{1}, A Honarmand\textsuperscript{2}, S Ansari\textsuperscript{3}
\textsuperscript{1}Saint Francis Hospital, Evanston, IL, \textsuperscript{2}Northwestern University, Chicago, IL, \textsuperscript{3}Northwestern Memorial Hospital, Chicago, IL
Purpose
The purpose of this exhibit is to briefly summarize the usual origin, development, and branches of the ophthalmic artery as well as its anatomical variants in origin and collateral flow by using angiographic imaging.

Materials and Methods
A literature search of review of the anatomy, anatomical and angiographic variants, and collateral routes of the ophthalmic artery was performed and relevant case reports will be obtained from Northwestern Memorial Hospital. A review of normal origin, development, and branches of the ophthalmic anatomy as well its anatomical variants in origin and collateral flow will ensue with examples from angiographic imaging.

Results
We will review: 1. The segments and branches of the ophthalmic artery. 2. The embryology of the ophthalmic artery with special emphases on description by Padget and Lasjaunias, et al. 3. The variants in origins of the ophthalmic artery, the most common of which is the middle meningeal artery. Other variants in origin (i.e., persistent dorsal ophthalmic artery) involving the ophthalmic artery also will be discussed with special emphasis on the clinical significance of the relevant variations. 4. The several potential orbital collateral routes from the external carotid artery to the ophthalmic artery will be discussed as well. The most common of these involves the middle meningeal and anterior deep temporal arteries.

Conclusions
Several variants can involve the origin of the ophthalmic artery, the most common of which involves the middle meningeal artery, which also serves as a collateral route with connection between the external carotid and ophthalmic artery. MR and traditional angiography can play an important role in differentiating and identifying these variants in origin. By reviewing the common variants in origin and collateral routes of the ophthalmic artery, the radiologist will be able to provide surgeons and/or interventionalists with relevant information that can prevent blindness during surgical or embolization procedures.

6:30AM - 9:00PM

Pediatric Parotid Lesions: Review of Pathologic Entities and Role of MR Sialography

V Kalra¹, D Durand¹, P Mehta¹, B Judson¹, E Baum², A Malhotra¹
¹Yale University School of Medicine, New Haven, CT, ²Connecticut Pediatric Otolaryngology, Madison, CT

Purpose
Parotid lesions in the pediatric and adult population may arise from a variety of pathologies, many with nonspecific imaging appearances. Many of these entities are mistaken for only occurring in the adult population. We present a review of the various pathologic entities affecting the pediatric parotid gland with imaging examples, emphasizing characteristic imaging appearances of certain pathologic entities.
Materials and Methods
Pediatric parotid lesions are presented by pathologic category: inflammatory/infectious, congenital/developmental, autoimmune, adenopathy, mesenchymal neoplasia, benign parenchymal neoplasia, and malignant parenchymal neoplasia. Otolaryngologic epidemiological data is reviewed to show relative incidences of lesions in pediatric and adult populations. Role of specialized imaging, including ultrasound, conventional and MR sialography is highlighted.

Results
Pediatric parotid lesions can be classified as inflammatory/infectious, congenital/developmental, autoimmune, adenopathy, mesenchymal neoplasia, benign parenchymal neoplasia, and malignant parenchymal neoplasia. • Inflammatory/infectious etiologies are far more common than neoplastic changes in children compared to adults. Diffuse bilateral gland enlargement can be seen in acute bacterial and viral inflammation, however lymphoma may rarely have a similar appearance. Juvenile recurrent parotitis, presenting in mid-childhood and frequently resolving by puberty, has characteristic ultrasound and MR imaging appearances of multifocal punctate sialectasis, partially overlapping with HIV sialopathy, which can be distinguished with serologic testing. • Congenital/developmental lesions are most commonly hemangiomas and venolymphatic malformations. Hemangioma, the most common neonatal lesion, is characterized by a trans-spatial enhancing mass with phleboliths and frequently spontaneously resolves. First branchial cleft cysts are congenital lesions that present during childhood, most commonly with parotitis, and may demonstrate a fistulous tract to the external auditory canal on imaging. • Autoimmune disease is most commonly Sjogren's syndrome, with children demonstrating early tooth decay from xerostomia. • Adenopathy is the most common lesion as the parotid gland is not encapsulated and contains intraparotid lymph nodes. • Mesenchymal neoplasia includes neurofibroma and rhabdomyosarcoma. • Benign and malignant parenchymal neoplasia pathologic entities occur in similar relative frequencies as adults, with pleomorphic adenoma being the most common benign neoplasia and mucoepidermoid carcinoma being the most common malignant neoplasia.

Conclusions
The presentation will review the normal anatomy of parotid space, imaging assessment of parotid lesions in children and the different pathologies involving the pediatric parotid gland. Specific imaging pearls would be provided. Malignancy and Sjogren's syndrome should be included in differential diagnosis of pediatric parotid lesions. Although many pathologic entities have overlapping imaging appearances, hemangioma may be characterized specifically by presence of phleboliths, venolymphatic malformations by fluid-fluid levels, and first branchial cleft by external auditory canal fistulous tracts. MR sialography, with thin, heavily-weighted T2-weighted images, may demonstrate multifocal punctate sialectasis characteristic of juvenile recurrent parotitis.

Peripheral incidentalomas—Soft tissue lesions in review areas on neuroradiological images: what are they and what you should do? A pictorial review.

A Horsburgh¹, T Massoud²
¹Queen's Hospital, Romford, Essex, UK, ²Stanford University School of Medicine, Stanford, CA
Purpose
In clinical practice incidental subcutaneous and soft tissue lesions commonly are encountered on MR imaging (MRI) and CT of the brain, head, and neck. It is important for neuroradiologists to detect such lesions and to be familiar with their appearance, so as to appreciate which lesions can be ignored and which require further evaluation. Cutaneous and subcutaneous lesions of the head and neck regions can comprise a broad and potentially confusing array of benign and malignant processes. Characterization of these lesions often can be problematic despite advances in imaging. Clinical history, lesion location, calcification, and signal intensity on MRI can help determine the diagnosis and narrow the differential diagnosis for lesions that demonstrate indeterminate characteristics. We present a pictorial review of the spectrum of subcutaneous and soft issue masses constituting the most common and some rarer subcutaneous entities. We provide a systematic approach to assessment of these incidental soft-tissue lesions.

Materials and Methods
We review the imaging findings in a wide spectrum of common and uncommon, benign and malignant subcutaneous lesions which can be found on brain, head, and neck MRI and CT imaging.

Results
The lesions presented include neoplastic processes such as skin squamous cell carcinomas, melanomas, a variety of sarcomas, and metastatic disease. We also demonstrate some examples of benign lesions such as lipomas, hypertrophic scar, keloid scars, pilomatrixoma, epidermal inclusion cysts and desmoid tumors. We discuss subcutaneous manifestations of systemic diseases such as phakomatoses, iatrogenic and cosmetic augmentation changes such as silicon or Alloderm foreign bodies. We also discuss infectious processes and vascular abnormalities such as hemangiomas.

Conclusions
Neuroradiologists should be able to thoroughly assess incidentally encountered subcutaneous lesions, taking into consideration the spectrum of possible causes and direct the need for further examination or investigations. This presentation will aid in differentiating the often overlooked imaging appearances of subcutaneous lesions on images of the head and neck.

EdE-70

Postsurgical Temporal Bone: A Pictorial Essay of Commonly Encountered Neurootologic Surgical Approaches and Postoperative Imaging Appearance

M Penta¹, M Pinho¹, B Isaacson¹, J Kutz¹, C Perez²
¹University of Texas Southwestern Medical Center, Dallas, TX, ²University of Texas Southwestern, Dallas, TX

Purpose
Interpreting the imaging findings of the temporal bone after middle ear, mastoid, and internal auditory canal surgery can be challenging for neuroradiologists in training as well as those in practice. We aim to review the more commonly encountered neurootologic surgical approaches and their indications as well as the expected postoperative findings on cross-sectional imaging of
the temporal bone. A greater understanding of the radiologic postoperative appearance facilitates the recognition of complications and recurrent disease.

Materials and Methods
We aim to present a pictorial essay coupling schematic illustrations of various neurootologic surgical procedures with corresponding cross-sectional imaging. Intraoperative photographs also will be presented when applicable. Special attention will be given to indications and distinguishing features associated with each surgical procedure.

Results
The intrinsically complicated anatomy of the temporal bone can be especially intimidating after being altered by surgery. However, familiarization with the types of highly specialized surgeries practiced by otolaryngologists and their indications as well as their appearance on cross-sectional imaging is essential to demystifying the postoperative temporal bone. This enables the radiologist to expertly detect recurrent disease and potential complications which then can be communicated accurately to clinicians. We will review the various types of mastoidectomy, including canal-wall-up (CWU) mastoidectomy and the more extensive canal-wall-down (CWD) mastoidectomy. We also will review the surgical approaches to the internal auditory canal, namely the translabyrinthine, retrosigmoid, and middle cranial fossa approaches. Ossicular reconstruction will be described, highlighting stapedectomy with prosthesis placement and the fundamental concepts underlying partial and total ossicular replacement prostheses. Finally, we will describe cochlear implant surgery with attention to facial recess approach, round window niche, and desired electrode placement within the cochlea.

Conclusions
Although potentially complicated, imaging of the postsurgical temporal bone is vital to evaluating for recurrent disease and complications. Familiarity with the various surgical procedures commonly encountered in the temporal bone and expected postoperative findings enables the radiologist to provide expert interpretation to the surgeon.

KEYWORDS: Postoperative Findings, Temporal Bone
Spectrum of Atypical Sites of Distant Metastases in HPV-Positive Oropharyngeal Carcinoma: A Case Series

S Cantrell¹, G Li², Q Wei², E Sturgis², L Ginsberg²
¹University of Texas Health Science Center at Houston, Houston, TX, ²University of Texas MD Anderson Cancer Center, Houston, TX

Purpose
To describe unusual sites of distant metastases occurring in patients with HPV-positive squamous cell carcinoma of the oropharynx (SCCOP).

Materials and Methods
We describe a retrospective case series of patients with HPV-positive SCCOP and distant metastases at presentation or distant metastatic recurrence without local-regional recurrence. HPV-positivity was defined by positive p-16 immunohistochemical staining and situ hybridization. Chart and imaging review were performed and sites of distant metastases are described.

Results
Eighteen patients with distant metastases were identified. Twelve of these presented with
isolated distant metastases after successful local regional control with chemoradiotherapy. The remaining six patients had metastatic disease on initial presentation prior to treatment. Among the 12 patients presenting with local-regional control but distant metastatic recurrences, the interval between successful completion of chemoradiotherapy and identification of distant metastases ranged from 3 to 14 months with mean of 7.5 months. Clinical characteristics of patients with HPV-positive SCCOP presenting with isolated distant metastases are presented in Table 1. Half of these distant metastatic recurrences were at nonpulmonary sites including soft tissues/skeletal muscle (3), bone (3), brain (2), and thyroid (1). With the exception of brain metastases, all sites were biopsied with histology revealing squamous cell carcinoma in the absence of known synchronous or metachronous squamous cell tumors. Metastatic lesions to the orbit and ethmoid were HPV-positive by in situ hybridization. In particular, brain, skin and skeletal muscle metastases presented within our series are atypical sites for isolated distant metastases of oropharyngeal squamous cell carcinoma. Of the patients presenting with distant metastases, sites of metastatic disease included the pterygopalatine fossa (1), parotid (3), thyroid (3), submandibular gland (1), femur (1) and liver (1). All metastases demonstrated squamous cell histology. Two of three thyroid metastases, one parotid metastasis and the pterygopalatine fossa metastasis were p-16 positive. Of note, one patient presented with pathologic femur fracture and unknown T1 base of tongue tumor, prompting the search for the primary tumor. Limitations to our retrospective review included small sample size and lack of testing of all distant metastases for p-16 and HPV-positivity.

Conclusions
Patients with HPV-positive SCCOP may develop distant metastatic recurrence despite local regional control. Given these sites of distant recurrence being at atypical (nonpulmonary) sites, clinicians and radiologists should consider distant recurrence when evaluating unusual symptoms or imaging findings. Additionally, when evaluating patients presenting with metastatic squamous cell carcinoma with unknown primary tumor, familiarity with unusual sites of distant metastatic disease related to HPV-positive SCCOP may prompt consideration of an oropharyngeal primary lesion in the absence of other known primary squamous cell tumor.

**To Leak or not to Leak: Imaging Manifestation of Spontaneous Cerebrospinal Fluid Leak**

N Nguyen¹, M Letzing², A Vahkaria³, R Bhatia²

¹University of Miami Miller School of Medicine/Jackson Memorial Hospital, Miami, FL, ²University of Miami School of Medicine/Jackson Memorial Hospital, Miami, FL, ³University of Miami School of Medicine, Miami, FL

**Purpose**

Spontaneous cerebrospinal fluid (CSF) leak refers to the drainage of CSF outside of the normal dural venous sinus system. The pathogenesis of this disease is dynamic and involves multiple factors, namely the presence of elevated CSF pressure and associated prominent arachnoid granulations that exert detrimental effect on the surrounding bones over time resulting in thinning, erosion, formation of meningoceles/meningoencephaloceles, and eventually CSF leakage. Skull sites prone to this process include the temporal bone, sphenoid sinus, and ethmoid roof. Abnormal congenital thinning of bone at these sites has been proposed as a predisposing factor to CSF leak. In this retrospective study, we investigate CT and MR images for findings that suggest CSF leak versus intracranial hypertension in patients with clinical and imaging presentation suspicious for spontaneous CSF leak.

**Materials and Methods**

A total of 14 subjects were selected retrospectively between 2007 and 2013 based on the presence of meningoceles/meningoencephaloceles, prominent arachnoid granulations, and clinical suspicion of cerebrospinal fluid leakage. Their images are analyzed closely for the presence of empty sella, tegmen tympani dehiscence, arachnoid granulations, encephaloceles, middle fossa/sphenoid sinus pits, and degree of sinus pneumatization. Imaging signs of intracranial hypertension (prominent perioptic nerve sheath CSF, optic nerve blunting, and sclera flattening) also were sought for. Correlations are made with medical records for clinical presentation of CSF leak and intracranial hypertension.

**Results**

Twelve of 14 subjects have imaging and clinical presentation of spontaneous cerebrospinal fluid leak. These subjects have an average age of 67 and the majority of them (8 of 12) are female. All 12 subjects have imaging finding of arachnoid granulations and encephaloceles. None of the patients have thick skull base. The majority have middle fossa pits (10 of 12). The incidence of empty sella and sphenoid sinus pits are less pronounced (6 of 12) and (4 of 12), respectively. There is no discernible trend regarding signs of intracranial hypertension in these 12 patients.
Among the two patients without diagnosis confirmation of CSF leak, one patient has imaging finding of thick skull base and clinical evidence of intracranial hypertension. The second patient has imaging findings of right cribiform plate dehiscence but no tegmen tympani dehiscence or clinical presentation of CSF leak.

Conclusions
Spontaneous cerebrospinal fluid leak is a complex and dynamic disease that requires time to fully manifest itself. Patients with this disease tend to not seek medical work up until signs and symptoms of actual fluid leakage occur, which is often late in their lives. This is reflected by a rather advanced average age seen in our spontaneous CSF leak group, and overwhelming evidence on CT and MR imaging of spontaneous CSF leak at initial presentation. Alternatively patients may present with headache and imaging findings of intracranial hypertension at younger age, as seen in one of our subjects. We suspect that these younger patients with intracranial hypertension will proceed to have CSF leak later on in life as the skull base eventually gives way to the elevated pressure, or they may continue with signs/symptoms of intracranial hypertension if they have a congenitally thick skull base.

Uncommon Solid and Cystic Orbital Masses

W Chwang¹, P Doshi¹
¹Henry Ford Hospital, Detroit, MI

Purpose
Many orbital masses overlap in clinical and radiological presentation. While typical orbital masses such as hemangioma, lymphoma, and pseudotumor are commonly seen, there is a wide spectrum of entities for which the orbit is an uncommon location. The purpose of this Education Exhibit is to illustrate examples of uncommon orbital masses that can help expand the radiologist's differential diagnosis.

Materials and Methods
First, we will present a brief review of basic orbital anatomy. Then we will illustrate uncommon solid and cystic orbital masses that we have seen at our institution. We will show pathologically proved cases of cholesterol granuloma, dermoid cyst, chondrosarcoma, undifferentiated carcinoma, melanoma, malignant fibrous histiocytoma, and metastatic paraganglioma occurring in the orbit.

Results
Many etiologies often are not thought of when confronted with an unknown orbital mass. Having an awareness of some uncommon orbital masses, based on their composition and location, is important for generating an appropriate differential, making the correct diagnosis, and guiding clinical management.

Conclusions
A wide spectrum of masses can occur in the orbit, which can look very similar and present with overlapping clinical symptoms. Knowing the imaging features of some uncommon solid and cystic orbital masses is helpful for expanding the differential diagnosis.
“Plug in Your Jug!”: An Imaging Review of Jugular Vein Thrombosis

N Koontz¹, R Wiggins², L Shah²
¹University of Utah School of Medicine, Salt Lake City, UT, ²University of Utah, Salt Lake City, UT

Purpose
While identifying jugular vein thrombosis (JVT) on imaging is relatively straightforward, the difficulty comes in determining its etiology and identifying associated pathology and complications. The purpose of this educational poster is to provide a comprehensive review of the critical anatomy, pathophysiology, etiologies, imaging findings, and diagnostic pitfalls of JVT.

Materials and Methods
We reviewed our institution’s imaging database for illustrative cases of JVT and present a selection of multimodality (CT, MRI, US, angiographic, and nuclear medicine) imaging. Additionally, a review of the current medical literature was performed.

Results
Jugular vein thrombosis is a serious finding occasionally encountered by radiologists. While identifying thrombus within the internal jugular vein (IJV) usually is not a diagnostic dilemma, the sundry etiologies, potentially devastating complications (including pulmonary embolism, septic emboli, and dural sinus thrombosis), and high association with neoplasm warrant careful consideration by the interpreting radiologist. The pathophysiology of JVT is rooted in the well-known Virchow triad, which posits that three broad categories of factors are at play in the development of vascular thrombosis: static blood flow, endothelial injury, and hypercoagulability. A disruption of one or more of these variables increases the risk of developing a thrombus. In its native state, the IJV is unlikely to spontaneously develop
thrombus, due to its paucity of valves and gravitational venous return. Altering the dynamics of the Virchow triad can shift patients into a prothrombotic state. While JVT is most commonly encountered in patients with thrombogenic central venous catheters or postoperatively following neck dissections, various etiologies of JVT exist beyond the obvious iatrogenic sources. These include neoplastic, infectious, traumatic, hematologic, rheumatologic, gynecologic, congenital, endocrine, and idiopathic causes, which we address in this educational exhibit.

Conclusions
Given the many etiologies of JVT, it is important for radiologists to consider the clinical context of this important imaging finding. In doing so, one can suggest an appropriate, patient-specific, clinically relevant differential diagnosis and add clinical value to a radiologic report. In addition to imaging clues, correlation with the medical record and consultation is often needed to answer the question of "Why?". The diagnosis of JVT should be seen as an investigational starting point and not simply a dead end observation.

Amplatzer Vascular Plug for rapid vessel occlusion in Interventional Neuroradiology

J Shankar¹, R Vandorpe¹

¹QE II Health Science Center, Dalhousie University, Halifax, Nova Scotia

Purpose
Amplatzer vascular plug (AVP) has been used for transcatheter embolization in peripheral vasculature; occlusion of abnormal vessel communications and other neurovascular conditions (4, 5). With the nonavailability of detachable balloons in the market, there is a need for a device with potential for rapid vessel occlusion. We believe AVP can be used in some of these scenarios. The purpose of this paper is to report different uses of endovascular AVP treatment for rapid vessel occlusion in the field of Interventional Neuroradiology.

Materials and Methods
We retrospectively reviewed our interventional neuroradiology database from November 2010 to October 2013 and found five patients who were treated with endovascular AVP treatment. Amplatzer vascular plug was used for rapid vessel occlusion in all of these patients. Two patients presented with carotid blowout with massive hematemesis from oral cancer, two patients had preoperative balloon test occlusion and sacrifice and the fifth patient had massive hematemesis from erosion of the right internal jugular vein from oral cancer.

Results
The right internal carotid artery (ICA) was sacrificed without balloon occlusion test (BOT) in two patients with carotid blowout. The left ICA was occluded after BOT in one patient and the left vertebral artery was occluded after BOT in one patient. The right internal jugular vein was occluded without BOT in one patient. Amplatzer vascular plug was deployed in all patients using 5 french guiding catheter. In two out of the five patients 2-3 coils were used in addition to the AVPs. In all cases, more than one AVP was used and the occlusion was almost immediate with no thrombo-embolic complications. Compared to expected number of coils needed to occlude these vessels, we believe use of AVP was significantly cheaper.

Conclusions
Use of AVP is a feasible, safe, fast and cost-effective method for rapid occlusion of larger size vessels for different indication. In the past in many of these situations, detachable balloons were being used for rapid vessel occlusion. Amplatzer vascular plug appears to be useful and cheaper alternative to detachable balloons for rapid vessel occlusion in many clinical scenario.

Congenital Pial Arteriovenous Fistulas in the Infant and Neonatal Population: Clinical Series and Review of the Literature

D Murph¹, B Bohnstedt¹, D Hsu², A DeNardo², J Scott²
¹Indiana University, Indianapolis, IN, ²Goodman Campbell Brain and Spine, Indianapolis, IN

Purpose
Pial arteriovenous fistulas (AVFs) are a rare entity with a paucity on the subject in the neurointerventional literature. Pial AVFs are characterized by having direct communication between a pial artery and a cerebral vein, absence of intervening nidus, an often dilated venous varix, and location in the subpial space. This characteristic architecture distinguishes this lesion from dural arteriovenous fistulas, vein of galen malformations, and cerebral arteriovenous malformations. The purpose of this exhibit is to describe the clinical presentation, imaging findings, and management of pial arteriovenous fistulas through four illustrative cases.

Materials and Methods
An IRB-approved, retrospective review of the Indiana University Health neurointerventional database from January 2005 to December 2013 was conducted for children presenting under the age of two years with pial AVFs confirmed by angiography. Only true single-hole and multiple-hole pial fistulas were included. Clinical histories and diagnostic imaging were obtained.

Results
Four children with congenital pial AVFs were reviewed. Profound high-flow congestive heart failure was the initial presentation in the two patients presenting within the first week of life. Seizure was the initial presentation in the two patients presenting within the first week of life. Initial diagnostic imaging varied and included transcranial doppler ultrasound, CT, and MRI. In each case, digital subtraction angiography demonstrated a dilated venous varix along with single or multiple hypertrophied arterial feeders. Three patients underwent a combination of endovascular coiling, N-butyl-cyanoacrylate (NBCA), and/or ethylene vinyl alcohol copolymer (EVOH, Onyx) embolization. Partial coil embolization with subsequent surgical resection was utilized in one case.

Conclusions
Pial arteriovenous fistulas are a rare form of congenital arteriovenous anomaly with an angi-architecture that differentiates it from other forms. The presentation is variable with some patients presenting very early in development with high output cardiopulmonary failure and others presenting with neurologic sequelae such as seizure. In this group, therapeutic management included endovascular embolization, and in one case, surgical disconnection and resection.

Extracranial Arteriovenous Malformation of the Head and Neck: Our Approach for Endovascular Treatment

M Akdol\textsuperscript{1}, A Amole\textsuperscript{1}, E Erdem\textsuperscript{1}
\textsuperscript{1}University of Arkansas for Medical Sciences, Little Rock, AR

Purpose
Arteriovenous malformations (AVM) of the head and neck are rare and complex vascular diseases. AVMs can potentially create long-term functional, cosmetic sequelae, and intractable bleeding; prompt and early intervention is required to address these problems. The interventions include a wide spectrum of treatments from surgical excision and reconstruction to endovascular embolization. Respective combination therapy also may be used depending on the location of the lesion and treatment goals. The aim of this presentation is to clarify our approach to endovascular treatment of head and neck AVMs, the various agents used including the advantages/disadvantages based on certain localizations and clinical situations.

Materials and Methods
The major determining factor for the treatment is the location and extent of the disease. Prompt surgical treatment is recommended for all accessible lesions at an early stage. This can be performed with or without presurgery embolization depending on the lesion size and presence of feeders originating from surgically difficult to reach areas. In our experience, patients with large AVMs and extensive soft tissue involvement tend to have better outcomes with staged embolization. Aggressive clinical follow up is required to minimize the progression of the disease process. Surgical intervention is warranted whenever resection and reconstructive
surgical procedures become viable option to control potential complications, cosmetic and functional disfigurement. Therefore, close collaboration with the surgical team and continuous assessment of the treatment progress is mandatory. In daily practice we favor liquid embolic agents over solid ones, like coils due to lack of intranidal flow control. The three major liquid embolic agents used are: dehydrated ethyl-alcohol (ETOH), n-butyl cyanoacrylate (NBCA) glue and ethylene vinyl alcohol copolymer in dimethyl-sulfoxide (Onyx). Each of them has unique capabilities and drawbacks. Specific characteristics are interrogated in this exhibit in detail.

Results
Head and neck AVMs are poorly understood and the progress of the disease process presents many dilemmas. Long-term follow up of the patients reveal high recurrence rate and progressive cosmetic, functional deformity of the structures involved. Pain and intractable bleeding also may present challenges to the patient. Aggressive follow up and surgical intervention are the mainstay approach. But, due to progressive nature of the process, it is unlikely to obtain a cure in most cases. With the introduction of new embolic agents and materials, endovascular embolization also became a viable option to control the course of the disease. As mentioned previously, several agents can be used. The localization, vascular architecture of the AVM nidus, extent of the tissue involvement, origins of the feeding branches are the major factors to determine the suitable embolic agent.

Conclusions
The head and neck AVM presents unique challenges to the patient and physician. High recurrence rate of the disease despite aggressive treatment, and progressive functional loss are the main difficulties. Especially in the setting of a large head and neck AVM, proactive, aggressive approach with combination of surgical and endovascular interventions may limit the disease progress and improve the patient's symptoms.

Spinal Arteriovenous Lesions: A Review of Imaging Manifestations, Diagnosis and Treatment

A Hurlbut1, F Rivas Rodriguez1, V Vadlamudi2, A Pandey2, N Chaudhary1, B Thompson2, J Gemmete1

1University of Michigan Medical Center, Ann Arbor, MI, 2University of Michigan Health System, Ann Arbor, MI

Purpose
To review in an interactive format the imaging manifestations of spinal arteriovenous malformations and arteriovenous fistulas to ensure appropriate diagnosis and treatment.

Materials and Methods
Use a series of case examples to illustrate the imaging appearance of the different subtypes of spinal arteriovenous malformations and arteriovenous fistulas. The cases will be presented utilizing a variety of imaging modalities including CTA, MR, MRA, and conventional angiography. In addition, we will review spinal cord, spinal vascular, and paraspinal anatomy as it pertains to diagnosis and treatment of spinal arteriovenous lesions. Intraprocedural and
postprocedural case examples also will be provided using both cross-sectional imaging and conventional angiography to discuss the full spectrum of the management process.

Results
Spinal arteriovenous lesions are uncommon; however, failure to accurately diagnosis and treat these complicated lesions can lead to poor patient outcomes. Therefore, a review of this complex subject is important to ensure the interpreting physician renders the appropriate diagnosis and guides the patient towards the next proper step in management. Understanding the pertinent spinal vascular anatomy, imaging manifestations, pathophysiology, and treatment options are important components to improving care in patients with spinal arteriovenous lesions.

Conclusions
The different subtypes of spinal arteriovenous lesions will be reviewed with emphasis on imaging findings, diagnosis, and treatment. We will use the series of case examples to improve the healthcare provider's knowledge of spinal arteriovenous lesions with the ultimate goal of improving patient management.

KEYWORDS: Spinal Angiography, Spinal Arteriovenous Malformation, Spinal Vascular Disorders
Congratulations, You Made the Diagnosis of Neurofibromatosis! Now What?

M O'Dell¹, D Fursevich¹, J Macke¹, B Harshman²
¹Florida Hospital, Orlando, FL, ²Florida Hospital - Radiology Specialists of Florida, Orlando, FL

Purpose
The phakomatoses are a group of heterogenous disorders characterized by congenital malformations of ectodermal origin. The most common, neurofibromatosis (NF), has several distinct subsets each with its own set of characteristics. We often focus on the characteristics necessary to make the diagnosis, possibly at the expense of identifying complications the disease can cause for the patient. This exhibit reviews some of the common tumors and subsequent pathology apparent when evaluating imaging of an NF patient.

Materials and Methods
A Montage search was performed with radiologic-pathologic correlation for all cases of neurofibromatosis within our hospital system over the last seven years. Our search for "neurofibromatosis" produced over 1080 studies, 26 of which had surgical pathology correlates. A sample of images was obtained from children and young adults under the age of 23. We then chose a representative group of cases where the disease process led to symptoms or where resection of a concerning lesion was necessary.

Results
Many of the surgical cases required resection of a benign lesion causing symptoms or a lesion suspicious for malignancy. It is important to be aware, that of the many tumors seen with neurofibromatosis, several have potential to be malignant. We briefly discuss the pathophysiology of NF and cover some lessons learned from a tertiary center with an NF clinic.

Conclusions
Although there are many "Aunt Minnie" features of neurofibromatosis, it is important to be aware of the complications and malignancies that may occur with this disease, and to develop a pattern of search to spot them.

KEYWORDS: Neurofibromatosis, Phakomatoses
Purpose
This pictorial essay will review T2* imaging techniques that are currently available. A brief discussion of the various susceptibility techniques used such as gradient recalled echo (GRE), susceptibility-weighted imaging (SWI), quantitative susceptibility mapping (QSM), and blood oxygen level dependent (BOLD) imaging will be included. We are presenting select case histories to demonstrate their clinical usefulness in pediatric neuroimaging.

Materials and Methods
Select cases demonstrating the utility of T2* imaging in the evaluation of pediatric pathology were identified retrospectively for this educational exhibit.

Results
T2*-based imaging is a technique that accentuates the paramagnetic properties of blood products such as deoxyhemoglobin, intracellular methemoglobin, and hemosiderin. It is particularly useful for detecting intravascular venous deoxygenated blood as well as extravascular blood products. It also is sensitive in detecting and quantifying the presence of iron. We have used this technique in the past several years to study a wide variety of pediatric neurological disorders. T2* relaxation imaging has the ability to reveal pathologic and physiologic conditions of the brain that alter regional susceptibility and reveal abnormalities that are unapparent on conventional MR sequences.

Conclusions
T2*-based imaging is a sequence with broad applicability and should be included in standard imaging evaluation of pediatric pathology.

KEYWORDS: BOLD FMRI, GRE, Susceptibility-Weighted Imaging

Diagnostic Value and Pitfalls of Double Inversion Recovery MRI: a Case Based Pictorial Essay

S Porter1, N Desai1, A Saindane1, B Soares1
1Emory University, Atlanta, GA

Purpose
Double inversion recovery (DIR) is a novel MR sequence that nullifies signals from both the cerebrospinal fluid and normal white matter. Selectively imaging gray matter structures is essential in the evaluation of various neurologic disorders, including inflammatory/demyelinating diseases, malformations of cortical development, mesial temporal sclerosis, and neoplastic processes in the adult and pediatric population. The aim of this educational exhibit is to illustrate the advantages and disadvantages of DIR brain imaging in patients with a variety of disease entities.

Materials and Methods
Using data aggregation and search technology software from our institution's PACS/RIS system,
several illustrative cases of the diagnostic value and pitfalls of DIR were identified for presentation as a pictorial essay.

Results

Superior delineation between gray and white matter can be achieved with DIR MR imaging (MRI) consisting of two inversion pulses applied to simultaneously suppress the signal from two tissues with different longitudinal relaxation times. By selectively suppressing CSF and white matter signals, gray matter only images can be obtained. Double inversion recovery has evolved over the years with recent research focusing on its feasibility at higher magnetic fields and three-dimensional MR imaging. Double inversion recovery is considered advantageous for increased sensitivity and improved lesion detection for a variety of disease entities. We illustrate the increased lesion conspicuity of multiple sclerosis plaques with DIR MRI, especially as it pertains to intracortical lesions. Double inversion recovery MRI has a proven role in lesion detection and lateralization in patients with epilepsy. We demonstrate the role of DIR MRI in epilepsy with cases of malformations of cortical development and mesial temporal sclerosis (MTS). We address the concept that DIR MRI may be over sensitive for the evaluation of MTS. Illustrative cases of the role of DIR to differentiate infiltrating/nonenhancing tumor and vasogenic edema are presented. Identification of cortical tubers in tuberous sclerosis with DIR MRI also has been described in the literature. Because suppression of the MR signal from normal white matter relies on its narrow range of T1 values, the diagnostic value of DIR MRI is limited in the incompletely myelinated child. This educational exhibit raises awareness of the advantages and potential interpretative pitfalls of DIR MRI.

Conclusions

Double inversion recovery MRI is a recent innovation that provides important insights into the study of many neurologic diseases. This case-based pictorial essay serves to broaden the radiologist's understanding of the diagnostic value and potential pitfalls of DIR MRI in a variety of disease entities.

6:30AM - 9:00PM

Diffusion Tensor Tractography of the Pediatric Cervical Spinal Cord Using 3.0 Tesla MRI

K Carey\(^1\), C Shah\(^2\)

\(^1\)Mayo Clinic Jacksonville, Jacksonville, FL, \(^2\)Wolfson Children’s Hospital, Jacksonville, FL

Purpose

Diffusion tensor imaging and fiber tractography of the spinal cord allows for imaging of the white matter tracts of the spine in vivo. Specifically, alterations of the spinal white matter tracts due to spinal lesions can be detected. This has great clinical utility for biopsy and neurosurgical treatment planning as well as follow up. Our aim is to review the application of diffusion tensor imaging of the spine in the pediatric population and provide example cases illustrating the impact of diffusion tensor imaging and fiber tractography on surgical planning.

Materials and Methods

We perform literature review about latest techniques used for diffusion tensor imaging and fiber tractography of pediatric spinal cord using 3.0 T MR imaging (MRI). We compare various
methodologies like reduced field of view, coronal acquisitions and axial acquisitions. Usefulness of spinal cord tractography to assess resectibility of intramedullary tumors will be discussed. We also address limitations of spinal cord tractography with current technique. We illustrate the utility of spinal cord tractography with example cases (graphic).

Results
Spinal cord tractography demonstrates displacement versus destruction of white matter fiber tracts. The location of fiber tracts with respect to the spinal cord lesion may help the neurosurgeon decide the approach for biopsy as well as surgical resection. Resectability of the spinal cord intramedullary masses can be assessed pre-operatively using this information.

Conclusions
Advanced MRI techniques like diffusion tensor imaging and fiber tractography of the pediatric spinal cord using 3.0 T MRI provides excellent information for surgical planning.

KEYWORDS: Diffusion Tensor Image, Pediatric Spine, Spinal Cord

Imaging Manifestations of Natural Course and Complications of Spinal Dysraphism following Repair

D Durand¹, V Kalra¹, C Silva¹, A Malhotra¹
¹Yale University School of Medicine, New Haven, CT

Purpose
Spinal dysraphisms refer to congenital spinal disorders in which there are anomalous differentiations of dorsal midline structures, with or without incomplete closure. They frequently are misclassified, with reports inaccurately swapping between "myelocele" and "myelomeningocele" from findings to impression. We review the correct terminology and classification of spinal dysraphisms, showing XR, US, CT, and MR imaging examples.

Materials and Methods
Spinal dysraphisms are classified as open or closed, depending on whether or not the abnormality is covered by skin. This exhibit begins with a review of normal spinal cord development and anatomy and then information is presented in pictorial format with open and closed spinal dysraphisms subtypes discussed individually, and then comparisons are made between lesions to reinforce similarities and differences to help the clinician narrow their differential diagnosis. Several examples of dysraphisms following repairs also will be presented with common complications including CSF leak, arachnoiditis, acquired arachnoid cysts, and postoperative meningocele/pseudomeningoceles. The natural course of each disease despite surgery also will be highlighted including hydronephrosis and scarring from neurogenic bladder, developmental hip dysplasia, progressive scoliosis from associated segmental spinal dysgenesis, decrease in size but persistence of the distal syrinx, persistent tethered cord and low-lying conus, and residual lipomyelocele resembling primary intradural lipoma.

Results
Open spinal dysraphisms involve neural tube closure defects with open communication of the spinal cord to the environment. They can be classified based on location of the neural placode with respect to the skin. In myelomeningocele and hemimyelomeningocele, the neural placode protrudes above the skin surface, whereas in myelocele and hemimyelocele, the neural placode is flush with the skin surface. Hemimyelomeningocele and hemimyelocele have associated diastematomyelia. Closed spinal dysraphisms (CSD) are skin-covered and are subdivided based on their association with a subcutaneous mass. CSDs with hypertrophic subcutaneous fat components include lipomyelomingocele (placode outside canal, widening of the subarachnoid space) and lipomyelocele (placode inside canal, no widening of the subarachnoid space). CSDs with herniation of CSF can be subdivided into whether the herniation includes neural tissue: in terminal myelocystocele a syringocele herniates into a meningocele whereas no neural tissue is seen in herniation with meningocele and nonterminal myelocystocele. CSDs without subcutaneous masses are categorized into simple or complex. Simple CSDs include intradural lipoma (fat inside dural sheath, usually tethered cord), filum terminale lipoma, tight filum terminale (short, thickened, nonfatty filum with tethering), persistent terminal ventricle, and dermal sinus (epithelium-lined tract extends from the skin surface with possible communication
with the subarachnoid space). Complex CSDs are separated by disorders of midline notochordal integration versus notochordal formation. Those with notochordal integration defects include dorsal enteric fistula (tubular structure extends from skin to bowel), neurenteric cyst (congenital cysts lined by intestinal epithelium), and diastematomyelia (type I vs II). Disorders of notochordal formation include caudal agenesis (types I and II) and segmental spinal dysgenesis.

Conclusions
Spinal dysraphisms represent a challenging group of lesions for the diagnostic radiologist. Understanding the key differences and imaging characteristics is invaluable for differentiating lesions. Increasing the specificity of the differential diagnosis and providing the referring provider appropriate management recommendations is of utmost importance. Through an understanding of the anatomical anomalies found in each defect using XR, CT, US, and MR imaging, a correct diagnosis can be made and necessary surgery performed before onset or progression of symptoms. Knowledge of the natural course and postoperative complications will aid in patient management.

KEYWORDS: Spinal Dysraphism

EdE-94

More Than Just a Headache: What You Need To Know about Pediatric Pineal Region Masses

M O'Dell¹, J Macke¹, D Fursevich¹, B Harshman²
¹Florida Hospital, Orlando, FL, ²Florida Hospital - Radiology Specialists of Florida, Orlando, FL

Purpose
The pineal region can be a blind spot for many radiologists given limited CT detail and anatomical complexity on otherwise innocuous exams. Pediatric patients often present with headache or hydrocephalus when a pineal tumor is still very small, necessitating early recognition. The differential is fairly predictable and when neoplasm is present, it is often benign or responsive to treatment. The purpose of our exhibit is to review normal pineal development and discuss the differential for pediatric pineal region tumors.

Materials and Methods
A Montage search was performed with radiologic-pathologic correlation for all pineal lesions within our hospital system over the last seven years. The search yielded 1509 radiological studies where a pineal lesion was described, 20 cases of which had surgical pathology correlation. A representative sample of images was obtained from children and young adults under the age of 23, including classic and uncommon cases.

Results
The pineal gland has a variable appearance in the pediatric population, typically growing until two years of age then stabilizing in size. The pineal gland may calcify in as many as 30% of patients by late adolescence. Calcifications under age six are uncommon and can be worrisome. The most common lesion overall is a pineal cyst. When tumor occurs, it is generally either germ cell or pineal cell origin with germinoma being the most common in the pediatric population. Treatment is often a combination of surgery and chemoradiation.
Conclusions
Although only a small percentage of central nervous system (CNS) tumors originate in the pineal region, they are several times more likely in children than adults and the consequences can be quite significant. Knowledge of anatomy and early tumor recognition is imperative. Our exhibit provides clinicians with a review of the pediatric pineal region with respect to development and neoplasms.

KEYWORDS: Pineal Calcification, Pineal Cell Tumor, Pineal Cyst

EdE-87

M Warade¹, H Branson¹, M Shroff¹
¹The Hospital for Sick Children, Toronto, Ontario, Canada

Purpose
1). To review and demonstrate Brain MR imaging (MRI) features of neonatal encephalopathy (NE) which suggest etiologies other than hypoxia-ischemic injury (HII). 2).To provide an easy to use road map for important alternative (other than HII) diagnostic considerations to the radiologist performing neonatal MRI.

Materials and Methods
A retrospective analysis of 750 consecutive neonatal MRI brain studies obtained between November 2010 and October 2013 at presentation of encephalopathy was performed to assess the imaging findings that suggest etiologies other than HIE. Inclusion criteria were term neonates (≥ 36 weeks gestational age) with seizures, hypotonia, altered sensorium, feeding difficulty or difficulty in maintaining respiration. Preterm babies and those studies performed for reasons other than the aforementioned were excluded from our study. Where feasible and necessary, additional information was obtained from patient's electronic charts. Entities with rare incidence such as some of the metabolic causes of NE, have been included selectively in this study from former hospital database for the sake of complete depiction of the spectrum.

Results
The causes of NE are heterogeneous. The outcomes of NE range from potentially reversible to severe long term morbidity such as cerebral palsy, intellectual disability, learning/behavioral problems and/or mortality. MR imaging evaluation has been extremely valuable to assess neonatal brain in NE for the purpose of diagnosis and prognostication. HII is the most common cause of NE for which characteristic MR appearances have been described. Neonatal brain imaging is becoming more commonplace and neonatal brain injury often leads to medico-legal cases involving physicians, hospitals and parents. Given the facts that there is a considerable overlap of clinical and MRI appearances of different etiologies and that more than one etiology may co-exist, it is exceedingly important to recognize the patterns of brain injury that constitute the complex imaging spectrum of NE. Diffusion-weighted imaging (DWI) and MR spectroscopic imaging are particularly useful and often problem-solving tools in the setting of metabolic encephalopathy. MR angiography, MR venography and susceptibility-weighted imaging compliment neonatal vascular imaging and neonatal head trauma at time of injury. MR
evaluation may, thus, point to an alternate and/or co-existent etiology, aiding in accurate
diagnosis and timely institution of specific therapy. Table 1 is a list of various etiologies (other
than HII) which will be reviewed and demonstrated as an easy to review road map for important
alternative diagnostic considerations.
Conclusions
Neonatal encephalopathy is etiologically diverse with a wide range of outcomes and broad MR
imaging spectrum. MR imaging appearances can help to identify additional and/or alternative
diagnosis in apparent HIE and point to a specific etiology. This is invaluable for appropriate
management decisions, prognosis and medicolegally.

Pediatric Brain Imaging in Congenital Heart Disease. A Pictorial Essay

P Caro Dominguez¹, D Pohl¹, J Davila¹
¹Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada

Purpose
The purpose of this pictorial essay is to illustrate and explain the spectrum of abnormalities visualized on brain MR in pediatric patients with congenital heart disease, including presurgical, surgical and postsurgical complications, cardiac arrest and infections.
Materials and Methods
We have retrospectively reviewed 500 brain MRI images from our pediatric institution in which the word "cardiac" was included in the report from March 2006 until November 2013. These studies have been reviewed by a pediatric neuroradiologist and a pediatric radiology fellow. A consultant pediatric neurologist reviewed the clinical chart of the cases shown in this review. Neurological symptoms, vascular studies and the pattern of ischemic changes were recorded.

Results
The studies were performed before surgery, within two weeks of surgery, and several months after surgery. Neurological complications after cardiac surgery included stroke, encephalopathy, persistent cognitive impairments and signs of infection. Acute imaging findings included infections/abscesses and stroke. Territorial stroke was seen associated with either septic or nonseptic cardiac emboli. The mechanisms underlying these neurological events may include microemboli and hypoperfusion during surgery, and postoperative atrial fibrillation.

Periventricular leukomalacia was found in multiple studies as previously shown by Galli et al (3). It was found in >50% of neonates after cardiac surgery but rarely in older infants. Hypoxemia and hypotension in the early postoperative period, particularly diastolic hypotension, may be important risk factors for periventricular leukomalacia (4). Brain imaging within 24-48 hours of postcardiac arrest was negative in four patients with diffuse positive finding in imaging performed later. On late imaging, it is frequent to see multiple foci of susceptibility on gradient-echo sequences in the deep and subcortical white matter as a unique finding in some patients with previous surgery. They could be the result of microhemorrhages from previous anticoagulation treatment or emboli.

Conclusions
Mild ischemic lesions, primarily in the form of PVL, occur in a number of neonates with CHD before surgery and >50% of patients postoperatively. Resolution of these lesions is common four to six months after surgery (1). Diffusion-weighted imaging (DWI) and gradient-echo sequences have shown to be the most sensitive sequences to detect ischemic changes; however, in cardiac arrest, the imaging findings may present after 48 hours. Thus, in our population, focal cortical lesions were common after open heart surgery, and, in addition, diffuse brain abnormality on MRI plus neurological sequelae were common after prolonged hypothermic circulatory arrest (5). More precise neuroimaging of patients with these complications may lead to a better understanding of the etiology and treatment of these disorders.

Pediatric Strokes: What You Need to Know

R Klinglesmith1, D Doan1, A Davis2, E Supsupin1
1University of Texas Houston, Houston, TX, 2Cook Children’s Hospital, Fort Worth, TX

Purpose
Pediatric stroke (PS) is a relatively uncommon but underdiagnosed condition with heavy consequences, both individual and social. Most survivors subsequently suffer some form of cognitive or neurologic impairment, adversely impacting functional status and quality of life.
This in turn increases burden on health care resources (1, 2). This pictorial essay focuses on increasing awareness of PS. Emphasis is on etiologies, general risk factors and predisposing conditions unique to different age groups, classification, imaging approaches to diagnosis, treatment options, and outcomes.

Materials and Methods
Clinical challenges resulting in misdiagnosis or delayed diagnosis that negatively impact overall outcome are presented. Cases depicting factors that may increase clinical suspicion, and thus aid in promoting awareness are included (1). Stroke mimics are discussed.

Results
Etiologies and risk factors for PS are substantially different from adults. Clinical presentation may vary depending on age (1, 3). Pediatric stroke is believed to be under-diagnosed or misdiagnosed in infancy and childhood (1, 3, 4). Yet the consequences are serious, with increased morbidity, variable long-term outcome and high costs (2). About half of survivors of PS may have neurologic or cognitive impairment. Just over a quarter of survivors will develop some form of epilepsy. Neonates are particularly vulnerable, making up to 25% of acute ischemic stroke patients in the pediatric population. Additionally, as many as 14% of newborns with seizures are diagnosed with cerebral infarction (4). Increasing knowledge about stroke in the pediatric population is crucial in order to reduce morbidity and mortality. Awareness of etiologies and risk factors unique to a specific age group may facilitate prompt referral.

Appropriate workup (including neuroimaging, metabolic, and hematologic investigation) is key to correct diagnosis and timely, optimal treatment. Although management strategies are mainly extrapolated from adults, pediatric-specific considerations (such as short-term anticoagulation and guarded recommendations on thrombolytics) remain useful.

Conclusions
Increased awareness may help overcome the clinical challenges that often result in misdiagnosis or delayed diagnosis of stroke in infancy and childhood. Timely diagnosis and referral coupled with optimal treatment may lead to a more favorable outcome.

### Pictorial Review of Childhood Primary Central Nervous System Vasculitis

L Verhey¹, M Moharir², M Shroff³

¹The Hospital for Sick Children Research Institute, Toronto, Ontario, Canada, ²The Hospital for Sick Children, Toronto, Ontario, Canada, ³The Hospital for Sick Children/University of Toronto, Toronto, Ontario, Canada

**Purpose**

Primary angiitis of the central nervous system (PACNS) is being recognized increasingly in children and represents an acute inflammatory disorder in which immune cells target the arterial endothelial cells of the CNS causing severe neurological deficits in previously healthy children. Three subtypes currently are recognized: nonprogressive large-medium vessel childhood PACNS (cPACNS), progressive large-medium vessel cPACNS, and small vessel cPACNS. We provide a pictorial review of the neuroimaging features of cPACNS.

**Materials and Methods**

The pictorial review represents the collaborative expertise essential to caring for children with cPACNS, and includes input from a multidisciplinary team of pediatric neuroradiologists, pediatric neurologists with expertise in inflammatory disease, and pediatric rheumatologists at The Hospital for Sick Children (Toronto, Canada). A review of the neuroimaging features of
Children with PACNS, who were identified from the neuroradiology and neurology databases at The Hospital for Sick Children, will be presented. Hallmark features on conventional MR imaging (MRI) and time-of-flight MR angiography, conventional catheter cerebral angiography, and advanced MRI techniques such as contrast-enhanced vessel wall imaging will be reviewed. 

**Results**

Large-medium vessel cPACNS shows irregularity and narrowing, and in some instances occlusion, of the vessels on MR angiography and conventional catheter angiography; T2-weighted and diffusion-weighted imaging show features of acute ischemic stroke. T2-weighted, gradient-echo, and susceptibility imaging have a role in detecting hemorrhage which can inform on acute therapeutic decisions. MR angiography and conventional catheter angiography is normal in children with small vessel PACNS, necessitating brain biopsy for definitive diagnosis. T2-weighted and FLAIR imaging features may resemble those of inflammatory demyelination; however, leptomeningeal enhancement may be a specific feature of small vessel cPACNS. Contrast-enhanced wall imaging provides new insight into the radiographic visualization of the pathologic processes of vessel wall inflammation operative in PACNS.

**Conclusions**

Neuroimaging plays a key role in the diagnosis of childhood PACNS. Recognition of patterns on multimodal neuroimaging is essential to identifying disease subtypes and screening patients for invasive diagnostic techniques such as conventional catheter angiography and brain biopsy. Serial neuroimaging is essential in the clinical care of children. Understanding MRI indices of neurological outcome is pivotal and relies on ongoing follow up of children followed in our program.

**EdE-92**

**Pictorial Review of Mimics of Acquired Inflammatory Central Nervous System Demyelination in Children**

L Verhey\(^1\), B Banwell\(^2\), M Shroff\(^3\)

\(^1\)The Hospital for Sick Children Research Institute, Toronto, Ontario, Canada, \(^2\)The Children’s Hospital of Philadelphia, Philadelphia, PA, \(^3\)The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada

**Purpose**

An acquired demyelinating syndrome (ADS) is characterized by acute neurological deficits and focal or multifocal areas of T2-hyperintensity in the brain, optic nerves, or spinal cord on magnetic resonance imaging (MRI). Common presentations include optic neuritis, brainstem syndromes, polyfocal neurological deficits, transverse myelitis, and acute disseminated encephalomyelitis. Acquired demyelinating syndrome may occur as a monophasic illness in some children, while it may represent the incident clinical manifestation of multiple sclerosis (MS) in others. The clinical features of acute demyelination are not specific. Clinicians must be aware of MRI features (i.e., "red flags") that should prompt consideration of diagnoses other than ADS and MS. We provide a pictorial review of MR imaging (MRI) features of diseases that mimic ADS and MS that radiologists should consider in the differential diagnosis.
Materials and Methods
Children less than 18 years of age who were initially considered to have acquired demyelination and for whom evolving clinical features, laboratory evaluations and MRI findings helped confirm an alternative diagnosis were included. Participants were identified from a national prospective study of children with CNS demyelinating disease (1) and from the neuroradiology database at The Hospital for Sick Children (Toronto, Canada). MR imaging features considered to be "red flags" that may assist radiologists in distinguishing inflammatory demyelination from other CNS disorders will be presented.

Results
Mimics of acquired demyelination in our cohort include malignancy (e.g., infiltrative astrocytoma), fibrocartilaginous embolic infarct of the spinal cord, small-vessel primary angiitis of the CNS (SV-pACNS), CNS lupus, Lyme disease, neurosarcoidosis, viral encephalitis, cerebellitis, and mitochondrial disease. "Red flags" seen on MRI include: leptomeningeal enhancement (seen in SV-pACNS and malignant and infectious processes), lesion expansion on serial MRI (although recognized in MS, this finding should prompt consideration of a diagnosis of neurosarcoidosis or tumor), and hemorrhage (acute necrotizing encephalitis, cerebellitis and CNS vasculitis).

Conclusions
Prompt diagnosis and early initiation of corticosteroid therapy are important in the clinical management of ADS and MS. However, their diagnoses remain challenging; early identification of atypical MRI features will facilitate proper investigations to aid in making an alternative diagnoses.

Stuffy Noses: A Review of Pediatric Paranasal Sinus Masses

M O'Dell¹, D Fursevich¹, J Macke¹, B Harshman²
¹Florida Hospital, Orlando, FL, ²Florida Hospital - Radiology Specialists of Florida, Orlando, FL

Purpose
The purpose of this exhibit is to review the CT and MR imaging features and pathology of common and more rare pediatric nasopharyngeal and paranasal sinus lesions. Such lesions often are not detected until later stages; therefore, it is imperative for the radiologist to be cognizant when reviewing head CTs for vague pediatric complaints such as headache. In addition, we will review common pitfalls and propose a few points for a more thorough pattern of search.

Materials and Methods
A Montage search was performed with radiologic-pathologic correlation for all nasopharyngeal and paranasal sinus lesions detected by CT or MR imaging of the skull at our institution over the last seven years. An exclusion age criteria of 25 years was used, since many pediatric paranasal tumors can be slow growing. Images were obtained in cases with designated classic, subtle or ambiguous findings.
Results
There is a broad differential for tumors in the paranasal sinuses of pediatric patients. Whereas in adults, squamous cell cancer is the most common tumor by far, the pediatric differential diagnosis is a little more complex. The epidemiology of benign and malignant paranasal sinus tumors is demonstrated with the selected cases. Additional mimics of benign and malignant lesions are presented.

Conclusions
Pediatric paranasal sinus lesions have a broad differential and when lesions are discovered, it is commonly late in the disease course. Given the often vague presenting complaints, it is important for the interpreting radiologist to have a strong search pattern and understanding of the pathology that can arise from the paranasal sinuses. This exhibit reviews imaging features and pathology of common and more rare pediatric nasopharyngeal and paranasal sinus tumors.

Thalamic Lesions in the Pediatric Population

K Carey1, C Shah2
1Mayo Clinic Jacksonville, Jacksonville, FL, 2Wolfson Children’s Hospital, Jacksonville, FL

Purpose
A large number of lesions involve the thalamus in the pediatric population. The purpose of this educational exhibit is to review computed tomography (CT) and magnetic resonance (MR) imaging findings of thalamic lesions in the pediatric population.

Materials and Methods
We retrospectively reviewed MR and CT images of multiple children with thalamic lesions diagnosed at our tertiary care children's hospital. We illustrate disease entities using advanced MRI techniques like tractography (figure), perfusion MRI and MR spectroscopy acquired using 3.0 T and 1.5 T MRI equipments. Differential diagnosis for the imaging findings and salient imaging features of each entity are discussed. We perform literature review to generate discussion of disease entities with focus on advanced MR imaging.

Results
The thalami are paired symmetric structures, which serve to relay signals between the cerebral cortex and midbrain. They are susceptible to various pathologies, some of which are predominantly seen in the pediatric population. Neoplastic, inflammatory, congenital, vascular, and traumatic processes affect the thalamus. We review the unique imaging features of each of these categories of lesions with specific example cases. These lesions include pilocytic astrocytoma, grade II astrocytoma, arteriovenous malformation, tumefactive multiple sclerosis, hypoxic ischemic injury, and neurofibromatosis type 1 lesions.

Conclusions
Awareness of the disease processes and diagnostic imaging features of thalamic lesions in the pediatric population are important to recognize in order to provide timely and appropriate management.

Bibliometric Research for the Neuroradiologist: A Review of Strengths, Limitations, and Case Examples

L Wing¹, T Massoud²
¹John Radcliffe Hospital, Oxford, UK, ²Stanford University School of Medicine, Stanford, CA
Purpose
We summarize the current and potential roles of bibliometric (quantitative analysis of research publications and citation rates) research in neuroradiology. We also demonstrate uses of bibliometric indicators in the neuroradiologist's academic and clinical practice, and introduce potential future research performance metrics and their uses.

Materials and Methods
The use of bibliometrics is becoming increasingly widespread in the academic community, with applications ranging from individual use in journal selection to institutional use in resource allocation and academic recruitment. Since the invention of Garfield's Scientific Citation Index in 1961 and the Journal Impact Factor shortly thereafter, a vast array of bibliometric indicators have been developed, many of which are in active use today. The way in which research findings are communicated to the academic community has evolved, heavily affecting the relevance of such bibliometric indicators. The abundance of citation-based metrics can pose many questions to today's neuroradiologist: What does each metric represent? Which metric should be used? How should they be interpreted?

Results
We present a clear and up-to-date explanation of the most commonly used citation-based metrics in the academic community (including Journal Impact Factor and H-index) in the context of today's increasingly online academic community. We explore the advantages and pitfalls of using such metrics through several case examples: (a) using a range of indicators to compare two hypothetical neuroradiologists' research output; (b) examining the academic output of neuroradiologists compared to other radiological subspecialties; (c) using temporal trends in publication output and citation rates to identify potential growth in research fields and therefore aid decisions in funding. Importantly, we also introduce newer concepts such as "altmetrics" and "webometrics", demonstrating their utility in neuroradiology research and education through case examples.

Conclusions
Bibliometric indicators have a wide range of applications in neuroradiology; from enabling us to compare the work of individuals to extracting trends from decades of research publication in an entire research field. As bibliometric information and data become increasingly prolific, we aim to demystify these seemingly complex metrics and provide a clear insight into their strengths and limitations to encourage neuroradiologists to use these powerful tools.

EdE-98

Meaningful Use and Electronic Health Records in Neuroradiology

A Siddiqui

1University of Tennessee Health Science Center, Memphis, TN

Purpose
To explore the meaningful use electronic health record incentive program and its impact on neuroradiologists.
Materials and Methods
Due to the government electronic health record incentive program, known as meaningful use, many hospitals and physician groups have begun implementing electronic health records. We evaluate the meaningful use regulations as they apply to neuroradiologists. Furthermore, we will evaluate the potential benefits of having access to detailed patient history.

Results
Meaningful use is a government-run program to accelerate the adoption of electronic health records in the U.S. Through a carrot and stick approach, physicians, including radiologists, can receive incentive payments for compliance and may be penalized for noncompliance. Following the 2012 rule-making, radiologists have received a five-year "significant hardship exemption", meaning that they can receive incentive payments for compliance but will not be penalized for noncompliance. Meaningful use is divided into stages, and everyone starts with stage 1. We look closely at stage 1 and stage 2 regulations and determine potential challenges in achieving meaningful use for neuroradiologists. For example, neuroradiologists (who do not do procedures) have very limited face-to-face contact with patients. While this initially may seem like a hurdle to meaningful use compliance, a lot of exclusions to the meaningful use regulations may be applicable. It could be possible to implement meaningful use with little or no interruption to current workflow. Accurate interpretation of functional MRI, diffusion tensor imaging, and advanced MRI protocols require detailed patient history. It is not enough to know if a patient has had surgery or radiation therapy, but what the time course of treatment has been. What medications has the patient received and when? It is not possible for a referring physician to impart all of the required information either in a requisition or even separate paperwork. When such paperwork is received, it often is disorganized and easily misplaced. Even when a hospital system has an electronic health record populated with patient information, it often is difficult to access. We look at the potential risks and benefits of having neuroradiologists improved access to a hospital's electronic health records. We also look at how an electronic health record can be filtered to suit the neuroradiologists workflow.

Conclusions
There are definite financial benefits in achieving meaningful use through incentive payments. However, the true benefit in meaningful use and electronic health records is complete access to the patient history. Neuroradiologists often are reading complex studies to answer complex questions, and having access to progress notes, medications, and lab results can significantly improve the quality of our reports and patient care. It is imperative that neuroradiologists become more vocal both within the radiology department and within the hospital administration about improving access to patient history. It is not enough to have access to the hospital's electronic health records but that access has to be optimized in order to display neuroradiology-pertinent information in a concise and timely manner. Modern day electronic health record software allows this flexibility. Cooperation between the neuroradiology department, electronic health record vendor, and hospital IT can lead to the creation of a neuroradiologist centered electronic health record that is more robust and better integrated into the daily workflow.

KEYWORDS: Economics
Purpose
The introduction of the Milestone Project by the ACGME for use in evaluation of residents and fellowship physicians poses new challenges to resident and fellowship curriculums. The purpose of this exhibit is to introduce the 12 milestones and show the need to adapt to this form of evaluating and at the same time strengthen our radiology and fellowship program's proposed new tools to adapt to the milestone project.

Materials and Methods
The ACGME milestones are a behavior, attitude or outcome related to general competencies that describe a significant accomplishment expected of a resident by a particular point in time, progressing from beginning of residency through graduation and are defined as the "knowledge, skills and attitudes, and other attributes for each of the ACGME competencies organized in a developmental framework from less to advanced". Milestones are to be used biannually as a review of resident or fellow performance. The Milestones evaluate the competencies and are arranged into levels from 1 through 5 that go from the resident demonstrates milestones expected for one who has had some education in radiology (level 1) to a level where the resident has advanced beyond performance (level 5). The milestones are part of the new accreditation system. In January 2013 the milestones of core programs were published, in July 2013 the subspecialty milestone development begins. Milestones: Patient care and technical skills. Consultant: Competence in procedures. Medical Knowledge: Protocol selection and optimization of images. Interpretation of examination system-based practice. Quality improvement. Health care economics. Practice-based learning and improvement. Patient safety: Contrast agents; radiation safety; sedation; Self-directed learning; Scholarly activities. Professionalism: Professional values and ethics. Interpersonal and communication skills. Effective communication with patients, families, and caregivers. Effective communication with members of the health care team.

Creating or adapting exiting tools as metrics to integrate into the milestone system is crucial.

Results
Fellowship program directors must be aware of the changes facing the programs in the near future.

Conclusions
Fellowship programs are facing new challenges, understanding and preparing to adapt to the Milestone Project.

Seeing the Unseen: Expanding Your Search Patterns to Make the Peripheral Findings

R Khan1, A Meshksar1, S Shroff2, G Choudhary1, D Pastel3, J Becker1, R Inampudi1, R Carmody2, W Erly1, W Kubal2, K Nael2

1University of Arizona Medical Center, Tucson, AZ, 2University of Arizona, Tucson, AZ, 3Dartmouth Hitchcock Medical Center, Lebanon, NH
Purpose
In an age of image overload and pressure to read more quickly, it is easy to focus individually on the brain, neck, or spine and overlook the peripheral findings that may be just as important or more important than the central ones. Masses, fractures, aneurysms, hemorrhage and other diagnoses can go unnoticed if not sought after. This exhibit is a multimodality review that focuses on peripheral imaging findings and how to make them consistently.

Materials and Methods
The exhibit includes a discussion of expanded search patterns, how to maximize images to obtain the highest diagnostic yield including windowing and leveling, and focuses on both difficult and more obvious peripheral diagnoses that can be overlooked. The exhibit is divided into brain, spine, and head and neck in both the traumatic and nontraumatic settings.

Results
Studies of the head include findings in the orbits, in the pterygopalatine fossa, and upper face and neck. Images of the neck cover findings in the brain, spine, mediastinum, lungs, and pleura. Those of the spine include findings in the skull base, neck, chest, abdomen, and pelvis. Individual diagnoses will include primary tumors, metastases, hemorrhages, fractures, vascular abnormalities, infection, and many more. Frequently missed lesions will be illustrated.

Conclusions
In reviewing this exhibit, radiologists will: 1. Be more familiar with search patterns that will lead to routine recognition of peripheral imaging findings. 2. Be exposed to a wide array of pathology outside of the central focus of dedicated neurological imaging studies.

KEYWORDS: Quality Assurance, Quality Control, Quality Improvement
Purpose
Review the complex formula that CMS (Centers for Medicare and Medicaid Services, or Medicare) uses to reimburse direct practice expense (PE). Discuss the multiple ways in which practice expense reimbursement to neuroradiologists has been cut by CMS in recent years.

Materials and Methods
1) Describe the Medicare Resource-Based Relative Value Scale (RBRVS) payment system with respect to the Technical Component of reimbursement under the Medicare Physician Fee Schedule. 2) Review of multiple (10) legislative and regulatory changes to that formula that are resulting in diminished Practice Expense reimbursement. 3) Discussion of recent unilateral regulatory changes in Medicare policies regarding equipment and labor costs that are having a further impact on neuroradiology CT and MR exams. 4) Describe current policy initiatives under development that may have further TC revenue impact -- direction and extent uncertain.

Results
The Medicare formula to determine PE reimbursement is complex, and includes allowance for the imaging equipment cost, equipment time, and the labor cost, adjusted by technologist type and time needed for a particular exam. Through regulatory and legislative action, there have been multiple cuts to the technical (TC) component of Medicare payment over the past few years, involving adjustments to various parts of the PE formula. Practice expense cuts prior to and including 2014 (these items will be described in the poster): Multiple Procedure Payment Reduction (MPPR) – TC (2006), Deficit Reduction Act (DRA) (2007), Physician Practice Information Survey (PPIS) (2010 and ongoing), Utilization Rate (2010 and ongoing), MPPR – TC (2010), Code bundling (2010 and ongoing), MPPR – TC (2011) – TC, Interest Rate (2013), New PE cuts for 2014: Utilization Rate: CMS Room Time and Labor Cost Assumptions – CMS unilaterally changed its method to calculate room time allocated per exam for advanced imaging tests beginning in 2012; less time means less PE reimbursement for the equipment and the labor costs per exam. This has been phased in on a per-code basis for those procedures that have been re-valued at the RUC. This will be discussed further, with examples. Neuroradiology codes affected beginning 1/1/14 include fluoro guidance for epidural injections; head CT codes; and brain/spine MR codes. In Process: PACS valuation transition – Film processing and viewing equipment costs are only now transitioning from analog to digital inputs for purposes of accounting TC. This transition may begin this calendar year, and may result in further diminution in TC reimbursement by CMS. Future: Separate MR/CT Cost Centers – Proposed by CMS, but ultimately postponed in the 2014 Final Rule, awaiting further data. Site-neutral assumptions – Same TC payments for outpatients, whether imaged in a hospital or in a separate outpatient facility. Proposed by CMS, postponed in Final Rule.
Conclusions
Medicare's technical reimbursement for radiology services has been cut by numerous methods over the past 5 years. As of January 1, 2014, new cuts to the technical component are directly affecting neuroradiology services. These cuts may create financial strain for imaging centers and hospitals that own advanced imaging equipment and employ technologists, and that bill either the TC component alone, or the global fee.

Abnormal Cord Signal Revisited: Anatomical and Pathophysiologic Approach

A Betts¹, H Morales¹
¹University Hospital/University of Cincinnati College of Medicine, Cincinnati, OH

Purpose
T2 hyperintense signal abnormalities within the spinal cord on magnetic resonance imaging (MRI) can evoke a broad differential diagnosis, and can present a diagnostic dilemma. We describe an approach to help radiologists provide a succinct and relevant differential diagnosis based upon imaging patterns and anatomical/pathophysiologic correlation. In a series of cases, we provide clues and imaging pearls, focusing on inflammatory, infectious, demyelinating, vascular, and metabolic involvement of the spinal cord.

Materials and Methods
Patterns of distribution of signal abnormality in the axial and sagittal plane are discussed. Injury or disease processes may have a predilection for anterior, central, or posterior cord. Therein, pathophysiology of the disease often correlates with the anatomical involvement, which can provide diagnostic clues. Furthermore, involvement of specific white matter tracts also may provide important diagnostic information. In general, syrinx and tumors have a distinct appearance. A syrinx presents with a well defined cavity, while tumors usually distort the architecture of the cord. Both entities will be described briefly as important considerations during the initial approach of signal abnormalities, but are not the focus of this exhibit.

Results
Short segment involvement typically is seen with multiple sclerosis (MS) and its mimics (e.g., sarcoid, vasculitis), as well as compressive myelopathy and metabolic abnormalities. Long segment processes involving more than two vertebral segments, is seen less commonly with inflammatory or demyelinating diseases such as transverse myelitis or neuromyelitis optica (NMO), as well as vascular diseases such as venous hypertension or arterial infarct. In both short and long segment processes, the distribution of abnormal signal in the axial plane may further narrow the differential diagnosis. Thus, correlating the location of the abnormality to the white matter columns and/or central gray matter is critical. Patchy signal that predominates in the
posterior or lateral white matter columns in an asymmetric distribution suggests MS. Well defined symmetric signal of the posterior central gray matter or ventrolateral posterior columns ("snake-eye" sign) commonly is seen with compressive myelopathy. Subacute combined degeneration (vitamin B12 deficiency) involves the posterior columns. Predominant gray matter abnormality of the anterior horns is seen with arterial infarction, often in a symmetric pattern. Centromedullary gray and white matter involvement is typical for transverse myelitis and NMO. Venous hypertension secondary to vascular malformations of the spine can lead to diffusely increased signal of the cord with a thin remnant of peripheral hypointensity on axial images. Infectious myelitis is particularly challenging. However, some patterns of involvement have been described. HIV-associated vacuolar myelopathy typically involves the thoracic spine and present symmetric involvement of the white matter columns (lateral and posterior). Polio or West Nile virus has a predilection for the anterior columns. These patterns of signal abnormality can overlap. However, we believe that careful evaluation of the anatomical distribution is helpful in most cases. Conclusions Intramedullary signal abnormalities of the spinal cord have a broad differential diagnosis. Evaluation of the pattern of cord signal abnormality in both sagittal and axial distributions can provide diagnostic clues. Correlation with the pathophysiology of the disease can assist radiologists in providing succinct and clinically relevant differential diagnoses.

Demystifying the MR Evaluation of Spondylolisthesis: Tricks of Our Trade.

H Hardin\textsuperscript{1}, A Singhal\textsuperscript{1}, G Roberson\textsuperscript{1}, S Vattoth\textsuperscript{1}

\textsuperscript{1}University of Alabama Birmingham, Birmingham, AL

Purpose

The goal of this presentation is to review the MR imaging features of lumbar spondylolisthesis with special emphasis on identifying the spondylolytic form. The presentation will provide useful teaching points that help the radiologist confidently identify spondylolysis when faced with an MR exam and no corresponding lumbar spine radiographs or CT.
Materials and Methods
The presentation will discuss the anatomical and pathological differences between "true" spondylolisthesis secondary to a pars interarticularis defect and "pseudo" or degenerative spondylolisthesis. MR features that distinguish the two entities will be presented with an emphasis on properly diagnosing spondylolysis in the lumbar spine.

Results
Concern for degenerative disease in the lumbar spine is the most common indication for a clinician to order a lumbar spine MR imaging (MRI). Often we are faced interpreting these studies without an accompanying conventional radiograph or CT. MR imaging alone is adequate to evaluate spondylolisthesis but proves difficult to completely assess the nature of the patient's pathology. In any type of spondylolisthesis there will be anterior displacement of the vertebral body (along with the entire superior spine) in relation to the inferior vertebral body. The neural foramen will become obliquely oriented (instead of the normal vertical orientation) and assume a figure 8 configuration. Relying on the hypointense line solely to identify a pars defect can be tricky as a sclerotic pars can mimic a fracture. This presentation will describe and provide MR examples of three helpful findings to confirm pure spondylolysis: 1. "Step off sign" of the spinous process above the level of the pars defect, whereas the step off is below the level in degenerative spondylolisthesis. 2. Widening of the lower lumbar canal when compared to the L1 diameter, whereas the canal is narrower in degenerative retrolisthesis. 3. Epidural fat interposition between the dura and spinous process.

Conclusions
Spondylolysis of the lower lumbar spine can be a challenging diagnosis to make by MR alone. This presentation will provide the radiologist with three practical tools to use in the reading room to help correctly and confidently differentiate spondylolytic from other forms of spondylolisthesis.

Exophytic Midline Spinal Cord Hamartoma: MRI Features of a Distinct Clinical Entity

G Gong¹, M Auster¹
¹Johns Hopkins University School of Medicine, Baltimore, MD

Purpose
Congenital midline spinal cord hamartomas are relatively rare with only 16 cases reported. Correct diagnosis can be made by characteristic MR imaging (MRI) findings. This exhibit reviews those imaging findings, differential diagnosis from other intraspinal masses, the key anatomical and clinical features, and current clinical management recommendations.

Materials and Methods
The authors report a case of congenital cervical spinal cord hamartoma in a young woman who presented with progressive bilateral upper extremity weakness and paresthesia. MR imaging findings and protocol suggestions, histological and anatomical features, clinical presentations and management recommendations of this entity are discussed with literature reviews of reported cases.
Results
The more commonly seen congenital spinal cord masses include lipomas, epidermoids, dermoids, and teratomas, etc. Congenital midline spinal hamartomas are relatively rare. It is believed that they represent embryologic neural tube error. They are composed of mature and well differentiated histological components which are in an abnormal location/configuration. Spinal hamartomas can be seen in any segment of the spinal cord. Most patients harboring this anomaly are neurologically intact but may present with a skin dimple, cutaneous angioma, subcutaneous mass, or normal overlying skin. These lesions are not related to brain malformation or neurofibromatosis. On MR imaging, these lesions demonstrate isointensity with the adjacent spinal cord parenchyma on all MRI sequences. They are mostly peg-like appearing tissue broadly based on the dorsal midline spinal cord parenchyma with a pointed narrow end inferiorly, possibly due to tethering of the cord. They may show a dermal sinus tract with vascularity that tethers the cord at the level of the lesions. Adequate MRI sequences should include precontrast routine axial and sagittal T1- and T2-weight images with thin sections through the lesion. Postcontrast fat saturation sequence images also may be obtained for differential diagnosis. The differential diagnosis is straightforward from other spinal masses on the basis of MRI findings. Teratomas are characterized by heterogeneous signal and by contrast enhancement. Most dermoids have a signal intensity similar to fluid on both T1- and T2-weighted images. Most dermoids are T1 bright and appear similar to intraspinal lipoma. Surgical consultation is recommended for clinical management with possible intervention to prevent neurological damage resulting from tethering of the cord in young patients, to prevent infection of the dermal sinuses, or to correct focal cosmetic defect.

Conclusions
Midline spinal cord hamartoma is an uncommon but distinct congenital spinal lesion representing embryologic neural tube error caused by both incomplete and possibly premature disjunctions. They are likely being increasingly encountered due to wide availability of MR imaging. Most of the patients are asymptomatic or only have minimal neurological deficits. MR imaging features allow one to distinguish them from other intraspinal masses. This case review adds help for recognizing this entity based on MRI features – isointensity signals with the spinal cord on all sequences.

Pictorial Demonstration of Imaging, Diagnosis, and Treatment of Traumatic Spinal Injury in Patients with Ankylosing Spondylitis

B Patel¹, J Acharya², C Harnain³, S Bobra³, H Mehta³
¹Westchester Medical Center, Greenwich, CT, ²Westchester Medical Center PMB 578, Valhalla, NY, ³Westchester Medical Center, Valhalla, NY

Purpose
-To review the unique features of pathogenesis, natural history, imaging features and treatment of acute spinal injury in patients with seronegative spondylopathy such as Ankylosing Spondylitis (AS).
-To present multiple examples of different types of spine injuries in AS patients so as to improve diagnosis through recognition of areas to specifically look for injury.
-To review the unique biomechanics of spine fracture in AS patients.
-To demonstrate salient radiographic, CT, and MR imaging features of traumatic spine injury in AS patients.
-To demonstrate the necessary surgical treatment options and challenges for AS patients with traumatic spine injuries.

Materials and Methods
Pathophysiology and epidemiology of spine fractures in seronegative spondylopathy patients.
-Brief discussion of the current literature on this specific disease. Review of imaging findings:
-Radiographic imaging findings.
-CT imaging findings with discussion regarding important anatomical regions to direct focus to help avoid missed diagnosis.
-MR imaging findings with optimization of diagnosis and secondary findings. Discussion of treatment options, including pre- and postoperative imaging, and a review of outcome with significant clinical and educational ramifications.

Results
Recognition of the history, epidemiology, biomechanics, imaging features, and treatment for trauma patients with Ankylosing Spondylitis is important for both patient treatment and outcome. We review the optimal imaging methods and search patterns to evaluate these patients.

Conclusions
1. Discussion of the common radiographic findings for spine trauma in patients with seronegative spondylopathy.
2. Presentation of multiple cases of spine injuries in patients with seronegative spondylopathy such as Ankylosing Spondylitis through use of CT and MR, including pre- and postoperative imaging.

Sacroiliitis. Diagnosis by MRI

C Ortiz¹, S Bermudez², J Vega²
¹Fundación Santa Fe de Bogota, Bogota, Colombia, ²Fundación Santa Fe de Bogota, Bogota, Cundinamarca, Colombia

Purpose
To review and discuss the anatomy of the sacroiliac joints, the MR imaging (MRI) techniques, and radiological features of the sacroiliitis.

Materials and Methods
Based on a cases series of patients with inflammatory lumbar pain and suspected diagnosis of sacroiliitis taken from the radiology department of the Fundación Santa Fe de Bogota University Hospital, we did a complete review of the literature and discussed the radiological features of the different diseases affecting the sacroiliac joint, especially the sacroiliitis.
Results
In whom an MRI of the sacroiliac joints was performed, semiquantitative assessment of the degree, extension and activity of the inflamed sacroiliitis base on imaging findings was done.

Conclusions
The MRI findings allow an early diagnosis, staging and extension of the inflammation and patient follow up.

Spinal Meningeal Cysts: What Are They and Why Should I Care? An Interactive, Case-Based Tutorial

N Turman¹, W Smoker¹, L Gentry²
¹University of Iowa Hospitals and Clinics, Iowa City, IA, ²University of Wisconsin, Madison, WI

Purpose
1. Become acquainted with the anatomical classification of spinal meningeal cysts.
2. Identify the various types of spinal meningeal cysts.
3. Recognize various meningeal cyst mimics.
Materials and Methods
CT, MRI and CT myelography images of meningeal cysts of the cervical, thoracic, and lumbar spine are shown to highlight pathology and key features in distinguishing the correct diagnosis.

Results
Spinal meningeal cysts are rare lesions. They can be classified, based on their location and presence or absence of nerve root fibers within the cysts, into three categories: Type I are extradural meningeal cysts without spinal nerve root fibers (IA = extradural arachnoid cysts; IB = occult sacral meningoceles); Type II are extradural meningeal cysts with spinal nerve root fibers (Tarlov perineural cysts); and Type III are intradural meningeal (arachnoid) cysts. There are a number of pathologies that occasionally mimic these various cysts that need to be considered in the differential diagnosis of these lesions (transdural cord herniation may mimic a Type III meningeal cyst; post-traumatic pseudomeningoceles may mimic Type II meningeal cysts, dural ectasia may mimic a Type IB meningeal cyst, etc.). We present and discuss the various meningeal cysts and their mimics in an interactive, case-based tutorial that leads the reviewer to the correct diagnosis. Imaging includes plain radiographs, CT, MRI and CT myelography for various cases.

Conclusions
Spinal meningeal cysts are classified into three categories based on location and presence or absence of nerve root fibers within the cyst. There are a number of important differential diagnostic lesions that need to be considered. In this interactive tutorial the reader is presented with a variety of intraspinal cystic lesions and led to the correct diagnosis through a step-by-step analysis.

Spinal Subdural Space: Review of Normal Anatomy and Pathologic Imaging Findings

K Yadwadkar\textsuperscript{1}, A Sayah\textsuperscript{2}

\textsuperscript{1}Georgetown University, Washington, DC, \textsuperscript{2}Medstar Georgetown University Hospital, Washington, DC
Purpose
The subdural space of the spine is a common location for spinal pathology, but often is identified poorly and misunderstood. The purpose of this exhibit is to present a concise overview of the normal anatomy of the spinal subdural space and to review the imaging findings of the various pathologies that occur in this compartment.

Materials and Methods
The normal anatomy of the spinal subdural space is discussed, with accompanying images and diagrams. In addition, the imaging findings of spinal subdural space lesions are discussed and presented, and differentiated from the other spinal compartments including the epidural and subarachnoid space. Common pathologies of the spinal subdural space are reviewed via sample cases and relevant imaging findings.

Results
The spinal subdural space is a potential space between the outer surface of the arachnoid and the dura. Accurate localization of lesions within this space aids in differential diagnosis. Common conditions found in this space include spontaneous, traumatic, or iatrogenic spinal subdural hematomas, spinal hygromas, and empyemas. Subdural injection of contrast agent during myelography also can occur and is important to recognize. Spinal subdural space pathologies can spread easily along multiple levels of the spinal canal so accurate and timely diagnosis is important in appropriate patient management and favorable clinical outcome.

Conclusions
This exhibit will present the normal anatomy of the subdural space and the imaging findings of common associated pathologies. An understanding of the anatomy and imaging findings of the spinal subdural space can aid in accurate recognition and diagnosis.

Ventral Spinal Cord Herniation: A Report of Four Cases and Review of the Literature

K Anton\textsuperscript{1}, S Dalal\textsuperscript{1}
\textsuperscript{1}Geisinger Medical Center, Danville, PA

Purpose
Idiopathic spinal cord herniation is a widely under-recognized and under-reported cause of progressive Brown-Sequard syndrome. This rare entity results from anterior herniation of the spinal cord through a defect in the ventral dura, usually in the thoracic spine. The purpose of this case series is to display variant imaging findings and raise awareness of existence of this potentially reversible cause of myelopathy.

Materials and Methods
Four cases of reported idiopathic spinal cord herniation were identified retrospectively and their clinical charts reviewed. All patients had magnetic resonance imaging (MRI) of the spine. We present a case-based review of the variations in imaging findings of spontaneous ventral spinal cord herniation.

Results
Idiopathic spinal cord herniation has a fairly characteristic appearance on imaging and a
confident diagnosis frequently can be made on MR findings alone. Despite pathognomonic imaging features (1, 2), definitive diagnosis is commonly delayed until worsening clinical symptoms lead to surgical intervention and intra-operative confirmation of herniation. In our case series, classic findings were demonstrated on thoracic MRI, including focal ventral displacement and angulation. Each patient experienced the sequelae of focal anterior cord compression, including varying degrees of progressive lower extremity paresthesia and myopathy leading to gait instability (3, 4). There was evidence of cord signal abnormality suggestive of focal myelomalacia, a rare entity, in two patients.

Conclusions
Ventral spinal cord herniation is uncommon and patients frequently experience progressive symptoms for prolonged periods of time prior to diagnosis. Cognizance of the imaging findings of ventral spinal cord herniation can result in earlier diagnosis and prompt surgical intervention. In appropriate surgical candidates there is potential for reversal of neurological deficits (5).

"Imaging Highlights in Parkinsonian Syndromes" What The Radiologist Needs to Know.

L Amaral¹, P Hanagandi², F Goncalves³, V Marussi⁴
¹Medimagem - Hospital Beneficencia de Portuguesa de São Paulo and Hospital São Jose, São Paulo, Brazil, ²The Ottawa Hospital, University of Ottawa, Ottawa, Ontario, Canada, ³Brasilia Children's Hospital, Brasilia, Brasilia, Distrito Federal, Brazil, ⁴Medimagem - Hospital São Jose and Beneficencia Portuguesa de São Paulo, São Paulo, Brazil

Purpose
The purpose of this study is to describe and illustrate the imaging highlights of atypical Parkinsonian syndromes encountered in routine clinical and radiological practice that can mimic Parkinson's disease. The role of follow-up imaging in these cases will be highlighted to differentiate and recognize these uncommon diseases and differentiate from Parkinson's disease.

Materials and Methods
A wide spectrum of neurodegenerative diseases presenting with Parkinsonism syndromes will be described in this electronic educational exhibit with emphasis on the role of MR imaging and salient features described in neuroradiology literature and their differential diagnosis.

Results
A diverse spectrum of neurodegenerative diseases are encountered in routine neurology-neuroradiology practice presenting with common clinical symptoms of tremor, rigidity, ataxia and bradykinesia. Most of these diseases are clinically diagnosed as Parkinson's disease. During the initial presentation, routine MR imaging studies are unremarkable or subtle findings are often missed. To name a few diseases, we intend to highlight and summarize the imaging findings of Multisystem atrophy (MSA-P and MSA-C), CBD (cortico basal degeneration), PSP (progressive supranuclear palsy), NBIA (group of iron deposition disorders) postinfectious Parkinsonism, Shydragger syndrome, ALS (amyotrophic lateral sclerosis), Variants of Fronto temporal dementia, metabolic-toxic related conditions, tumors and vascular causes of Parkinsonism.

Conclusions
It is crucial to identify and interpret subtle and classical imaging findings in parkinsonian syndromes as most of the diseases are gradually progressive with poor outcome. Early diagnosis can aid in therapy, assessing posttreatment response, prognosis and future patient care.

KEYWORDS: MR Imaging, Neurodegenerative, Parkinson Disease
A Schwantastic Journey through the Cranial Nerves: Imaging Guide to Cranial Nerve Schwannomas

A Skolnik\textsuperscript{1}, K Learned\textsuperscript{1}, L Loevner\textsuperscript{1}, L Bagley\textsuperscript{1}

\textsuperscript{1}University of Pennsylvania Health System, Philadelphia, PA
Purpose
Schwannomas are typically benign slow-growing neoplasms, though can reach substantial proportions presenting with cranial nerve (CN) dysfunction or local mass effect, particularly upon the brainstem. Surgical biopsy of intracranial schwannomas rarely is indicated due to the high risk of CN injury. Therefore, imaging evaluation plays a crucial role. This exhibit will review the MR imaging (MRI) features for diagnosis and treatment of schwannomas arising from the intracranial and skull base courses of the 12 CNs.

Materials and Methods
Retrospective review of radiologic, pathologic and clinical evaluations of patients with intracranial schwannomas will be performed. Relevant normal anatomy and intracranial and skull base courses of the CNs are reviewed. Literature reviews of the general imaging features of CN schwannomas and their relative frequencies are summarized and illustrated by representative examples. The treatment options for intracranial CN schwannomas are discussed as well as the relevant post-treatment imaging features.

Results
The 12 paired CNs have complex courses through the cisterns and calvarial foramina and are increasingly visible with modern imaging techniques including steady-state free precession MRI. Improved depiction of these structures (Table) allows greater detection and characterization of associated pathology. Schwannomas occur anywhere along the anatomical course of the CNs from intracranial cisterns to skull base as small oval avidly and homogeneously enhancing masses expanding the nerves and skull base foramina and fissures. Occasionally, heterogeneous enhancement, cystic degeneration, or hemorrhage may be seen. Schwannomas arising along the courses of CN I and CN II are exceedingly rare. Vestibular schwannoma are most common, followed by trigeminal and facial nerve schwannomas. The unique course of CN VII gives rise to variable morphology of associated schwannomas, appearing tubular in the geniculate fossa, round in the middle cranial fossa, lobulated in the middle ear, and indistinct in the mastoid air cells. Neurofibromatosis type 2 is associated with bilateral vestibular schwannomas, and with schwannomas of other CNs, most commonly CN III and CN V. Other CN schwannomas are uncommon. Management options include observation, stereotactic radiosurgery, and surgical resection. Surveillance MRI evaluates for stability or slow growth. Stereotactic radiosurgery may cause initial expansion of the tumor for 12-18 months, commonly with central necrosis and subsequent shrinkage. Evaluation following surgical resection requires an understanding of the expected appearance specific to the surgical approach, for example, cerebellar atrophy following a suboccipital approach.

Conclusions
Understanding the unique anatomical courses of the CNs is essential for accurate diagnosis and treatment planning of CN schwannomas. Knowledge of the treatment options and expected post-treatment sequelae is crucial for the evaluation of stability and for assessment of new or recurrent neurologic deficits.

Alzheimer’s Disease: A Review of the Established and Updated Diagnostic Approaches and the Recent Achievements

M Watanabe¹, K Buch¹, J Thatcher¹, A Fujita¹, C Asai¹, Y Kimura², S Frank¹, O Sakai¹

¹Boston Medical Center, Boston University School of Medicine, Boston, MA, ²Jichi Medical University, Shimotsuke-shi, Tochigi-ken, Japan

Purpose
The diagnosis of Alzheimer's disease (AD) is classically based on clinical assessment. However, with recent advancements in neuropathology and genetics, the revised diagnostic criteria for AD include the role of neuroimaging and CSF biomarkers for AD. Moreover, new imaging biomarkers have been increasingly investigated. Knowledge of these evolving multidisciplinary efforts and new findings in the pathophysiology of AD is essential for proper radiological evaluation and to assist in the clinical diagnosis.

Materials and Methods
We present a review of (1) neuropathophysiological mechanisms of Alzheimer's disease,
established neuroimaging assessment with structural MRI and molecular imaging (amyloid-PET, FDG-PET), and (3) other neuroimaging techniques that may potentially provide specific neurobiological information, including diffusion tensor imaging, functional MRI, and molecular imaging using ligands specific to tau pathology or neuritis.

Results

Alzheimer's disease involves multiple pathological processes related to the abnormal deposition of β amyloid in the form of plaques, as well as, aggregates of hyperphosphorylated tau protein in the form of neurofibrillary tangles. Specific neuroimaging findings on each modality can be explained in connection to characteristic temporal and topographical distribution of those pathologies. Amyloid-PET is a biomarker for β amyloid accumulation, while decreased FDG uptake on PET imaging indicates impaired synaptic function due to tau pathology. Structural MRI evaluates cerebral atrophy, which is thought to reflect microscopic neurodegeneration as a resultant of tau pathology. Diffusion tensor imaging reveals disrupted white matter integrity, while resting-state functional MRI may serve as a potential biomarker for amyloid pathology. In PET imaging, the use of ligands specific to tau or neuritis has been investigated.

Conclusions

Neuroimaging is crucial to exclude potential secondary causes of dementia, most commonly cerebrovascular disease. Conventional MRI has some diagnostic value when the clinical diagnosis is uncertain. With the advent of more recent imaging techniques, the specificity of detecting AD has increased thereby making neuroimaging a definitive diagnostic tool for AD.

eEdE-44

An illustrated guide to the current use of MRI in Idiopathic Intracranial Hypertension: the spectrum of findings and useful techniques

S McEvoy1, M Elamin1, L Lavelle1, D McWeeney1, C MGuigan1, R Killeen1
1St Vincent's University Hospital, Dublin, Ireland

Purpose

Idiopathic intracranial hypertension is a clinical condition characterized by chronically elevated intracranial pressure. Its precise etiology is unknown. It typically occurs in obese young females and symptoms include headache and visual disturbance. It is diagnosed by demonstrating elevated cerebrospinal fluid (CSF) pressure. Historically, the sole purpose of MR imaging (MRI) was to rule out secondary causes of raised intracranial pressures. Advances in MRI now allow the detection of signs supportive of the diagnosis itself. The purpose of this educational exhibit is to illustrate the imaging findings of idiopathic intracranial hypertension.

Materials and Methods

1. We discuss postulated mechanisms resulting in intracranial hypertension. 2. We illustrate the MR findings of idiopathic intracranial hypertension. 3. We describe newer imaging methods, including diffusion-weighted imaging and multidetector CT/MR venography, and their use in diagnosing the condition. 4. A case-based self assessment quiz is included for radiology residents.
Results
The spectrum of typical MR findings of idiopathic intracranial hypertension of empty sella, posterior globe flattening, narrowing of Meckel's cave, tortuosity of the optic nerve and optic nerve sheath distension are shown. Newer described findings including cerebral sinovenous stenosis and restricted diffusion in the optic nerve also are illustrated.

Conclusions
MR imaging is an essential study in idiopathic intracranial hypertension allowing exclusion of secondary causes of intracranial hypertension as well as assessment of signs frequently seen in the condition as outlined above. Novel imaging methods have additive diagnostic value and can identify potential etiology.

KEYWORDS: Idiopathic Intracranial Hypotension

Anatomic Variants: Know the Dangers and Avoid Disasters

E Bonfante¹, E Supsupin¹
¹University of Texas HSCH, Houston, TX

Purpose
This is a pictorial depiction of dangerous vascular anatomical variants in the head and neck, with emphasis on their practical clinical implications.

Materials and Methods
The theme focuses on the importance of recognizing hazardous or potentially dangerous anatomical variants. The cases illustrate how the underlying anatomy may place the patient at an increased risk of injury. Variants that may explain an individual's clinical manifestations and predisposition to morbidity are shown. More importantly, emphasis is made on how these anatomical circumstances may direct surgical approach and clinical management of head and neck pathology.

Results
Certain anatomical variants may predispose to an increased risk of injury. In the surgical setting, variants exemplified by transsphenoidal persistent trigeminal artery, aberrant petrous internal carotid artery (ICA), and anomalies of the jugular bulb may result in life threatening injury if not diagnosed appropriately. An ossified, elongated styloid process may provoke ICA dissection in trauma. Surgical interest in the aberrant course of the ICAs is driven by risk of vascular injury (i.e., transection or pseudoaneurysm formation) and exsanguination or hemorrhage requiring transfusion during tumor resections and other procedures such as tonsillectomy. Retropharyngeal course of the ICAs renders them vulnerable to injury through the oral cavity. Pulsatile sensation in the oropharynx has been described. In extreme cases, compressive symptoms such as hoarseness and upper respiratory distress were attributed to the anomalous course of the ICAs, particularly if bilateral. Anomalous origin and course of the vertebral arteries also have been implicated in posterior circulation strokes. The ability to recognize dangerous anatomical conditions and timely communication of findings to the referring clinician are crucial. Only then can treatment approach be suited accordingly, in order to avoid serious iatrogenic injury and
prevent catastrophe. Clearly, anatomical circumstances may greatly impact surgical planning and procedural course.

Conclusions
Failure to recognize dangerous anatomy may lead to catastrophic consequences. Knowledge of anatomical variants and their practical implications is crucial.

Applications of Dual energy CT in Neuroimaging.

A Patil\textsuperscript{1}, V Bachhav\textsuperscript{1}, S Byrd\textsuperscript{1}, S Ellika\textsuperscript{1}
\textsuperscript{1Rush University and Medical Center, Chicago, IL}
Purpose
Dual energy CT is a recent advance in CT technology, which allows for rapid acquisition of datasets at two different energies. Current dual energy CT scanners offer improved temporal resolution which may be helpful in CT angiography and increased photon flux, which may be helpful in imaging obese patients. Dual energy CT provides information about how materials behave at different energies, provides capability to generate virtual unenhanced datasets and improves detection of iodine-containing substances on low-energy images. This leads to improved tissue characterization and analyses of chemical composition of materials.

Materials and Methods
In this exhibit we will demonstrate the neuroradiologic applications of dual energy CT for various pathologies in the head, neck and spine using demonstrative examples wherever relevant. In addition the physics of dual energy scanners also will be discussed in this exhibit.

Results
Neuroradiological applications of dual energy CT include differentiation of tumor bleeding from pure ICH, differentiation of hemorrhage from contrast staining in patients postvascular intervention, better quantification of carotid stenosis with removal of hard plaques from the vessels, bone removal on head and neck CT angiography and improved characterization of thyroid nodules. In addition metal artifact reduction by dual energy CT using monoenergetic extrapolation may be helpful in patients with spinal instrumentation including CT myelography.

Conclusions
Dual energy CT capabilities are promising for improved detection and characterization of lesions in the head, neck and spine and for evaluation of vascular structures. Further research is needed to validate these applications before their use becomes widespread. Reductions in radiation dose are possible if the need for true unenhanced datasets is eliminated and if low tube currents are used, radiation doses delivered in dual energy CT are similar to those used in single energy CT.

KEYWORDS: Dual-Energy CT, Neuroradiology Training

Autoimmune Mediated Encephalopathy: Why the Confusion and Madness?

J Kim¹, J Starkey², A Capizzano¹, Y Ohgiya³, Y Sato¹, T Moritani¹
¹University of Iowa Hospitals & Clinics, Iowa City, IA, ²University of California San Francisco, Mill Valley, CA, ³Showa University School of Medicine, Japan

Purpose
Autoimmune mediated encephalopathy (AME) is a recently described entity associated with autoantibodies directed toward the central nervous system (CNS) that often is under-recognized or misdiagnosed. The primary goal of this presentation is to illustrate the MR imaging findings of pathologic CNS conditions associated with paraneoplastic and nonparaneoplastic disorders and present a systematic approach to aid the radiologist in diagnosis.

Materials and Methods
We organize the imaging presentations of AME into five major categories: limbic encephalitis,
cerebellar degeneration, striatal encephalitis, brainstem encephalitis, and leukoencephalopathy. For each imaging presentation, we discuss the pathophysiology and differential diagnoses.

Results
Autoimmune mediated encephalopathy can be divided into paraneoplastic and nonparaneoplastic disorders. Etiologies of paraneoplastic encephalopathy include neoplasms of the breast, lung, prostate, ovary, testicle, and lymphoma. Commonly associated antibodies are anti-NMDAR, anti-Yo, anti-Ri, anti-Hu, and anti-Tr. Nonparaneoplastic encephalopathy etiologies include anti-VGKC, celiac disease, and Hashimoto’s encephalopathy. These entities share common and often overlapping imaging features of limbic encephalitis, striatal encephalitis, brainstem encephalitis, and cerebellar degeneration. The clinical history along with imaging features can help the radiologist direct clinicians to the correct diagnosis through further laboratory and imaging studies.

Conclusions
We illustrate the imaging manifestations of autoimmune mediated encephalopathies and discuss their pathophysiology and differential diagnoses. A good working knowledge of AME is vital to providing early and accurate diagnosis of the paraneoplastic and nonparaneoplastic disorders and improve patient prognosis.

KEYWORDS: Encephalitis, Encephalopathy, Paraneoplastic
Brain & Neck Time of Flight Magnetic Resonance Angiography (TOF-MRA) - Review of methodology with common and uncommon angiographic appearances.

N Pierson¹, U Rassner²

¹University of Utah Health Science Center, Salt Lake City, UT, ²University of Utah, Salt Lake City, UT
Purpose
Time-of-flight (TOF) MR angiography (MRA) is a mainstay of noninvasive MR vascular imaging. Familiarity of the underlying physics and acquisition technique is vital for accurate interpretation, particularly when uncommon appearances occur.

Materials and Methods
The physics of TOF MRA is reviewed and applied to common and uncommon imaging appearances.

Results
Time-of-flight MRA relies on partial saturation of stationary tissues with flow related enhancement resulting in high intravascular signal. To avoid flow related enhancement from veins, a saturation band is placed above the imaged slice or slab. This methodology of image acquisition can result in imaging pitfalls related to technique, anatomy, and tissue characteristics. The potential imaging pitfalls discussed include: 1. Overestimation of the degree of stenosis due to turbulent flow; 2. Artificial loss of intravascular signal in the setting of flow reversal or when a tortuous vessel dips into a lower slab in 3D TOF MRA (Figure 1a); 3. Loss of vessel signal due to incorrect ratio of slab thickness and flow velocities; 4. Venous signal when flow direction is caudo-cranial or in the setting of an arterio-venous shunting lesion (Figure 1b); 4. Apparent flow-related enhancement in the absence of flow, when blood clot is present with pronounced T1-shortening.

Conclusions
Familiarity of the technical detail of TOF MRA methodology is necessary for accurate interpretation and differentiation of pathology from artifacts related to imaging technique in order to correctly guide clinical management.

Bread and Butter: Routine Neuroimaging MR sequences and the Physics Behind Them

L Nakamura¹, F Goerner¹, M Wintermark¹
¹University of Virginia, Charlottesville, VA

Purpose
As MR has advanced technologically so has its complexity. The purpose of this exhibit is to return to the basics and provide an efficient and practical way to understand the physics of MR, as it relates to neuroradiology. By explaining through images rather than equations and pulse sequence diagrams, this exhibit will be a useful review for current radiologists and a great learning tool for current residents, especially those preparing for the new ABR boards.

Materials and Methods
1. Review concepts behind T1 and T2 contrast. 2. Review concepts behind fluid suppression. 3. Review differences behind gradient echo and spin echo imaging. 4. Review concepts behind diffusion-weighted imaging (DWI), apparent diffusion coefficient (ADC), and b-values.

Results
1. Use gray matter heterotopia to demonstrate differences in T1 and T2 relaxation. 2. Use multiple sclerosis to demonstrate the importance of fluid suppression sequences. 3. Use diffuse axonal injury as an example of how gradient echo imaging is useful. 4. Use images of stroke and lymphoma to demonstrate DWI and ADC values.

Conclusions
The physics of MR can be better understood by linking the basic principles of physics with the common pathologies neuroradiologists see on a daily basis. This exhibit aims to help radiology residents learn and practicing radiologists review the basic principles of MR physics related to neuroradiology.

KEYWORDS: Fluid-Attenuated Inversion Recovery, Gradient Recall Echo, MR Imaging/Diffusion

Carotid Artery dissection: how to study this condition using Computed Tomography

L Saba¹, E Raz², M Anzidei³, G Argiolas⁴, E Genovese³, M Piga³
¹University of Cagliari, Monserrato, Italy, ²New York University Medical Center, New York, NY, ³University of Cagliari, Cagliari, Italy, ⁴AOB, Cagliari, Italy

Purpose
The identification of dissection of the carotid artery (DCA) can be complex. One of the most used imaging technique in the analysis of the carotid artery is the computed tomography (CT) and in this exhibit our purpose was to understand the physiopathology of the DCA, to review MDCT and to identify a flow chart that can help to recognize DCA by using MDCTA.
Materials and Methods
In our Institute about 500 CT exams for the study of carotid arteries are performed each year and about 25 cases of dissections of carotid artery are found. We present our experience in this field that is obtained using multiple CT scanners (16 - 40 - 64 slices and multi-energy). In most cases of dissection we will present MR imaging (MRI) and ultrasound correlation.

Results
The eposter will present the following sections: 1) Physiopathology of the DCA, 2) Histopathological classification of DCA, 3) Clinical presentation of DCA in typical and atypical condition, 4) CT imaging findings, 5) pathologic features (intimal tear, intramural hematoma, and dissecting aneurysm), 6) Limits and potentialities of MDCT in the detection of DCA, 7) MDCT-based diagnostic flow-chart for, 8) Causes of misinterpretation of DCA, 9) Comparison of MDCT with MR and US in the detection of DCA, 10) Analysis of advanced techniques like dual-energy and multispectral imaging.

Conclusions
Dissection of carotid artery is a potentially disabling yet probably under-recognized condition that often occurs in young adults and because of the great diversity in the clinical features of cranio-cervical artery dissection, imaging plays a primary role in its diagnosis. Currently, MDCT can identify and characterize DCA and in particular the use of dual-energy and multispectral CT imaging may help in detecting this dangerous condition.

KEYWORDS: Carotid Dissection
Carotid artery plaque: imaging of the remodelling

L Saba¹, J Suri², E Genovese³, E Raz⁴, P Lucatelli⁵, G Argiolas⁶
¹University of Cagliari, Monserrato, Italy, ²Biomedical Technologies, Pocatello, CA, ³University of Cagliari, Cagliari, Italy, ⁴New York University Medical Center, New York, NY, ⁵University la Sapienza, Roma, Italy, ⁶AOB, Cagliari, Italy

Purpose
The concept of "plaque remodelling" indicates the morphological and ultrastructural variation of a plaque in the time. Several investigations have demonstrated that the carotid artery plaques change and it is possible that some determinants of instability are transitory. Moreover, some drugs (such as statins, apolipoprotein) change the composition of the plaque by increasing or reducing its volume. In this exhibit our purpose was to understand the physiopathology of plaque remodelling and to review CT, MR and US imaging findings of this phenomenon.
Materials and Methods
In this exhibit we will present the carotid artery plaque remodelling using our MR-CT-US database to show examples. Several histopathological correlations will be used.

Results
In the exhibit we will organize the work: 1) To review the concept of carotid artery plaque remodelling 2) histology of the plaque according to the AHA classification. 3) The biomechanical effect of plaque eccentricity. 4) MR, CT, and US imaging findings of carotid artery plaque follow up that demonstrate the plaque remodelling. 5) Limits and potentialities of MR, CT and US in the follow up of the carotid artery plaque. 6) The drug effect: how the therapies may change the plaque in terms of regression and progression. 7) presentation of relevant cases.

Conclusions
The unique geometrical configuration and flow properties of the carotid bifurcation contribute to the formation of atherosclerotic plaque that may markedly change over time. Currently, imaging techniques can identify and characterize the plaque remodelling and in particular the use of MR allows to precisely distinguish plaque components and characteristics and to identify the plaque's changes. In the last years it was demonstrated that some dedicated may trigger a regression and progression of the carotid artery plaque and imaging must recognize these changes.

KEYWORDS: Carotid Artery, Carotid Plaque
Carotid artery vulnerable plaque: Multi-modality imaging approach

L Saba¹, J Suri², P Lucatelli³, F Zaccagna⁴, R Montisci⁵, M Piga⁵
¹University of Cagliari, Monserrato, Italy, ²Biomedical Technologies, Pocatello, CA, ³University la Sapienza, Roma, Italy, ⁴University of Rome - Sapienza, Rome, Italy, ⁵University of Cagliari, Cagliari, Italy

Purpose
A "vulnerable plaque" is considered an atherosclerotic plaque that contains a large necrotic lipid core covered by a thin or disrupted fibrous cap and it is characterized by a higher tendency to rupture, resulting in embolization or thrombosis. In this exhibit our purpose was to understand the physiopathology of vulnerable plaque and to review CT, MR, US and Nuclear Medicine (NM) imaging findings of carotid vulnerable plaque with histological correlation.

Materials and Methods
In this work a didactic approach will be used by explaining the vulnerable plaque from the histopathology to the advanced imaging. We will try to explain "what is" a vulnerable plaque and what the different imaging techniques can offer. We will present several diagrams, tables and figures by presenting numerous cases of correlation between histology and imaging findings.

Results
This work will be organized in the following sections: 1) To review the concept of carotid "vulnerable" plaque, 2) Classification of plaque type, 3) Elements associated to the plaque instability: type of plaque, thrombus, intraplaque hemorrhages, ulcerations, fissured fibrous caps. 4) MR, CT, US and NM imaging findings with histological comparison of carotid vulnerable plaque. 5) Limits and potentialities of MR, CT, US and NM. 6) Algorithm for the automated plaque analysis. 7) Presentation of advanced techniques like molecular imaging and multispectral CT imaging.

Conclusions
Carotid plaque morphology and composition play an important role in the embolic risk and should be considered as key parameters for the choice of the therapeutical approach. Nowadays, imaging techniques can identify and characterize a carotid vulnerable plaque and in particular the use molecular imaging and multispectral CT imaging allows to precisely distinguish plaque components and characteristics.

KEYWORDS: Carotid Plaque
Carotid Cavernous Fistula: An interactive module on the diagnosis and treatment of a rare vascular abnormality

A Batouli¹, M Goldberg¹
¹Allegheny General Hospital, Pittsburgh, PA

Purpose
Carotid cavernous fistula (CCF) is a rare type of vascular abnormality that can be difficult to diagnose. We aim to use an interactive teaching module to illustrate the anatomy, pathophysiology, epidemiology, clinical presentation, imaging findings, complications, and treatment options of CCF.

Materials and Methods
We will begin with an overview of the anatomy of the cavernous sinus, with attention to the various segments of the cavernous carotid artery utilizing multiple accepted classification systems. An interactive quiz will help strengthen the viewer's anatomical knowledge. We then will differentiate between direct and indirect CCF, with an outline of the pathophysiology, epidemiology, typical clinical presentation, preferred imaging modalities, imaging findings, and treatment options for each one. Finally, we will use an interactive module to demonstrate salient
teaching points with illustrative cases, allowing viewers to employ their clinical and radiological skills to properly diagnose and choose treatment for each patient.

Results
The cavernous sinus is a trabeculated venous cavity located just lateral to the sella turcica. The sinus includes the internal carotid artery (ICA) and cranial nerves III, IV, V1, V2, and VI. Carotid cavernous fistulae are abnormal shunts which allow blood to flow from the carotid artery into the cavernous sinus. Direct CCF is caused by traumatic or aneurysmal rupture of the cavernous ICA, creating a direct high flow connection with the cavernous sinus. Indirect CCF is a low flow vascular malformation, where branches arising from the internal and external carotid arteries connect with the cavernous sinus. While indirect CCF are insidious and nonspecific in clinical presentation, patients with direct CCF often present with specific characteristic signs and symptoms which include proptosis, chemosis, orbital bruits, ophthalmoplegia, and headache.

Although angiography sets the gold standard for diagnosis, CT, CTA, MRI and MRA are usually the primary imaging modalities, providing very high levels of sensitivity and specificity. Imaging can show dilation of the superior ophthalmic vein, proptosis, enlargement of extraocular muscles, and premature contrast filling of the cavernous sinus during the arterial phase of enhancement. Treatment options include conservative management, coil embolization, open surgical intervention, radiosurgery, or more recently, endovascular flow diverting stent placement. Specific clinical and imaging criteria are used to determine the optimal treatment for each patient.

Conclusions
Carotid cavernous fistula is a diagnostically challenging vascular malformation with significant potential for associated morbidity and mortality. Our educational exhibit, with its interactive case-based assessment modules, will help radiologists serve their patients more effectively by becoming more confident in the diagnosis and management of this disease.

KEYWORDS: Carotid Cavernous Fistula, Cavernous Carotid Artery, Cavernous Carotid Fistula
Purpose
To introduce a novel new imaging phantom and review the physics of dual energy CT scanning and cerebral blood flow (i.e., Poiseuille's law).

Materials and Methods
Our carotid CT acquisition (CTA) phantom is an anatomical and physiologic model. U.S. Provisional Patent Serial No. 61/695, 859. It uses the following items: – PVC tubing to mimic the carotid arteries, jugular veins, Circle of Willis and dural sinuses. – Tums® tablets to mimic calcified atherosclerotic carotid plaques. – Helmet to mimic normal head size. – Mandible from a skull. – 5L flow reservoir with flow meter for accurate basal cerebral blood flow. We followed several patients before and after introduction of our scanning and recorded the total scanning and postprocessing time following dual energy CT acquisition. Data then were collected and analyzed to demonstrate the efficacy of our phantom.
Results
• There was 50% reduction in total scanning time after our CTA phantom was introduced to the technologists. • One technologist was quoted saying "All that is required is about 10-20 minutes of downtime a few times per week in between cases in order to gain the comfort level needed for this particular imaging sequence". • Some criticism included incorporating more bone in our phantom and our small study sample size. • With the advent of new imaging modalities and protocols, technologists need to maintain knowledge in proper scanning techniques.

Conclusions
• A significant obstacle in familiarizing technologists with a new imaging modality or technique often is lack of experience. The time to learn is not when a patient is on the table awaiting evaluation. • Our dynamic carotid CTA phantom provides a highly effective way for technologists to practice (in our case dual energy CT), and significantly reduce the total scanning and post-processing time. • Although our sample size is small, we are confident that the phantom is useful. • Our CTA phantom allowed our technologists to master dual energy CT without exposing patients to unnecessary radiation.

KEYWORDS: Carotid Plaque, CT Angiogram, Dual-Energy CT
Image of phantom. Helmet and maxillofacial bones mimicking patient head. Cardboard providing platform for tubing. Tubing mimicking circle of Willis. Calcium tablets attached to tubing to mimic atherosclerotic plaques. *Not shown is fluid reservoir and power injector, which allows for injection of contrast at 1L/min to mimic basal cerebral blood flow.

Pre-processing MIP images of phantom with calcium tablets. Post-processing images available, demonstrating successful "plaque removal" by DSCT.
Cerebral microbleeds: causes, clinical relevance and imaging approach.

S Kanekar¹, A Agarwal²
¹Penn State Milton S Hershey Medical Center, Hershey, PA, ²Milton S Hershey Medical Center, Hershey, PA

Purpose
1. To discuss in brief physics of susceptibility-weighted imaging (SWI). 2. To discuss the various causes of cerebral microbleeds (CMBs) and discuss their clinical significance.

Materials and Methods
With the development of MR imaging (MRI) techniques (gradient-recalled echo and susceptibility-weighted sequences) exquisitely sensitive to paramagnetic blood products, microbleeds are commonly encountered on routine brain MRI. The clinical significance remains elusive. We retrospectively studied MRI brain of 1200 patients from PACS system. Axial T2, T1 and SWI images were compared and then were correlated with the clinical findings and final diagnosis of the patient.

Results
The incidence of CMBs was highest with prior history of trauma, and intracerebral hemorrhage. Second and third most common causes were in patient with prior history of stroke/hypertensive encephalopathy, and; neurodegenerative diseases such as amyloid angiopathy, and Alzheimer disease, respectively. Various other causes found on our study include CADASIL, CARASIL, CMBs due to cardiac (endocarditis, myxoma and cardiac valve), Fabry's, vasculitis, post RT, moyamoya, PRES, and various blood disorders.

Conclusions
We discuss in brief the physics of SWI sequence and its role in detection of cerebral microbleeds. We give an algorithmic approach in evaluation and mapping of CMBs with respect to their clinical significance.

KEYWORDS: Microbleeds, Susceptibility-Weighted Imaging

Characterization of Intima Media Thickness Variability (IMTV)

L Saba¹, J Suri², M Piga³, E Genovese³, F Zaccagna⁴, R Montisci³
¹University of Cagliari, Monserrato, Italy, ²Biomedical Technologies, Pocatello, CA, ³University of Cagliari, Cagliari, Italy, ⁴University of Rome - Sapienza, Rome, Italy

Purpose
Recently a new parameter based on the intima-media-thickness (IMT) was introduced: the so-called Intima-Media-Thickness Variability (IMTV). The purpose of this exhibit is to present the mathematical concept of the IMTV and its potential value and application.
Materials and Methods
Our group developed the concept of the intima media thickness variability that represents the standard deviation of the IMT in the length of the carotid artery. We will explain the mathematical basis as well as the algorithm that allows the analysis of the IMT. Our database is more than 2000 ultrasound patients of the carotid arteries and we will present the different classification of the IMTV.

Results
This electronic poster will cover the following points: 1) histology of the carotid artery wall, 2) algorithm of the IMTV and mathematical basis, 3) difference between IMT and IMTV, 4) Limits and pitfalls of the different imaging modalities (US, CT, MR) in the IMTV analysis. 5) Presentation of cases.

Conclusions
It is well demonstrated that the IMT quantification may play an important role, because the increase in IMT is correlated with coronary and cerebrovascular complications. Some preliminary studies showed that IMTV seems to be a better parameter of IMT in some conditions such as the cerebrovascular events. In this exhibit the IMTV concept will be presented.

Clinical Application of PET-MRI in Neuroradiology

A Chaudhry\textsuperscript{1}, J Yoon\textsuperscript{2}, R Matthews\textsuperscript{2}, D Franceschi\textsuperscript{3}, R Peyster\textsuperscript{2}
\textsuperscript{1}Stony Brook University Medical Center, Westbury, NY, \textsuperscript{2}Stony Brook University Medical Center, Stony Brook, NY, \textsuperscript{3}SUNY Stony Brook, Stony Brook, NY
Purpose
The aim of this exhibit will be to provide a comprehensive overview of the physical principles, techniques and clinical applications of the emerging hybrid modality: PET-MRI (positron emission tomography-magnetic resonance imaging). This hybrid modality attempts to provide the functional imaging obtained from a PET study and detailed structural information obtained from an MRI study.

Materials and Methods

Results
1. Physical principles and techniques of PET-MRI: Relevant concepts involving image acquisition, postprocessing and interpretation will be provided. 2. Overview of clinical applications of PET-MRI in neuro-oncology patients: An overview of initial tumor diagnosis, discussion of tumor biology and its effect on tumor imaging (e.g., tumor metabolism, angiogenesis, cellularity, etc.), post-treatment follow-up imaging evaluation and its role in therapy selection will be provided. 3. Role of PET-MRI in evaluation of neurodegenerative and inflammatory conditions (including MS). 4. Pearls and Pitfalls: Common pitfalls and controversies regarding PET-MRI in neuroradiology will be discussed. 5. Future of PET-MRI: A discussion of future applications and challenges facing PET-MRI in neuroradiology, specifically neuro-oncology and neurodegenerative disorders will be provided.

Conclusions
PET-MRI is an emerging hybrid imaging modality offering detailed functional and structural imaging with promising clinical applications especially in the field of neuro-oncology, neurodegenerative and inflammatory CNS conditions. This case-based exhibit provides the viewer an in-depth review of the relevant concepts underlying the technical and clinical aspects along with common pearls and pitfalls of PET-MRI allowing for better integration and relevant usage of this modality in clinical practice.

KEYWORDS: MR Imaging/PET
Clinical utility of “Incomplete-Rim” sign and Uhthoff's phenomenon

M Gul¹, A Chaudhry², A Chaudhry³, R Peyster⁴
¹Winthrop University Hospital, Mineola, NY, ²Stony Brook University Medical Center, Westbury, NY, ³St John's University, Westbury, NY, ⁴Stony Brook University Medical Center, Stony Brook, NY
Purpose
The "Incomplete ring sign" aka "open-ring" sign is a fairly specific sign for demyelination and narrows the differential diagnosis in patients with ring-enhancing lesions in the brain. The enhancing component of the lesion represents the most active area of active demyelination within the CNS white matter, whereas the nonenhancing segment represents gray matter. Given the high specificity of this sign, it can be used reliably to forgo brain biopsy and begin empiric therapy with steroids. Another benefit of foregoing brain biopsy is that the histologic findings in active demyelination can mimic neoplastic process such as glioblastoma multiforme and infectious processes such as toxoplasmosis. Therefore, avoiding biopsy not only avoids the obvious risks associated with an invasive procedure, but it also saves clinicians from further clouding the case with perplexing biopsy results. Uhthoff's phenomenon is known to occur in a significant number of patients with multiple sclerosis. It refers to worsening of symptoms (including pain, fatigue, weakness, etc.) when patient's body temperature increases (e.g., from weather, exercise, hot showers, etc.). It is theorized to result from alteration in nerve conduction from temperature changes. The presence of "incomplete rim" sign on imaging along with presence of Uhthoff's phenomenon are two fairly sensitive and specific findings that can essentially confirm diagnosis of a demyelinating process and help forgo biopsy.

Materials and Methods
We present a case-based review of the clinical features, imaging, pathophysiology, histologic features, treatments and prognosis of various demyelinating diseases including multiple sclerosis, neurobehcets, neuromyelitis optica, ADEM, etc. We will describe the characteristic imaging MRI features of these entities. In addition, we will highlight the presence of "open-rim" sign in these entities, which is an extremely helpful sign in distinguishing these mass-like lesions from other tumor-like mimics (glioblastoma multiforme, abscess, lymphoma, toxoplasmosis, tuberculoma, etc.). Clinical presentation, imaging features and histopathologic findings of each of the mimics will be discussed briefly as well.

Results
Multiple different presentations of tumefactive demyelinating entities will be shown, each exhibiting presence of an incomplete-rim sign within the brain and spinal cord. We also will show cases of similar appearing entities on MR imaging (MRI) such as lymphoma, metastases, nocardiosis, tuberculosis, astrocytoma, sarcoma, sarcoidosis, hemangiopericytoma and malignant fibrous histiocytoma, with an emphasis on differentiating these from a demyelinating lesion. Brief discussion of MRI findings (including various other sequences: diffusion-weighted imaging, diffusion tensor imaging, susceptibility-weighted imaging, etc.) of the aforementioned entities highlighting key features will be presented. We also will discuss the presence, utility and/or absence of Uhthoff's phenomenon in each of the aforementioned cases.

Conclusions
The differential diagnosis for ring-enhancing lesions in the central nervous system is broad and includes entities such as abscess, metastasis, glioblastoma multiforme, inflammatory demyelination, and lymphoma. "Incomplete-Rim" sign also referred to as "open-ring" sign is a fairly specific imaging finding for a demyelinating process including Tumefact Multiple Sclerosis and essentially excludes the remainder of the differential. Uhthoff's phenomenon is known to occur in a significant number of patients with multiple sclerosis. It refers to worsening of symptoms (including pain, fatigue, weakness, etc.) when patient's body temperature increases (e.g., from weather, exercise, hot showers, etc.). It is theorized to result from alteration in nerve
conduction from temperature changes. The presence of "incomplete rim" sign on imaging along with presence of clinical Uhthoff's phenomenon are two fairly sensitive and specific findings that essentially can confirm diagnosis of a demyelinating process and help forgo biopsy.

eEdE-05

CNS Angiitis: A Brain Tumor Mimic with a Characteristic Branching Vascular Abnormality on Susceptibility Imaging

M Mabray¹, K Kallianos¹, A Kansagra¹, S Cha¹
¹University of California San Francisco, San Francisco, CA

Purpose
Central nervous system (CNS) angiitis may present as a large brain mass lesion that is indistinguishable from a malignant brain tumor on imaging, a presentation that can lead to unnecessary and aggressive surgical resection. The purpose of our exhibit is to present several examples of CNS angiitis that mimic brain tumors on MR imaging with emphasis on the key imaging features on susceptibility imaging which can help differentiate these lesions from malignant brain tumors.

Materials and Methods
MR imaging features of primary CNS angiitis mimicking a large aggressive brain tumor will be reviewed with discussion of the clinical presentation, imaging course, treatment, pathology, and clinical follow up. Special emphasis will be made on characteristic vascular features on susceptibility imaging of CNS angiitis that help to differentiate from brain tumors, hence avoiding misinterpretation and unnecessary surgical resection.

Results
Central nervous system angiitis is a vascular inflammatory disease of the brain involving small arteries and veins of various sizes. Due to exuberant inflammatory changes within the brain, CNS angiitis can present as a large mass lesion with surrounding edema and mass effect indistinguishable from a malignant brain tumor. Differentiation between CNS angiitis and brain tumor is essential for proper medical management and, more importantly, avoidance of unnecessary and potentially harmful surgical resection. On MR imaging, CNS angiitis may demonstrate a characteristic branching pattern of magnetic susceptibility outlining the florid inflammatory process involving the vasculature that can serve as an important diagnostic clue to its non-neoplastic nature.

Conclusions
Central nervous system angiitis may present as a mass lesion with an MR imaging appearance indistinguishable from a malignant brain tumor. A characteristic branching pattern of a vascular abnormality on susceptibility imaging can aid in the accurate diagnosis of CNS angiitis and in avoiding unnecessary and potentially harmful surgical intervention. After reviewing this exhibit attendees will be familiar with this entity and what features help distinguish it from a brain tumor.

KEYWORDS: Tumor-Like Conditions
Crime Scene Investigation, Neuroradiology Unit: Can you solve the case?

J Holstadⁱ, A Rubinⁱ, S Levⁱ

¹Nassau University Medical Center, East Meadow, NY
Purpose
Crime Scene Investigation (CSI) is a crucial discipline in law enforcement which has captured the public imagination, with a multitude of legal and criminal dramas in the media and popular culture. The viewer of this exhibit, as an integral member of the investigative team, will solve a series of fictitious scenarios inspired by actual cases, both common and unusual. He or she must sift through a vast amount of detailed information, replete with potential detractors. We present complex story lines, and through active participation, the neuroradiologist will learn to optimize a search pattern and consider the mechanism of injury.

Materials and Methods
We retrospectively reviewed the interesting case logs at our level 1 trauma center, choosing studies (CT/CTA, MR/MRA) which illustrate the spectrum of traumatic brain injury (TBI). Maxillofacial and spine imaging, 2-D reformatted images and 3-D reconstructions may be provided. Each CSI episode is founded on an actual clinical history, for which we further envision a plausible narrative. Imaging studies will be combined with corroborative evidence, including police and witness testimonials, and photographic documentation. We challenge the viewer to determine if the injury was accidental or intentional, to establish the credibility of eyewitness accounts, and to deduce the sequence of events. As the case unfolds a vivid reconstruction will emerge.

Results
Cases are organized by mode of injury. Penetrating injuries include gunshot and knife wounds. Considerations for firearms include trajectory and missile migration, fragmentation and deformation, entrance and exit wounds, and position of the victim or shooter. Secondary fractures result from an explosive increase in intracranial pressure. Placement of skull fragments can demonstrate the temporal sequence of events. Stabbing can produce vascular compromise such as pseudoaneurysms, A-V fistulas, and carotid occlusions/transections. Domestic violence includes child and elder abuse. Pediatric intracranial hemorrhages and complex skull fractures from "short falls" and "accidental" facial bone fractures without associated massive trauma are suspicious. Shaking injuries are due to rotational and acceleration forces. Regarding the fragile elderly, it can be difficult to demonstrate abuse with multiple comorbidities and osteoporosis. Maxillofacial fractures and defensive injuries are common. Falls are the most common cause of TBI overall and display characteristic patterns. They may be intentional or accidental, low or high, intrinsic (postural control) or extrinsic (environmental). Injuries to the head and cervical spine are more common in falls up to 20 feet, while body trauma tends to occur above that. Our series of blunt object assaults examines associations of maxillofacial fractures and intracranial hemorrhages. Uncomplicated facial fractures herald more ominous injury. Motor vehicle accidents are the second most common cause of TBIs and occur from deceleration/acceleration or direct impact. In diffuse axonal injury the severity correlates with the velocity of the accident. Contusions, cerebral edema, and extra-axial hematomas, may occur with musculoskeletal and blunt cervical vascular injuries. Anoxic injuries include hanging, drowning, strangulation, and poisoning by carbon monoxide or drug overdose. MR imaging can demonstrate toxic damage and acute encephalopathy.

Conclusions
The radiologist is by nature a detective - an investigator with a penchant to unravel the mystery of an unknown case. The simulations we provide are intended to help the viewer filter out the misleading evidence from the many pertinent clinical and radiological clues. Awareness of injury
mechanisms and appropriate study utilization is essential for optimal triage and management of trauma patients.

Cruetzfeldt Jakob Disease: Etiopathology, Genetics And Imaging

M Bajaj¹, G Bathla¹, P KIRBY², Y Ohgiya³, T Moritani¹
¹University of Iowa Hospitals & Clinics, Iowa City, IA, ²University of Iowa, Iowa City, IA,
³Showa University School of Medicine, Tokyo, Japan

Purpose
This educational exhibit aims to: 1. Discuss the etiopathogenesis of Creutzfeldt-Jakob disease (CJD) with enumeration of diagnostic clinical criteria. 2. Describe pertinent findings on MR imaging (MRI) with analysis of different MR sequences. 3. Illustrate evolution of radiological findings on follow-up imaging. 4. Identify common imaging differentials to be considered and pitfalls to be avoided. 5. Briefly discuss genetics and genetic susceptibility in Creutzfeldt Jakob disease.

Materials and Methods
We retrospectively evaluated MR imaging findings in more than 30 patients with diagnosis of CJD confirmed on biopsy and/or positive CSF prion protein 14-3-3 present to radiology departments of authors/co-authors over a period of 10 years. A thorough correlation with clinical profile and other investigations also was performed. We present the important imaging findings in the form of an educational exhibit describing • Etiopathogenesis of CJD: Sporadic, New Variant, Iatrogenic, Genetic. • Diagnostic Criteria: WHO(1998), MRI-CJD Consortium criteria(2009). • Imaging findings: Role of different imaging sequences, sequential imaging for follow up to observe evolution of findings. • Pattern of involvement on MRI: Basal Ganglia, Cortex, Thalami. • Pathological correlation where possible. • Common imaging differentials: Postictal changes, toxic/metabolic encephalopathy, autoimmune /infectious encephalitis. •Genetic aspects of CJD in brief.

Results
Creutzfeldt-Jakob disease is a fatal infectious disease characterized by rapidly progressive neurodegeneration. Definitive diagnosis can be made only on brain biopsy or autopsy. MR imaging findings are typical and can settle diagnosis in a suggestive clinical scenario. Diffusion-weighted imaging (DWI) is most sensitive in picking up signal changes in cortex as well as basal ganglia. False negative cases can show positive findings on follow up. Pattern of involvement of brain structures can point to diagnosis as sporadic versus new variant CJD. Isolated bilateral thalamic involvement points to new variant CJD. Distribution of abnormal signal intensity areas may differ in different genetic types of sporadic CJD as well. A knowledge of common imaging differentials can help prevent overdiagnosis and alter management as many such diseases are treatable.

Conclusions
MR imaging may play an important role in guiding diagnosis of CJD if radiologist is aware of
common imaging findings, imaging differentials and pitfalls. A knowledge of underlying etiopathology and genetic aspects will ensure better understanding of the disease process.

KEYWORDS: Creutzfeldt-Jakob Disease, Genetics, MR Imaging

Demonstration of cerebral venous collaterals by using susceptibility weighted images

T Panyaping¹, M Castillo²
¹University of North Carolina Hospital University of North Carolina, Chapel Hill, NC, ²University of North Carolina Chapel Hill, Chapel Hill, NC

Purpose
Susceptibility-weighted imaging (SWI) depicts veins due to susceptibility effects of relatively deoxygenated blood and thus can be used to identify normal and abnormal blood vessels. Our purpose is to demonstrate the utility of SWI in the detection of cerebral venous collaterals in various disorders.

Materials and Methods
We searched our SWI database for the terms: collateral circulation, abnormal veins, venous thrombosis, developmental venous anomalies, and vascular malformations. We then classified our results as showing either decreased or increased veins, segmental or general, cortical or deep, or generalized. We also correlated the SWI findings with those of other sequences especially the postgadolinium T1 images and time of flight MR venograms.

Results
Susceptibility-weighted images better demonstrate venous collaterals of the brain, which appear diffusely throughout the brain or focally in some area. Increased venous collateral of the brain is caused mostly by venous obstruction, especially in dural venous sinus thrombosis with cerebral venous congestion or dural AV fistula with retrograde flow through venous collaterals. In our cases, there are prominent and dilated cortical veins on SWI accompanying with evidence of venous congestion in cases of superior sagittal sinus thrombosis and diffusely dilated venous collaterals in cases of dural AV fistula. Focal venous collateral is seen in case of cortical vein thrombosis as well as focal dilated deep medullary veins in case of Sturge Weber syndrome. The degree of prominence and dilatation of cortical veins is better demonstrated on SWI compared with other conventional MRI sequences such as T2-weighted or postcontrast images.

Conclusions
Susceptibility-weighted imaging is the excellent MRI technique to early depict and better demonstrate cerebral venous collaterals due to magnetic susceptibility effects of intravascular deoxyhemoglobin in cerebral veins. The degree of prominent and dilated cerebral veins is better visualized on SWI. Therefore, SWI is useful in detection of venous collaterals in setting of cerebral venous obstruction, AV shunting and/or venous congestion.

KEYWORDS: MR Imaging, Susceptibility-Weighted Imaging, Venous Obstruction
Diffusion Imaging of the Brain– Is Kurtosis the Next Frontier?

A Steven¹, J Zhuo¹, E Melhem²
¹University of Maryland School of Medicine, Baltimore, MD, ²University of Maryland Med. Ctr., Baltimore, MD

Purpose
The purpose of this electronic educational exhibit is to review the principles and applications of diffusion imaging in the brain, as well as introduce diffusion kurtosis imaging (DKI). While the basic premise of diffusion imaging is easily grasped, the technical considerations are commonly misunderstood. This presentation will include a basic primer on diffusion weighted imaging (DWI) and diffusion tensor imaging (DTI) as well as review the basis, technical requirements, and potential applications for an emerging diffusion technique, DKI.

Materials and Methods
Through a variety of illustrations and animations the basic components of diffusion imaging are reviewed. A number of real-life cases will be presented to reinforce important concepts and emphasize the clinical utility of these techniques.

Results
Measuring the free movement of water molecules is the basis for all diffusion imaging. In its simplest form, DWI, strong motion sensitizing gradients are used measure this motion, which is recorded in a scalar form known as the 'apparent diffusion coefficient'. Although there are numerous clinical applications, it is most classically used in the diagnosis of acute infarction. Diffusion tensor imaging applies a directional component, where diffusion measurements are made in at least 6 non-collinear directions. The resultant information can be displayed as a three-dimensional ellipsoid known as the 'diffusion tensor.' When diffusion is equal in all directions, or isotropic, this is reflected as a sphere. When diffusion is heavily skewed in a particular direction, or anisotropic, the resultant tensor becomes elongated and exhibits a specific orientation. Fractional anisotropy is a scalar measurement of how skewed in a given direction the diffusion for a given voxel is. The clinical applications for DTI are varied and far-reaching throughout.
neuroradiology. One of the most visually appealing applications is tractography, which allows
the ability to model major white matter tracts within the brain. DWI and DTI calculations assume
the Gaussian diffusion of water molecules, which is not typical in biological systems. Kurtosis is
a mathematical term used to describe non-Gaussian behavior, or variation from a normative
distribution. DKI attempts to provide a more accurate model of diffusion while determining the
extent of variation from a Gaussian distribution (mean kurtosis). The clinical significance of
these measurements is yet to be determined. However, this information seems to offer insight
into the microstructural environment and cellular heterogeneity of tissue beyond that of
traditional imaging techniques.
Conclusions
Diffusion imaging has become a mainstay in neuroradiology with numerous applications from
the rapid evaluation of stroke to assessment of traumatic brain injury to the pre-operative
mapping of white matter tracts in neurosurgical patients. DKI is a recent expansion of this
technique focused on the non-Gaussian diffusion properties of tissue, which appears to offer
distinct and complimentary information to traditional methods. This exhibit should reacquaint
the user with many familiar terms as well as explore potential future applications of this exciting
MR technique.

KEYWORDS: Diffusion Kurtosis Imaging, Diffusion MR Imaging, Diffusional Kurtosis
Imaging,
information in addition to that obtained with static contrast-enhanced MRA images. Cases include arteriovenous malformation, dural arteriovenous fistula, subclavian steal, pseudoaneurysm, luxury perfusion, arterial and venous stenoses and occlusions.

Conclusions
After reviewing this exhibit, radiologists will: 1. Understand the basic principles of time-resolved MRA (TWIST). 2. Recognize the clinical utility of this technique through multiple representative cases and know how to integrate this technique into neuroradiology practice.

Dual Energy CT And Intra arterial Stroke Therapy

O McDonnell¹, N Khorrami¹, J Shewchuk¹
¹Vancouver General Hospital, Vancouver, Canada

Purpose
To demonstrate the usefulness of dual energy computed tomography (DECT) in patients who have undergone intra-arterial stroke therapy in allowing reliable detection of hemorrhagic transformation a known complication of reperfusion therapy.

Materials and Methods
A dual-energy CT scanner was used for imaging at 80 and 140 kV, and a three-material decomposition algorithm was used to obtain virtual unenhanced images and iodine overlay images. Follow-up single energy CT images were reviewed and correlation performed.

Results
There was 100% agreement in detection of intracranial bleeding on virtual and conventional unenhanced images.

Conclusions
Dual-energy CT is highly accurate in distinguishing intracranial hemorrhage from iodinated contrast staining and has many advantages over MR imaging (MRI) including time and cost benefits patients who have contraindications to MRI. It can play a major role in management of acute stroke management and in guiding future antithrombotic therapy.

KEYWORDS: Acute Ischemic Stroke, Acute Stroke, Dual-Energy CT

Dural-based Tumors and Mass-like Lesions: Five Imaging Clues to Diagnose Meningioma Mimics

C Starr¹, G Punch¹, J Starkey¹, S Cha¹
¹University of California San Francisco, San Francisco, CA

Purpose
The purpose of this education exhibit is to present various dural-based brain lesions that can
mimic meningioma on imaging and to illustrate key imaging features that can help to
differentiate these potential mimics from meningiomas.

Materials and Methods
This exhibit will provide a brief overview of several dural-based intracranial lesions and their
imaging features. Pathologies including hemangiopericytoma, solitary fibrous tumor,
plasmacytoma, lymphoma, chloroma, chondrosarcoma, schwannoma, astroblastoma, and
epidural empyema will be presented in a case-based format along with relevant clinical
information. Characteristic imaging features that help distinguish these potential mimics from
meningioma will be emphasized along with important teaching points.

Results
A wide spectrum of dural-based masses can mimic meningioma on both clinical presentation and
imaging appearance thus a high index of suspicion should be maintained when evaluating extra-
axial masses. Distinguishing these mimics from meningioma has great clinical and prognostic
implications but at times can be extremely challenging for radiologists since the vast majority of
dural-based masses are meningiomas. Based on our review, the following five key differential
imaging clues on both computed tomography (CT) and MR imaging (MRI) can be extremely
helpful in differentiating other dural-based masses from meningiomas: 1) lack of dural tail, 2)
osseous destruction. 3) very dark T2 signal, 4) high T2 signal, 5) leptomeningeal extension

Conclusions
Meningioma accounts for up to 20% of all intracranial tumors and is the most common type of
brain tumor. There are, however, a wide variety of intracranial mass lesions, both benign and
malignant, that can closely mimic meningioma on imaging. It is essential to maintain a high
index of suspicion and evaluate for key imaging features to differentiate meningioma and its
mimics for proper surgical and medical management of patients. This educational exhibit
demonstrates several pathologic entities that can mimic meningioma and provide key imaging
features to facilitate differentiation.

eEdE-14

Early white matter tract involvement in global hypoxic injury following cardiac arrest
L Yap, C Romanowski
Royal Hallamshire Hospital, Sheffield, UK

Purpose
Global brain ischemia during cardiac arrest results in heterogeneous injury to the brain. Large projection neurons of the cerebral cortex, cerebellar Purkinje cells, and the CA-1 area of the hippocampus are the most vulnerable areas. Basal ganglia may be involved but areas such as the brainstem and thalamus are more resistant to injury. White matter involvement is documented less well. We describe a case series of patients with out-of-hospital cardiac arrest who demonstrate early involvement of the white matter tract.

Materials and Methods
A retrospective case series study was performed on four patients with postcardiac arrest hypoxic brain injury who underwent MR imaging (MRI) with additional diffusion-weighted imaging (DWI) between day 4 to 10 after initial insult. The imaging findings were reviewed with specific attentions to the cortex, deep gray matter and white matter.

Results
Case 1 shows high T2 signal within the cortical ribbon of the posterior frontal, parietal and occipital lobes bilaterally. On DWI, whilst, the cortex does not appear particularly restricted in diffusion, there is restricted diffusion within the deep white matter of the centrum semiovale, closely related to the anatomical distribution of the cortical high signal. Case 2 shows abnormal signal over most cortical areas and both hippocampi. There is ground glass appearance to the deep white matter. Diffusion-weighted imaging demonstrates restricted diffusion within the deep white matter particularly in the posterior frontal-parietal lobes, extending into the splenium of the corpus callosum. Case 3 shows high T2 signal within the cortical ribbon of both parietal and occipital lobes bilaterally. There is slightly reduced apparent diffusion coefficient (ADC) within the immediately subadjacent white matter. Case 4 shows extensive high signal within the cortex of both hemispheres and the basal ganglia bilaterally. There is subtle increased signal within the subcortical white matter. On DWI, there is restricted diffusion within the hemispheric white matter and the splenium of the corpus callosum. Follow-up MRI at 26 months following initial insult shows gross cerebral and cerebellar atrophy.

Conclusions
In this case series, DWI obtained during subacute phase show diffuse hyperintensity with decreased ADC (restricted diffusion) in the white matter, although the changes are not as obvious on the conventional MR images. The white matter changes are either localized to the subcortical region immediately adjacent to cortical lesion, along the deep white matter or to the entire white matter. The exact mechanism for white matter changes is unclear. Energy failure is thought to be the initial insult during global hypoxia. This can cause excitotoxic brain injury; secondary degeneration such as Wallerian degeneration may occur as a result of excitotoxic mechanisms propagating through axons or synapses. As such, the white matter change seen may represent the early phase of Wallerian degeneration where restricted diffusion demonstrated on DWI represents axonal intramyelinic swelling. This case series demonstrates that early cortical involvement with subsequent subcortical or deep white matter change may be the typical pattern of progression of global hypoxic injury following cardiac arrest before the surviving patients go on to develop diffuse atrophy.
Evaluation and comparison of open-source DTI processing software

A Choudhri¹, A Siddiqui¹
¹University of Tennessee Health Science Center, Memphis, TN

Purpose
Diffusion tensor imaging is an important clinical and research tool, providing insight into the white matter structure and integrity. Processing diffusion tensor imaging (DTI) data to obtain parameters such as axial diffusivity, radial diffusivity, fractional anisotropy, and tractography information is not available in all DTI software packages. Several open-source DTI software packages exist; however, each has different features, may or may not have been validated, and may be limited to specific computing platforms. We performed a review of existing open source DTI processing packages to compare the functionality and feature set to allow researchers to quickly find the package that best serves their needs.

Materials and Methods
Twenty separate freely available DTI software packages were evaluated. We evaluated the software platforms and hardware requirements for each. The ability to calculate axial diffusivity, radial diffusivity, mean diffusivity, fractional anisotropy, directionally-encoded fractional anisotropy maps was evaluated. The ability to perform fiber tracking by both deterministic and probabilistic methods was evaluated, as well as coregistration with structural images. The ability to perform histogram analysis, data resampling, as well as diffusion kurtosis processing is evaluated. The usability of software, including ease of installation, ability to uninstall, and availability of online documentation was assessed.

Results
Information regarding the features and differences between different software packages will be presented.
Conclusions
Multiple freely available software packages for DTI processing exist; however, each has
different strengths and limitations, and different packages may be more appropriate for certain
research projects. We feel that this comparison will allow researchers to more rapidly identify
the appropriate software package for their needs, allowing research time to be spent on research
and not software evaluation.

Everything you want to know about frontotemporal dementia

T Seki¹, H Vinters¹, N Salamon¹
¹David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA

Purpose
The purpose of this exhibit is: 1) To familiarize the recent classification of frontotemporal
dementia (FTD), 2) To review the imaging characteristics of FTD, and 3) To demonstrate the
functional assessment of FTD by using the novel techniques such as diffusion tensor imaging
and resting-state functional magnetic resonance imaging (MRI).

Materials and Methods
We demonstrate classification of FTD highlighting recent progress in genetic and pathologic
prospects. 1) Review of the clinical, genetic, and pathological classifications of FTD; Clinical
syndrome (e.g., behavioral variant FTD, semantic dementia, and progressive nonfluent aphasia),
genetic mutations (e.g., MAPT, GRN, and C9ORF72), and pathology (e.g., tau, TDP-43, and
FUS). 2) Neuroimaging gallery of FTD with anatomopathological correlation. 3) The structural
connectivity map of FTD using the diffusion tensor imaging and functional connectivity map
using resting-state functional MRI.

Results
Frontotemporal dementia is a clinically and pathologically heterogeneous spectrum of non-
Alzheimer dementias. Because FTD classification is complicated and evolved, many
neuroradiologists may not be familiar with how to approach this disease. The knowledge of the
classification and characteristic imaging findings with pathological correlation will be helpful for
the better understanding of FTD to allow the appropriate patient management.

Conclusions
This exhibit will be a practical tool and resource not only for radiology residents and
neuroradiology fellows but broader neuropsychiatric professionals and neuroscience researchers
to better understand the basic concept and current status regarding FTD.

Functional Motor Neuroanatomy - What Every Neuroradiologist Needs to Know.
N Khanna¹, W Altmeyer², A Steven³
¹University of Maryland Medical Center, Frederick, MD, ²University of Texas Health Science Center San Antonio, San Antonio, TX, ³University of Maryland, Baltimore, MD

Purpose
The purpose of this interactive electronic educational exhibit is to review the anatomy of motor function from the primary motor cortex through the spinal cord. In addition to anatomical landmarks used on conventional imaging, the exhibit will include a basic primer on blood-oxygen-level dependent functional magnetic resonance imaging (BOLD fMRI) and diffusion tensor imaging (DTI) with a discussion on the increasing role of these advanced imaging techniques.

Materials and Methods
Utilizing a case-based approach, the exhibit will review relevant anatomy with an emphasis on the somatotopic organization of the primary motor cortex. Discussion of advanced MR techniques including BOLD fMRI and DTI will be geared towards the general radiologist. The exhibit will utilize numerous pathologic processes including stroke, tumor, trauma and neurodegenerative disorders to exemplify and reinforce these important concepts.

Results
Relying on the intrinsic discrepant magnetic properties of oxyhemoglobin and deoxyhemoglobin, blood-oxygen-level dependent contrast (BOLD) imaging is used to indirectly measure neuronal activity by observing regional changes in cerebral blood flow. This technique has allowed researchers and clinicians to localize neural tissue involved in a variety of different functions. Mapping of the brain with BOLD fMRI has confirmed the somatotopic organization of the motor homunculus in the precentral gyrus and activation of the supplementary motor area in the planning phases of complex movements. While fMRI has changed functional neuroimaging of gray matter, diffusion tensor imaging has revolutionized the visualization of white matter tracts. Diffusion tensor imaging utilizes the same principles of DWI, but incorporates a directional component. Predicated on the idea that water diffuses most easily parallel to white matter tracts, the process of tractography is used to connect diffusion tensors, thus serving as a surrogate for white matter tracts in the brain. These techniques have not only improved our understanding of the complex inner workings of the brain, they now are being employed commonly clinically as part of the pre-operative assessment for patients with a variety of neurosurgical diseases.

Conclusions
Although functional neuroimaging is still in its infancy when one considers their potential applications, it is already being used to guide therapy and provide a reliable method of assessing motor function in the diseased brain. While the technology will inevitably evolve, the anatomy will not. A firm grasp of the functional motor neuroanatomy should aid the radiologist over the entire course of his/her career.

KEYWORDS: Functional Brain Mapping, Functional Diffusion Maps, Motor Mapping

eEdE-67

Carotid ultrasound is a frequently used tool to screen and stratify patients at risk for thromboembolic complications related to atherosclerotic disease primarily at the carotid bulb. This exhibit aims at reviewing important technical concepts and common pitfalls of vascular ultrasound examinations of the neck. Correlation to CTA/MRA studies will be provided to emphasize the advantages and limitations of sonographic examinations.

Materials and Methods
A series of cases will be selected from institutional teaching files and will be presented in a quiz format to highlight important concepts and pitfalls of cervical vascular ultrasound studies. Diagrams and cross-sectional imaging correlations will be added to emphasize advantages and limitations of the sonographic examinations.

Results
Selected cervical vascular ultrasound cases will illustrate the typical appearance of atherosclerotic disease (e.g., noncalcified, calcified, ulcerated, unstable) and its resulting degrees of carotid artery stenosis as determined by velocity measures as well as by grayscale and color Doppler images. In addition, more rare disease processes such as subclavian steal phenomenon, pseudoaneurysm formations and postsurgical changes/complications also will be discussed. This exhibit will particularly focus on frequently encountered technical challenges and pitfalls of sonographic examinations of the neck vasculature. Emphasis will be placed on findings that are concordant or discordant to computed tomography (CT)/MR angiography (MRA) correlates and key pearls will be provided to address the mismatch.

Conclusions
Vascular ultrasound remains the most commonly used screening tool for detection of carotid atherosclerosis. There are published guidelines that aim at standardizing interpretation and appropriate stratification of patients. However, some of the vascular ultrasound studies are compromised by inherent limitations of the sonographic technology. This exhibit provides key pearls for addressing commonly encountered limitations of vascular ultrasound studies resulting in discordant CTA/MRI findings, thus allowing for interpretation of these studies with a higher degree of confidence.

KEYWORDS: Carotid Plaque, Carotid Stenosis, Ultrasonography
hereditary optic neuropathy (LHON) and multiple sclerosis (MS). It was first described in 1970 by Dr. Wallace in which he presented a case of patient LHON who had additional neurologic findings of spasticity with increase deep tendon reflexes and encephalopathy. In 1992, Dr. Harding and colleagues presented a case series of patients with LHON who presented MS-like symptoms, which led to the coining of the term Harding's syndrome. We aim to shed light on this rare clinical entity with detailed review of clinical findings, imaging feature, pathophysiology, treatment and prognosis.

Materials and Methods
We present a case-based review highlighting clinical features, imaging findings, pathophysiology, histologic features, treatments and prognosis of Harding's syndrome. We will describe the characteristic imaging (CT and MRI) features of Harding's syndrome. Information will be presented on the various conditions that mimic Harding's syndrome including neuromyelitis optica, neurobehcet's, CADASIL disease, etc. Clinical presentation, histopathologic discussion and key imaging findings of each entity will be reviewed.

Results
Clinical findings of Harding's syndrome will be detailed including primary involvement of the optic nerves resulting in bilateral acute-to-subacute vision loss (usually before the age of 30), plus triad of circumpapillary telangiectatic microangiopathy, pseudoedema resulting from swelling of the peripapillary retinal nerve fiber layer and negative staining on fluorescein angiography. Additional key clinical finding is that these patients respond little, if at all, to immunosuppressive therapy. Characteristic CT and MRI findings of Harding's syndrome will be discussed including early cerebrocortical volume loss and marked bilateral optic nerve involvement. Mimics of Harding's syndrome include MS, neuromyelitis optica, neurobehcets amongst other inflammatory CNS disorders. Imaging findings in conjunction with patient's clinical course and treatment response can help narrow the differential diagnosis.

Conclusions
Harding's syndrome is a rare disorder characterized by presence of both Leber's hereditary optic neuropathy and multiple sclerosis. It presents in young patients, with slight female predilection, resulting in acute-to-subacute vision loss with additional neurologic symptoms including encephalopathy and spasticity. Although MS is much more common than Harding's syndrome, it should be strongly considered in the differential diagnosis of patients with progressive vision loss plus other neurologic deficits that are not responding to immunosuppressive therapy. For equivocal cases, genetic tests can be performed to isolate the mitochondrial mutation(s) resulting in Harding's syndrome. It is important to arrive at the correct diagnosis as this has significant cost (health and financial) and prognostic implications.

KEYWORDS: Demyelination, Optic Nerve
Purpose
The purpose of this poster is to illustrate the imaging appearances of Parkinson's disease (PD) and the Parkinson's plus syndromes (PPS) and other common movement disorders on 123I-FP-CIT single photon emission computed tomography (SPECT) molecular imaging of dopamine transporters (DaT) so that they may be recognized by a neuroradiologist in practice. In particular, it will outline the quantitative SPECT analysis techniques utilized in our institution to increase diagnostic accuracy in this patient cohort. The poster also will provide MR imaging (MRI) correlation in relevant cases.

Materials and Methods
The current literature on the utility of 123I-FP-CIT imaging in PD and PPS will be reviewed with regard to the accuracy of clinical diagnosis and the utility of 123I-FP-CIT SPECT in identifying patients with PD or PPS. Examples from our own practice will be used to illustrate the patterns that are seen on 123I-FP-CIT in PD and PPS including multiple-system atrophy, progressive supranuclear palsy and corticobasal degeneration, with MR correlation where applicable.

Results
Movement disorders are among the most common neurologic illnesses, with the parkinsonian syndromes (PSs) playing a predominant role. PS is a syndromal umbrella term that comprises four etiologically different entities: Parkinson disease (idiopathic parkinsonian syndrome, or PD; Parkinson disease with dementia (PDD), familial PS, atypical PS (PS caused by other neurodegenerative diseases, or aPS), and symptomatic (secondary) parkinsonism, including common differential diagnoses such as specific tremor syndromes. The group of aPS includes multiple system atrophy (parkinsonian and cerebellar types), progressive supranuclear palsy, corticobasal degeneration, spinocerebellar atrophy, and Lewy body-type dementia (DLB). Vascular, drug-induced, toxic, and metabolic parkinsonism; parkinsonism associated with inflammation, trauma, and tumor; and normal-pressure hydrocephalus belong to the category of secondary parkinsonism. Essential tremor (ET) and other tremor syndromes are further common differential diagnoses additional to PD and aPS. The main clinical application of 123I-FP-CIT imaging is the differentiation of degenerative parkinsonism from conditions not associated with dopamine deficit, such as essential tremor and drug-induced, vascular, or psychogenic parkinsonism. Most authors state that, in individual cases, DAT imaging does not allow for reliable discrimination of a PD subject from an aPS subject or for further discrimination of the latter. The use of quantitative analysis in 123I-FP-CIT shows great promise as a tool to facilitate this process.

Conclusions
123I-FP-CIT is a useful imaging tool for the diagnosis of patients with movement disorders. We have found a combined approach of visual assessment and quantitative analysis of tracer binding to be useful in analysis of 123I-FP-CIT imaging.

KEYWORDS: Molecular Imaging, Motor Impairment

Figure 1
Axial 123I-FP-CIT (below left) showing abnormal, period-shaped striatal uptake bilaterally supporting a diagnosis of a Parkinsonian syndrome.
Axial T2W image (below right) from subsequent MRI demonstrates normal middle cerebellar peduncles, making MSA an unlikely diagnosis.

eEdE-69

Image Artifacts In Neuro MRI: What The Neuroradiologists Need To Know

B Rehani¹, J Kirsch², A Krishnamoorthy³, O Rapalino³, P Schaefer³, R Gonzalez³
¹Massachusetts General Hospital, Harvard Medical School, Boston, MA, ²Siemens Healthcare, USA MGH/Athinoula A. Martinos Center for Biomedical Imaging, Charlestown, MA, ³Massachusetts General Hospital, Boston, MA

Purpose
MR imaging (MRI) artifacts can pose a diagnostic challenge for neuroradiologists as they can simulate pathology and interfere with image interpretation. Our aim is to illustrate the different types of MRI artifacts encountered in neuroimaging in a pictorial review format. We also
examine the origin of each artifact and suggest optimal imaging methods to minimize these artifacts.

Materials and Methods
A review of the imaging database was performed to depict examples of different types of MRI artifacts. Each MRI artifact was classified by causative mechanism, and subsequently potential solutions or strategies to minimize each artifact were analyzed.

Results
Artifacts can be classified into broad categories, as those easily explained by k-space sampling errors (aliasing, truncation, radiofrequency external interference, raw data spike artifact), timing and flow related errors (slice-to-slice crosstalk, flow void artifact, flow enhancement artifact, ghosting due to motion or pulsation), and radiofrequency or main field inhomogeneity errors (B1 shading, metal artifact, fat saturation inhomogeneity, Dixon fat-water separation error, chemical shift, susceptibility). Other miscellaneous artifacts also are discussed.

Conclusions
MR imaging artifacts can obscure abnormalities, mimic pathology, decrease the image quality and lead to diagnostic dilemmas in neuroimaging. However, knowledge of these artifacts and how they can be prevented or minimized can improve diagnostic effectiveness in neuroimaging.

KEYWORDS: Artifacts

Imaging Findings in Primary Central Nervous System Vasculitis.

M Gaha¹, L Letourneau-Guillon¹, F Guilbert¹, C Bard¹, S Lanthier¹, M Bélair¹
¹Centre Hospitalier de l'Université de Montréal, Montréal, Québec, Canada

Purpose
Primary central nervous system vasculitis (PCNSV) is a rare primary vasculitis limited to the brain and spinal cord. Clinical manifestations are nonspecific. Brain biopsy is the diagnostic gold standard, but may be falsely negative when unaffected tissue is sampled. Imaging procedures are a key part of the investigation of PCNSV patients. This review discusses the state-of-the-art of current imaging techniques in the workup of PCNSV patients and highlights future prospects.

Materials and Methods
Over the period of 2002 to 2012, we have listed at the CHUM (Centre Hospitalier de l'Université de Montréal) eight patients with confirmed PCNSV proven by stereotaxic cerebral biopsy in seven cases. We also realized systematic review of the literature about PCNSV articles in databases (MEDLINE, PubMed, EMBASE, Cochrane Library and Scopus).

Results
MR is extremely sensitive but nonspecific. The most common findings are multiple bilateral ischemic lesions often involving white and gray matter. Conventional or magnetic resonance angiography (MRA) typically shows segmental narrowing and dilation in multiple cerebral arteries. However, atypical findings also have been described both with magnetic resonance and angiography. Imaging techniques can be used to document the extent and type of lesions, to gauge response to treatment, and sometimes as surrogates for brain biopsy.
Conclusions
Accurate and early diagnosis of PCNSV is mandatory in order to prevent complications. Imaging techniques can contribute to establish the diagnosis and to evaluate disease activity with the extent of the disease in various vascular regions.

KEYWORDS: Arteriography, Arteriopathy, MR Imaging/MR Angiography

Imaging of Status Epilepticus with Emphasis on Diffusion-weighted Imaging

D Bui1, M Bajaj1, A Capizzano1, P KIRBY2, Y Sato3, T Moritani1
1University of Iowa Hospitals & Clinics, Iowa City, IA, 2University of Iowa, Iowa City, IA, 3University of Iowa Health Care, Iowa City, IA

Purpose
To review the imaging findings of patients with status epilepticus in the acute postictal period with emphasis on diffusion-weighted imaging primarily through a pictorial essay format. These imaging findings will be discussed in conjunction with pathology and pathophysiology in order to improve understanding and reinforce findings.

Materials and Methods
Using a pictorial essay format, imaging findings, pathology and pathophysiology related to status epilepticus will be illustrated in a logical and stepwise fashion through graphics, diffusion-weighted images (DWI) and gross pathology images. The key findings will be reinforced in tables with bulleted points.

Results
Status epilepticus has a complicated pathophysiology as evidenced by the ever evolving guidelines for diagnosis. In its most basic form, it can be thought of as neuronal injury that results from a hyper-excitatory state mediated by activation of excitatory receptors, primarily glutamate receptors. The cause of status epilepticus is diverse which includes congenital anomalies, mesial temporal sclerosis, neoplasm, trauma, inflammation/infection, toxic/metabolic disease, autoimmune disease, and many special syndromes. Clinically, this manifests as seizures lasting longer than five minutes and biochemically as a self-sustaining metabolic cascade. In the acute postictal phase diffusion restriction typically is seen representing neuronal injury in the form of cytotoxic edema. This at least can be partially reversible, unlike in cerebral ischemia where cytotoxic edema is secondary to irreversible failure of oxidative metabolism. Areas most vulnerable to injury include the hippocampus, amygdala, pyriform cortex, thalamus, cerebellum and cerebral cortex. Cytotoxic edema may extend to the subcortical white matter. It also may involve the entire hemisphere. Although the absolute time course for diffusion-weighted imaging and normalization are unknown, some experimental models showed ADC was decreased at about three hours to 48 hours and normalized or increased after this. In addition to accurately differentiating cytotoxic from vasogenic edema, diffusion-weighted imaging has the added benefit of being more sensitive to gray and white matter involvement. Multiple studies have showed positive correlation between electroencephalographic findings and diffusion-weighted imaging in terms of localization and lateralization.
Conclusions
Status epilepticus is a complex hyper-excitable and self-sustaining neurologic state resulting in neuronal injury. This typically manifests as diffusion restriction in the acute postictal period representing cytotoxic edema. In addition to differentiating cytotoxic edema from vasogenic edema, diffusion-weighted imaging has the added benefit of increased sensitivity for gray and white matter involvement. Diffusion-weighted imaging abnormalities correlate with electroencephalographic findings in terms of localization and lateralization. These findings illustrate the potential future role of diffusion-weighted imaging in the diagnosis and evaluation of status epilepticus.

**eEdE-04**

*Imaging spectrum of brain microhemorrhages on SWI*
Purpose
Microhemorrhages (MH) in cerebral and cerebellar parenchyma are due to various underlying causes. Conventional MR sequences and CT are not sufficient for their detection and determination of their distribution. Susceptibility-weighted imaging (SWI) is a new, full velocity compensated high-resolution three-dimensional (3D) gradient echo (GE) sequence, useful for the evaluation of various pathologies including MH. Our aim is to present and discuss various pathologies that present with brain MH and their distinctive imaging features on SWI.

Materials and Methods
We discuss various pathologies associated with brain MH and their distinctive imaging findings on SWI. For it, we searched in our teaching files for the following keywords: SWI, microhemorrhages, hemorrhage, trauma, brain injury, hypertension, stroke, infection, radiation therapy, amyloid angiopathy, vasculitis, encephalitis, cavernoma, embolus, PRES, fat emboli, sickle cell disease, tumor, and metastasis and evaluated the images for size, distribution and locations and number of MH. When available, we also compared the SWI to other MR sequences and/or CT. A literature review also is provided regarding the value of SWI in the detection and evaluation of the MH in different pathologic settings.

Results
In the evaluated brain MR examinations, the following entities were characterized by brain MH on SWI were identified, including traumatic brain injury, diffuse axonal injury (DAI), systemic hypertensive hemorrhages, invasive mucormycosis, postradiation MH, metastasis, tumors, multiple cavernomas, amyloid angiopathy, stroke, fat embolism, sickle cell disease, hemorrhagic PRES, and hypoxic ischemic encephalopathy. Susceptibility-weighted imaging is particularly helpful for detection and determination of distribution of MH which are more conspicuous than on CT or conventional MR imaging sequences. Some MH have a distinctive pattern such as the deep subcortical white matter, posterior corpus callosum and midbrain location of DAI; cortical distribution of amyloid angiopathy; peripheral distribution in sickle cell disease, basal ganglia and cerebellar location of hypertensive MH, perivascular distribution of invasive mucor, and diffuse involvement in fat emboli. However, in some entities the distribution of MH was not characteristic. In these cases, the clinical information and patient history were helpful in reaching the correct diagnosis.

Conclusions
Susceptibility-weighted imaging provides additional useful clinical information that is often complementary to conventional MR imaging sequences, and it can be used in the evaluation of various neurologic disorders especially in entities characterized by MH. Susceptibility-weighted imaging has higher sensitivity than conventional T2*GE sequences for detecting the size, number, and distribution of microhemorrhages in brain.

The Ottawa Hospital, University of Ottawa, Ottawa, Ontario, Canada, Medimagem - Hospital Beneficenci Cencia Portuguesa de São Paulo and Hospital São Jose, São Paulo, Brazil, Brasilia Children's Hospital, Brasilia, Brasilia, Distrito Federal, NM Medical Centre, Mumbai, Mumbai, Maharashtra, India, Montreal General Hospital, McGill University Health Centre, Montreal, Quebec, Canada, Bombay Hospital, Mumbai, Mumbai, Maharashtra, India

Purpose
To highlight the imaging features and presentation of various metabolic, degenerative, vascular, infectious and inflammatory pathologies involving the dentate nucleus.

Materials and Methods
We intend to describe the diverse CT and MR imaging (MRI) features of a wide spectrum of central nervous system (CNS) conditions involving the dentate nucleus. The pictorial includes a collection of common and rare metabolic, neurodegenerative, infectious/inflammatory and vascular pathologies.

Results
Among the several deep cerebellar nuclei, the dentate is the largest and most laterally situated nucleus and forms part of the neo-cerebellum. Its primary functions include skilled voluntary motor co-ordination and has strategic connections with the red nucleus, thalamus and premotor cortex and communicates with the contralateral side through the ponto cerebellar fibers. Dentate nucleus pathologies can be seen in several common and uncommon leukodystrophies, toxic/metabolic, neurodegenerative conditions, vascular pathologies, infectious/inflammatory conditions and few congenital anomalies. The educational exhibit will have a wide spectrum of diseases like maple syrup urine disease, cerebrotendinous xanthomatosis, metronidazole toxicity, aceruloplasminemia, glutaric aciduria type 1, mitochondrial diseases, hypertrophic Olivary degeneration, neurofibromatosis type 1, Fahr's disease, Langerhan's histiocytosis, postradiation, lupus vasculopathy, amyloid angiopathy, progressive multifocal leucoencephalopathy, cryptococcosis, rhombencephalosynapsis, Alzheimer disease with myoclonus and T2 hypointensity in dentate nucleus in multiple sclerosis patients.

Conclusions
The radiologist has to be aware of several entities involving the dentate nucleus and their varied clinical and imaging appearances which can be seen in different age groups.

KEYWORDS: Degenerative, Metabolic, MR Imaging
Imaging Spectrum of Intracranial Meningiomas

G Choudhary¹, S Shroff¹, A Meshksar¹, A Bauer¹, K Nael¹, R Khan¹

¹University of Arizona, Tucson, AZ
Purpose
While the diagnosis of meningioma usually poses minimal diagnostic challenge, in certain instances meningiomas may deviate in several imaging parameters, reflective of the various histological subtypes. Variation in signal intensity, perfusion characteristics, diffusion attributes, location, size and morphology can lead to diagnostic difficulty. Recognition and appreciation of this variation is crucial for accurate radiographic diagnosis.

Materials and Methods
Various presentations of intracranial meningiomas will be reviewed in a multimodality case-based format. The cases will emphasize the range from classic to atypical morphological appearances as well as the multitude of tumor locations.

Results
The spectrum of imaging appearances of intracranial meningiomas will be displayed according to the following outline: 1. Tumor location, Supra or infratentorial, Intraventricular, Optic nerve, Cerebellopontine angle. 2. Growth patterns, En plaque, Intra-osseous. 3. Histologic grade, Relationship between histology and imaging findings. 4. MR imaging (MRI) signal characteristics. 5. Specific radiographic features, Dural tail sign, cerebrospinal fluid (CSF) cleft sign, "Mother-in-law sign", "Tram-track sign".

Conclusions
Although common and frequently characteristic in radiographic appearance, meningiomas may present with a wide spectrum of imaging characteristics, the familiarity of which is essential in diagnosis. After reviewing this exhibit, radiologists will recognize the spectrum of appearances and locations of meningiomas and integrate this knowledge into practice.

Imaging Spectrum of the “P and M” Visual Pathways and the “What and Where” Doctrine and Related Disorders.

B Tantiwongkosi¹, F Yu¹, N Salamon²
¹University of Texas Health Science Center San Antonio, San Antonio, TX, ²David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA
Purpose
This pictorial review illustrates the relevant anatomy, connections, and diseases affecting the higher cortical visual pathways. Radiologic and clinical neuro-ophthalmologic correlation is emphasized.

Materials and Methods
A specific group of patients suffering damage to higher cortical visual areas may have normal visual field and acuity, but suffer from inability to read or recognize colors, objects, faces, motion, etc. These association areas (V2-V5) are divided anatomically and functionally into ventral (occipitotemporal) and dorsal (occipitoparietal) pathways. The ventral pathway is an extension of the parvocellular (P) pathway, helping individuals to recognize objects ("What"). The dorsal pathway represents continuation of the magnocellular (M) pathway, responsible for object location ("Where"). Damage to these areas produces specific localizing signs and symptoms that tremendously help the neuroradiologist focus on particular anatomical structures. We present this pictorial review by utilizing CT, MR imaging (MRI), diffusion tractography, functional MR imaging (fMRI) and simplified diagrams superimposed on CT/MRI in order to elucidate the anatomy, function, and related diseases.

Results
The cerebral anatomy of the visual association areas is mapped on 3D MR imaging (MRI) reformatted reconstructions (Figure 1) and functional MRI (fMRI). The connections of the ventral and dorsal pathways to the primary visual cortex are demonstrated using diffusion tractography. Characteristic clinical syndromes and their corresponding structural damages include alexia without agraphia (left occipital lobe and splenium of corpus callosum), hemiachromatopsia (contralateral occipitotemporal lobe in the fusiform and lingual gyri), Balint syndrome (bilateral parieto-occipital lobes), visual hemi-inattention (right inferior parietal lobule), etc. Diseases vary by location to include neoplasms, demyelinating diseases, infection, and strokes. Imaging characteristics of each disease and differential diagnostic clues are discussed.

Conclusions
Recognizing the characteristic clinical and neuroimaging findings of higher cortical visual disorders is invaluable for neuroradiologists in providing accurate diagnoses and management guidance.

N Supakul¹, J Tejada¹
¹Indiana University School of Medicine, Indianapolis, IN

Purpose
To review the basics of inferior petrosal sinus sampling (IPSS) including definition, conventional anatomy and anatomical variants, indications, procedural technique, accurate sampling, pitfalls, complications, interpretation of the angiographic results as well as pathology results and clinical outcomes after surgery.

Materials and Methods
From our computerized radiology information system (2008-2013), we identified patients who
were referred for IPSS. All medical charts, initial cross-sectional studies, diagnostic venogram and IPSS were reviewed.

Results
Ten patients (1 male, 9 females, and age range 19-75 years old) were included. All patients presented with clinical findings of Cushing syndrome. All patients had initial MRI sella with contrast; four showed no evidence of pituitary mass, three had inconclusive studies and the rest of them had a positive MR imaging (MRI) for pituitary microadenoma. All patients had a positive IPSS (either desmopressin or acthrel stimulation), seven of them (70%) had pathological proven pituitary microadenoma. Two of them showed no evidence of micro on pathology; however, one of these showed a good clinical outcome while the other one (male patient) has not had a follow up at our institute. One patient decided to not have surgery and has not followed at our institute. We will demonstrate conventional anatomy and anatomical variations of the inferior petrosal sinus (IPS). We will review indications and contraindications of the procedure. Procedural techniques and how to obtain an accurate sample with pharmacologic stimulation test as well as common pitfalls during the procedure will be discussed. Result interpretation and clinical outcomes will be reviewed.

Conclusions
1. Inferior petrosal sinus sampling is a useful diagnostic technique to localize adrenocorticotropic hormone (ACTH)-producing tumors in patients with normal or equivocal MR imaging studies, and it is considered a gold standard test. 2. With bilateral simultaneous sampling, it is an extremely sensitive, specific, safe and accurate test to diagnose Cushing disease. 3. Anatomical variants in the IPS are not rare and a complete understanding of these variants is required. The basic concepts of the procedure can help management of Cushing disease.

Intracranial Hypotension: Often overlooked under pressure

G Paek1, V Nguyen2
1Long Island Jewish Medical Center, New Hyde Park, NY, 2North Shore Long Island Jewish Medical Center, New Hyde Park, NY

Purpose
Headache is one of the most common patient complaints, with an estimated overall lifetime prevalence of 0.2-60% for headache of any kind. The ACR Appropriateness Criteria for workup of headache based on certain features almost all include cross-sectional imaging of some kind to evaluate for devastating emergencies (for example subarachnoid hemorrhage) versus chronic issues (i.e., migraine). Intracranial hypotension is a cause of chronic headache that waxes and wanes and often is overlooked as the imaging findings are subtle and radiologists who are not provided with relevant history may overlook as a treatable cause of patient ailment. This exhibit will explore the world of intracranial hypotension with its clinical presentation, imaging findings, recommended follow-up imaging, and treatment of several causes.

Materials and Methods
Diagnosis of intracranial hypotension has been proven to be challenging as there are several
subtle, commonly overlooked findings. Common imaging findings on cross-sectional imaging will be reviewed, as well as recommended follow-up imaging. In addition, pertinent information elicited from a thorough clinical history would best provide guidance to further diagnostic workup as there are several different causes of intracranial hypotension.

Results
Most patients with intracranial hypotension will present with headache and first line imaging usually involves computed tomography (CT) or MR imaging (MRI). Findings on baseline cross-sectional imaging include enlargement of the extra-axial spaces disproportionate to ventricular size, ‘sagging’ of the corpus callosum, effacement of the basal cisterns, as well as downward displacement of the posterior fossa into the foramen magnum. In addition, the etiology of intracranial hypotension varies and this exhibit will review the common causes of intracranial hypotension which are spontaneous versus iatrogenic. Elucidating the cause is important for both follow-up imaging as well as for treatment. For example, a cerebrospinal leak from prior lumbar puncture may require a simple epidural blood patch, versus a patient who has a history of a transphenoidal resection who may require preoperative cisternography before surgical intervention. Lastly, treatment of intracranial hypotension will be discussed, which is predictably heavily based on etiology of its causes. This can involve something as simple as a blood patch versus a fat packing procedure performed by the otolaryngologists or neurosurgeons.

Conclusions
Headache caused by intracranial hypotension often is a difficult diagnosis to make without familiarity with this entity and its possible causes. Our role as radiologists include recognition of the common imaging findings and proper follow-up evaluation to elucidate and help guide patient management and treatment.

Intracranial Manifestations of HIV disease: A Pictorial Review with Diagnosis Algorithms

C Pluguez-Turull1,2, C Quintero-Estades1, S Maldonado1, M Rivera1, G Tantillo1, G Santacana-Laffitte1, E Labat1
1University of Puerto Rico - Medical Sciences Campus, San Juan, PR, 2Transitional Year Program – San Juan City Hospital, San Juan, PR

Purpose
In the era of highly active antiretroviral therapy (HAART) mortality has decreased substantially among human immunodeficiency virus (HIV)-infected people with access to HAART. However, there is still a large contingent currently undergoing treatment, recently diagnosed or undiagnosed HIV positive individuals that present with atypical manifestations of intracranial disease. Evidence to the severity of this was offered by the ART Collaboration Cohort study in 2006 with a retrospective 10-year cohort of 1,876 deaths amongst 40,000 HIV positive patients in Europe and the U.S., which led authors to conclude that at less than four years of HAART, HIV patients were still more likely to die of an HIV/AIDS-related illness. This educational exhibit will review the pathophysiology, clinical presentation and characteristic imaging findings to aid in the diagnosis of HIV-associated infections, neoplasms and neurodegenerative disease.
Materials and Methods
Radiological images and relevant clinical information was extracted from our PACS station and MEDITECH™ integrated healthcare system at our supratertiary hospital network. Images were retrieved from recent imaging studies to review a wide spectrum of the major central nervous system (CNS) pathologies afflicting patients with confirmed HIV/AIDS.

Results
In this educational exhibit we intend to present a wide range of CNS pathologies frequently encountered in confirmed HIV/AIDS patients at our institution. Particular attention was paid to the differential diagnosis from the clinical interpretation of corresponding CT and MR images. Diagnostic algorithms were created to aid in the discrimination of the main differential diagnostic considerations based on their typical imaging features.

Conclusions
Opportunistic infections, neoplasms and HIV-associated neurodegenerative disease occurring secondary to immunodeficiency are still a major cause of morbidity and mortality among HIV positive patients even in the era of HAART. Proper differentiation among these pathologies may prove to be difficult. Radiologists must be able to use neuroimaging in conjunction with a complete clinical evaluation to obtain the best possible diagnosis to guide subsequent therapy for optimal patient outcomes.

Intracranial Venous System and its Diseases on TOF- vs CE MR Venography

J Slaunwhite¹, J Shankar²
¹QEII Health Science Center, Halifax, Nova Scotia, ²QEII Health Science Center, Dalhousie University, Halifax, Nova Scotia

Purpose
The venous system of our brain is an important part of the vascular tree and gets affected in a number of disease processes. There are a number of variations in the normal venous anatomy. The best way to avoid misdiagnosis is to know all the possible variations of the venous anatomy as some of the pathological states may mimic the normal variation of the venous anatomy. Some of the examples of the venous pathologies that may mimic the normal venous anatomical variations are venous stenosis in idiopathic intracranial hypertension, venous sinus thrombosis, etc. This requires a good imaging technique. Magnetic resonance venography (MRV) is one of the preferred imaging tools to study the normal venous anatomy, its variations and the pathological state of the venous system. Two techniques of acquiring MRV are (i) contrast-enhanced MR Venography (CEMRV) and (ii) time-of-flight MR Venography (TOFMRV). Both of these tools have been used extensively and CEMRV has been described as a better tool in demonstrating the normal anatomy, variations as well as pathology. The aim of this exhibit is to demonstrate normal venous anatomy, its variations and different pathologies on both TOF and CE-MRV. The secondary aim of this exhibit also is to show that CEMRV is significantly better than TOFMRV in this demonstration.
Materials and Methods
The CEMRV was acquired using a timing sequence with 2 cc of multihance followed by an intravenous injection of 15 cc of multihance using a MedRad injector to deliver the contrast at a rate of 2 ml/sec followed by 25 cc of saline injected at a rate of 2 ml/sec. Maximum intensity projection images were created and sent to PACS. Both TOF and CE-MRV images were compared for depiction of normal anatomy, variations, different venous pathologies and confidence level of neuroradiologist in diagnosing a venous pathology. From Dec 2011, we prospectively collected patients where both TOF and CE-MRV were acquired at the same time for various clinical indications. All patients were scanned on a 1.5 T magnet with an 8-channel head coil. The TOFMRV and the CEMRV sequences were acquired with the para. The CEMRV was acquired using a timing sequence with 2 cc of multihance followed by an intravenous injection of 15 cc of multihance using a MedRad injector to deliver the contrast at a rate of 2 ml/sec followed by 25 cc of saline injected at a rate of 2 ml/sec. Maximum intensity projection images were created and sent to PACS. Both TOF and CE-MRV images were compared for depiction of normal anatomy, variations, different venous pathologies and confidence level of neuroradiologist in diagnosing a venous pathology. Meters shown in the Table.

Results
Each case example will prompt the viewer to anticipate and recognize a specific anatomical variation or disease of the venous system. This also will demonstrate the superiority of the CEMRV in demonstration of venous anatomy, variation and pathologies. This will highlight the false positivity on TOFMRV in many different cases.

Conclusions
The different case examples will demonstrate different anatomical variations and pathologies of the venous system. This also will demonstrate the superiority of CEMRV over TOFMRV in demonstrating this.

Introduction to Segmentation, Registration and Volume Analysis for Imaging Genomics

O Ashour¹, A Chaddad¹, P Zinn¹, R Colen¹
¹MD Anderson Cancer Center, Houston, TX

Purpose
Image processing is essential for extracting data for any type of research study dealing with quantitative imaging variables. Before any type of volumetric analysis, the volumes in question should be well defined and presented as data types that are easy to deal with. In this exhibit we look at the methodology for image registration, segmentation and model building that we used for our study imaging genomic mapping in GBM.

Materials and Methods
We used Slicer software for the purposes of all the image analysis, manipulation and segmentation. 3D Slicer (www.slicer.org) is a free open source software platform for medical image processing and 3D visualization of image data. The platform provides functionality for segmentation, registration and three-dimensional visualization of multimodal image data, as well as advanced image analysis algorithms for diffusion tensor imaging (DTI), functional magnetic resonance imaging (fMRI) and image-guided therapy. FLAIR series was used for segmentation of edema and postcontrast T1-weighted imaging (T1WI) for segmentation of enhancement (defined as tumor) and necrosis. These sequences thus were selected to compute and obtain quantitative edema/invasion volumetry. Each sequence was loaded in Slicer as a volume. The “Parse Directory” function was used to parse the series and show all the series available in the data. We selected all the desired series separately to be opened in the volume module. The Volume module loads, saves and adjusts the display parameters of volume data. A volume can
be set for raw images of a certain sequence or label map and various options are available to adjust the way a volume is displayed.

Results
Registration: Different scans may be recorded at different angles, at different voxel thicknesses and use different number of slices. We need to register these scans, so that they correspond and are rigidly aligned to each other. Modules used: A. Transformation module: It helps to create and edit Slicer transformation nodes. Transformation nodes are matrices of data that map the voxels of every volume and are used to map different volumes, they can be both linear (expressed as 4 by 4 matrix) or nonlinear warp transformations. The transformation module allows you to edit only linear transformation nodes. We usually specified the T1 volume as the fixed base volume, and the FLAIR as the moving "transformed" volume. We used the "Translation" and "Rotation" tools to manually align every two volumes in space coordinates. B. Resample Scalar/Vector/DWI Volume: This module implements image and vector-image resampling through the use of ITK transforms. Resampling is performed in space coordinates, not pixel/grid coordinates. It is quite important to ensure that image spacing is properly set on the images involved. Segmentation: The segmentation was carried out in a simple hierarchical model of anatomy, proceeding from peripheral to the central. Edema, necrosis and tumor were segmented and later modeled. Segmentation Module (Editor): This is a module for manual segmentation of volumes. The overall goal is to precisely define structures within their volumes as "label map volumes". These label maps can be used for building models or for further processing. We used the single label map approach to create models of different tumor volumes on the same label map. Model Making: Using the "Make Model" tool of the "Editor" module, the models of edema, tumor and necrosis are generated from the previously performed segmentation. Data Display: It gives a complete view of the hierarchical (tree) representation of the MRML Scene.

Conclusions
Manual segmentation provides the advantage of higher accuracy compared to automated methods, especially if performed or supervised by an experienced radiologist. It is however more time consuming and has intersegmenter variability. Automated methods include: - Thresholding: Using set gray-scale levels as cut-offs for inclusion or exclusion of image elements and regions. - Region-growing: Uses a group of seed points to initiate an expansion of the segmented region through neighboring pixels to cover the desired tissue element. - Atlas-based techniques: - Clustering: By grouping voxels of similar properties into groups.

eEdE-31

6:30AM - 9:00PM

Is it recurrent, or residual, or radiation necrosis or pseudoprogression? What physician expects and what radiologist can deliver.

S Kanekar\(^1\), A Agarwal\(^2\)

\(^1\)Penn State Milton S Hershey Medical Center, Hershey, PA, \(^2\)Milton S Hershey Medical Center, Hershey, PA

Purpose
1. To highlight the limitations of the conventional imaging techniques in evaluation of recurrent
brain tumor. 2. To demonstrate the importance of cellular and molecular techniques (MR spectroscopy, DWI-ADC, MR perfusion/permeability and DTI) in evaluation of posttreatment brain tumor.

Materials and Methods
We retrospectively studied 114 patients from our oncology data which formed the basis for this exhibit. All patients were treated for brain tumor with surgery and radiation therapy. Sixty-nine patients also had received chemotherapy. Pre and multiple posttreatment contrast-enhanced MR images (MRIs) including stealth study were available for analysis. Depending on the need, some of these patients also had higher end imaging techniques like MR spectroscopy, MR perfusion/permeability. Sixteen patients also had DTI of the brain while 11 patients had PET imaging.

Results
In this exhibit we discuss the various cellular and molecular imaging techniques in respect to angiogenesis, recurrent tumor, radiation necrosis, pseudoprogression and perilesional hyperintensity. We also discuss in brief the effect of angiogenesis inhibitor on imaging.

Conclusions
1. Diagnosis of recurrent brain tumor is always challenging. The combination of newer cellular and molecular imaging techniques has increased the sensitivity in the diagnosis of early recurrent tumor. 2. Combinations of these techniques (e.g., MRS + MRP or MRS + DTI/PET) are more sensitive and specific in differentiating recurrent from radiation necrosis, than single advanced imaging techniques.

Meckel's Cave Dwellers: A Review of Tumors and Tumor Mimickers

M Khan1, A Wang1, R Jain1
1William Beaumont Hospital, Royal Oak, MI

Purpose
Meckel's cave, or the trigeminal cave, is a cerebrospinal fluid (CSF) filled pouch arising from the posterior cranial fossa which houses the gasserian ganglion. There are a myriad of pathologic processes which can arise primarily within this area or may infiltrate it secondarily. It is important for the radiologist to be familiar with not only true tumors but also various pseudolesions which can lead to unnecessary surgery if there is a misdiagnosis.

Materials and Methods
We will review the axial and coronal MR anatomy of Meckel's cave and provide a case-based review of various lesions including benign and malignant masses, granulomatous lesions, perineural tumor spread, and metastasis. We also will discuss the appearance of various pseudolesions which can mimic tumors such as cephalocele, aneurysms and postradiation enhancement.

Results
Meckel's cave is a dural recess in the medial posterior and inferior portion of the middle cranial fossa with the dura and temporal bone as the lateral boundary, the precavernous ICA as the
medial boundary, and the cavernous sinus as the anterosuperior boundary. On MR imaging (MRI), it appears as ovoid, smooth CSF-filled cisterns on axial and coronal scans resembling "open eyes" which appears as symmetrically hypointense on T1, and hyperintense on T2. When pathology occurs within the cave, one may see a "winking" sign, in which one side becomes filled with soft tissue rather than CSF, leading to an asymmetric appearance which may appear with increased signal intensity on the contrast-enhanced imaging. Our review will discuss in greater detail the characteristic imaging findings of pathologic lesions which occur in this space. Conclusions

Familiarity with the anatomy and imaging characteristics of lesions within Meckel's cave will help the radiologist to establish the diagnosis and not mistake tumors from the tumor mimickers.

Meningiomas and Mimics: A "Tail" of Extraaxial Masses

A Sundblad1, W Lake1, M Salamat1, P Turski2, T Kennedy3
1University of Wisconsin Hospital and Clinics, Madison, WI, 2University Of Wisconsin, Madison, WI, 3University Of Wisconsin Hospital, Madison, WI

Purpose

Meningiomas are the most common nonglial primary intracranial tumor accounting for approximately 25% of all primary intracranial neoplasms. They often are diagnosed easily by typical imaging findings. The purpose of this exhibit is to review typical features of meningioma, atypical imaging features, mimicking extraaxial neoplasms, and review advanced imaging techniques that may aid in differentiating benign from atypical/malignant meningiomas.
Materials and Methods
Typical and atypical imaging features of meningioma will be reviewed. Imaging of grade II and III meninogiomas will be discussed with emphasis on advanced imaging techniques (DWI, DSC perfusion) and whether these tools can reliably differentiate meninogiomas by grade. The histologic subtypes and histologic grading of meninogiomas will be correlated with imaging. Subsequently, other extraaxial masses that can mimic meninogioma will be reviewed.

Results
The typical imaging appearance of meninogioma is a hemispheric extraaxial mass that is slightly hyperattenuating to gray matter, T1/T2 isointense to gray matter, homogeneously enhancing, with a reactive dural tail and hyperostosis of the adjacent calvarium. Atypical imaging features include intratumoral or peritumoral cysts, ring enhancement, fatty metaplasia, heterogeneity, T2 hyperintensity, and bone destruction. A reactive dural tail is seen in up to 80% of meninogiomas, but is a nonspecific finding that can be seen in any extraaxial mass that involves the dura. Peritumoral edema is seen in up to 60% of meninogiomas and is associated with pial blood supply, tumor size, irregular tumor margins, loss of peritumoral T2 hyperintense cleft, and T2 hyperintensity of the tumor. The clinical implications of peritumoral edema are increased operative morbidity and increased tumor recurrence. Benign meninogiomas cannot be differentiated from atypical or malignant meninogiomas by conventional imaging features. Recent studies show decreased apparent diffusion coefficient (ADC) values in atypical and malignant meninogiomas compared to benign meninogiomas. Dynamic susceptibility contrast perfusion-weighted MR does not differentiate benign from malignant meninogioma, though CBV within the peritumoral edema has been noted to be higher with malignant meninogiomas. A pictorial display of extraaxial masses that can mimic meninogiomas including metastases, lymphoma, hemangiopericytoma, granulomatous disease, hemangioblastoma, solitary fibrous tumor, cavernoma, melanocytoma, and mesenchymal tumors will be included.

Conclusions
While meninogiomas often are diagnosed easily by typical imaging features, the radiologist must be aware of the various atypical imaging features of meninogioma and multiple other extraaxial processes that can mimic meninogiomas.

KEYWORDS: Extra-Axial, Meningioma

MR imaging of Mild cognitive impairment: State of art
6:30AM - 9:00PM

A Abdel Razek, M Elsayed, A Tantawy
*Mansoura University, Mansoura, Egypt

Purpose
The aim of this work is to review basic background about mild cognitive impairment (MCI), to illustrate the anatomical, morphometric and functional changes in MCI and to discuss role of MR imaging in patients with MCI.

Materials and Methods
1-Consensus criteria and guidelines of MCI. 2-Clinical, genetic and CSF biomarkers of MCI. 3-Neuropathology and neurobiology of MCI. 4-Normal anatomy of hippocampus and temporal
region. 5-Anatomical and morphometric MR imaging changes in MCI. 6-Diffusion MR, perfusion MR and MR spectroscopy findings in MCI. 7-MR imaging biomarkers for subtyping of amnestic from nonamnestic MCI. 8-MR imaging biomarkers and longitudinal study that predict conversion to Alzheimer disease (AD). 9-MR imaging findings differentiate MCI from other causes of dementia. 10-MR imaging of special forms such as MCI with Parkinson and depression. 11-Imaging biomarkers used to predict patient response to therapy and outcome. 12-Future directions and summary.

Results
MR imaging biomarkers are used for subtyping of amnestic from nonamnestic MCI. MR imaging biomarkers as ADC metabolites and longitudinal study are used to predict conversion to Alzheimer disease (AD). Also, MR imaging findings differentiate MCI from other causes of dementia and diagnose special forms such as MCI with Parkinson and depression. Finally, MR imaging biomarkers used to predict patient response to therapy and outcome.

Conclusions
We concluded that anatomical, morphometric and functional MR images, MR neuroimaging biomarkers has a role in subtyping of MCI, predict conversion to AD and differentiation from other causes of dementia.

MRI Artifacts in the Brain and Spine: The Good, the Bad, and the Ugly

B Griffith¹, N Kolicaj¹, S Patel², J Corrigan¹, D Hearshen¹
¹Henry Ford Health System, Detroit, MI, ²Henry Ford Hospital, Detroit, MI

Purpose
Magnetic resonance imaging (MRI) is the primary diagnostic workhorse in neuroradiology. Yet despite its capabilities, MRI remains prone to a number of artifacts, which often are compounded today by the use of higher field strength magnets. The purpose of this exhibit is to explore the full spectrum of artifacts encountered in MR imaging of the brain and spine, including causes and potential solutions, which will enable the neuroradiologist to more readily recognize and correct potential issues.

Materials and Methods
Using our case files, we will show examples of various artifacts encountered in MR imaging of the brain and spine. • Artifacts that will be discussed will include those related to: 1) MR hardware (e.g., zipper artifact and inhomogeneity artifacts); 2) Physiologic factors (e.g., patient motion, CSF pulsation, blood flow); 3) Foreign bodies (e.g., susceptibility artifact); and 4) Signal Processing (e.g., wrap around, Gibbs phenomenon). • Specific emphasis will be placed on artifacts that mimic pathology (e.g., pseudo-enhancement, false syrinx, pseudo-infarcts on diffusion-weighted imaging, flow void artifacts mimicking carotid stenosis, aortic pulsation artifact mimicking spinal cord pathology), as well as those that enhance pathology (blooming "artifact" of hemosiderin on susceptibility-weighted images). In addition, we will discuss specific pitfalls of particular imaging sequences (e.g., flow artifacts on FLAIR images), as well
as how choice of MR sequence may mitigate or enhance pathology. • For each artifact, we will discuss the underlying cause, as well as potential methods to correct the artifact.

Results
Artifacts in MRI of the brain and spine are not uncommon and typically can be classified as related to MR hardware or processing issues, physiologic factors, and the presence of foreign bodies. Aside from the obvious detrimental effects on image quality, artifacts can potentially play an important role in study interpretation, both for the good (e.g., use of susceptibility-weighted imaging to detect microbleeds) and the bad (artifacts mimicking pathology). Despite the potential limitations that artifacts introduce into MR interpretation, in the appropriate hands, these issues can be recognized easily and often corrected.

Conclusions
MR imaging of the brain and spine is an essential tool in neuroradiology today. However, despite its diagnostic capabilities, MR remains susceptible to a number of artifacts that can diminish its usefulness, and in some instances, actually lead to incorrect diagnoses. As such, it is essential that neuroradiologists have a strong understanding of the artifacts commonly encountered in imaging of the brain and spine, as well as appropriate steps to correct the artifacts. This case-based exhibit will explore the good, the bad, and the ugly of MR artifacts, strengthening the viewer's understanding of those artifacts commonly encountered in everyday practice, as well as providing the necessary steps to improve or correct the problem.

KEYWORDS: Artifacts, MR Imaging Brain, MR Imaging Spine

Neuroimaging Appearances and Positioning of Mini-craniotomies for Endoscopic Neurosurgery Compared with Traditional Craniotomies: A Pictorial and Educational Review

A Macdonald¹, L Wing², R Shah¹, T Massoud³, P Plaha¹
¹Oxford University Hospitals, Oxford, UK, ²John Radcliffe Hospital, Oxford, Oxford, UK, ³Stanford University School of Medicine, Stanford, CA

Purpose
There is an increasing drive for minimally invasive surgery across all surgical disciplines. Within neurosurgery this trend has manifested particularly in the increasing use of endoscopic methods for intraparenchymal tumor resection. Neuroradiologists are familiar with standard surgical approaches, craniotomy flaps, and their postoperative appearances. However, with rapid developments and increasingly innovative strategies in minimally invasive neurosurgery, many neuroradiologists may not be familiar with cross-sectional imaging appearances of mini craniotomies used for endoscopic neurosurgery. We present and discuss a series of images and their 3-D reconstructions that demonstrate the positioning and normal postoperative appearances of mini craniotomies for endoscopic neurosurgery. We also provide useful educational perspectives by comparing these images to the 'traditional' bone flaps that would have been required for removal of the same tumor.

Materials and Methods
As part of an ongoing development of neuroendoscopic tumor surgery at our institution a
database of patients undergoing minimally invasive surgery was available. All patients in this series underwent imaging with CT on the first postoperative day. We retrieved images that showed good alternatives to common approaches for traditional surgery. 3-D reconstruction was performed using BrainLab iPlan 3.0 software and the traditional craniotomy flap representation overlaid.

Results
We present the neuroimaging findings in a series of mini craniotomies with pre- and postoperative imaging and reconstructions. These include alternatives to the traditional frontal, pterional, temporal, convexity and suboccipital craniotomies. We provide a detailed educational review of mini craniotomies both from this series and in the literature, examining the relative differences with traditional approaches.

Conclusions
As neuroendoscopic techniques improve it is likely that traditional craniotomy flaps will be seen less frequently. It therefore is essential that neuroradiologists be familiar with the rationale, positioning and normal postoperative imaging appearances of newer minimally invasive approaches. In this exhibit we present a series of common mini craniotomies used at our institution for neuroendoscopic surgery in comparison to their traditional counterparts. We also review some of latest innovative types and locations of mini craniotomies that have been adopted for minimally invasive endoscopic neurosurgery.

KEYWORDS: Minimally Invasive Surgery, Postoperative Findings
3-D reconstruction from the post-operative CT of a patient who underwent an endoscopic resection of an occipital meningioma. The standard craniotomy that would have been required is overlaid in red.
Neuroimaging Manifestations of Radiation-Related Injuries to the Brain: Emphasis on Imaging Appearance and Radiobiology

F Cloran¹, D Sampathu², L Loevner³, S Mohan²
¹Wright Patterson AFB Medical Center, Wright Patterson AFB, OH, ²University of Pennsylvania, Philadelphia, PA, ³University of Pennsylvania Medical Center, Philadelphia, PA

Purpose
Radiotherapy and radiosurgery are used as primary and adjuvant modalities in the treatment of central nervous system disorders. There are a variety of unintended complications which can arise from radiation therapy ranging from ischemic to neoplastic. The diagnosis of a radiation-induced condition (i.e., radiation-induced meningioma) can significantly impact patient care as the radiation-induced condition may not respond similarly to standard treatment strategies. This education exhibit illustrates, in a case-based manner, a variety of conditions that may arise following intracranial radiation and highlights the clinical scenarios when these conditions are likely to arise.

Materials and Methods
A spectrum of imaging manifestations of radiation-induced intracranial conditions will be presented in a case-based manner with accompanying clinical vignettes. Some of the entities which will be presented include: 1. White matter radiation changes. 2. Treatment response, radiation necrosis and pseudoprogression. 3. Radiation-related vasculopathy. 4. Radiation-related cavernomas. 5. SMART syndrome (FIGURE 1 shows areas of cortical enhancement involving the medial aspect right frontal lobe and right insular region (arrowheads) in this case of SMART syndrome). 6. Radiation-induced meningiomas, gliomas and sarcomas. 7. Intravascular papillary endothelial hyperplasia/Masson's tumor [Figure 2 shows a hemorrhagic right parietal mass (arrowhead) and vasogenic edema in this case of Masson's tumor]. In addition to the stereotypical imaging findings, emphasis will be placed on the typical radiation doses and latencies associated with these manifestations to facilitate differentiation of the radiation-induced condition from the alternate nonradiation-related counterparts.

Results
There are a variety of MR manifestations of radiation-related conditions. While some are benign and beneficial (treatment-related response), other conditions portend significant morbidity (i.e., radiation-induced optic neuritis and SMART syndrome) and some can potentially be fatal (radiation-induced gliomas). As treatment for these conditions varies from their nonradiation-induced counterparts, knowledge of the expected latency is important to guide clinicians as to whether or not the condition is likely to be radiation-induced. Furthermore, knowledge of the site of treatment, the employed radiotherapeutic modality and delivered radiation dose also affects the likelihood of whether or not a condition is radiation-related.

Conclusions
This interactive review highlights conditions encountered after intracranial radiotherapy/radiosurgery. Knowledge of treatment history, imaging appearance of
complications and temporal relationship of these complications related to their treatment is essential in management of these patients.

Neuroimaging of Degenerative Diseases of the Brain: A Review of Imaging Findings and the Updates in Diagnostic Criteria
Purpose
The diagnosis of neurodegenerative diseases is primarily based on clinical assessment. However, with recent advancements in neuropathology and genetics, neuroimaging has been playing an increasingly important role in the diagnosis of such diseases. Over the past several decades, there has been much improvement in the scientific and clinical understanding of the disease concepts, diagnostic criteria, and neuroimaging techniques of neurodegenerative diseases. The knowledge of these advancements in conjunction with the underlying pathophysiology and genetics of neurodegenerative diseases is essential for appropriate radiological evaluation to assist in the clinical diagnosis.

Materials and Methods
We present a review of (1) the neuropathophysiological and genetic mechanisms involved in degenerative diseases of the brain, such as Alzheimer disease, dementia with Lewy bodies, Parkinson's disease, frontotemporal dementia, Creutzfeldt-Jakob disease, Wilson's disease, progressive supranuclear palsy, corticobasal degeneration, Huntington's disease, and multiple system atrophy, (2) multimodality neuroimaging findings, including structural MRI, and molecular imaging (PET, SPECT), and (3) advanced neuroimaging techniques that may provide increased specificity for diagnosis.

Results
Neurodegenerative diseases encompass a wide spectrum of disorders with the specific neuropathological findings. Specific neuroimaging findings of each disease can be explained in connection to characteristic temporal and topographical distribution of those pathologies. For example, in Alzheimer disease, abnormal accumulation on amyloid-PET is correlated with the distribution of amyloid pathology, and can be seen prior to symptomatic phases of the disease. FDG-PET in Alzheimer disease reflects density of disrupted synaptic activity as a resultant of tauopathy. In Parkinson's disease, dopamine transporter SPECT is a specific biomarker to assess the presence of presynaptic dopaminergic denervation. Structural MRI demonstrates a characteristic pattern of cerebral atrophy which is thought to reflect microscopic neurodegeneration (loss of synapses, dendritic processes, and neurons), while diffusion tensor imaging can visualize disrupted white matter and gray matter integrity.

Conclusions
While conventionally, the role of neuroimaging has been to exclude potential secondary causes of neurodegenerative diseases, recent advances in neuroimaging with improved specificity for detecting these diseases have made neuroimaging play a more central role in diagnosis.

KEYWORDS: Degenerative, Molecular Imaging, MR Imaging

Neuroimaging of Vascular Dementias

A Agarwal¹, S Kanekar²
Purpose
Vascular dementia (VaD) is the second most common cause of dementia, following Alzheimer disease (AD) and remains a diagnostic challenge in clinical settings all over the world. As a clinical syndrome, vascular dementia relates to different vascular mechanisms and changes in the brain and has different causes and clinical manifestations. This type of dementia represents a diagnostic challenge because of its various clinical manifestations and different vascular causes. This challenge is illustrated by the number of clinical diagnostic criteria that have been published and used over the past 30 years. The pathophysiology, diagnostic criteria, genetics and classification of vascular dementias are covered in depth in this exhibit. This exhibit also examines the role of conventional and advanced neuroimaging in VaD.

Materials and Methods
At least eight different clinical diagnostic criteria sets for vascular dementia or multi-ischemic dementia have been used in clinical and research settings including the original Hachinski Ischemic Scale, the criteria proposed by the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV), by the California Alzheimer's Disease Diagnostic and Treatment Centers (CAD–DTC) , and by the National Institute of Neurological Disorders and Stroke-Association Internationale and the Association Internationale pour la Recherche et l'Enseignement en Neurosciences (NINDS–AIREN). Two tools have been used successfully for the diagnosis of VaD with high specificity. They are the criteria developed by the NINDS–AIREN and by the California Alzheimer's Disease Diagnostic and Treatment Centers (CAD–DTC). These criteria, which have been validated by some neuropathological studies and a centralized imaging rater, have provided increased consistency in the diagnosis of VaD.

Neuroimaging is required for confirmation of cerebrovascular disease in VaD and provides information about the topography and severity of the vascular lesions.

Results
The traditional view has been that computed tomography (CT) and magnetic resonance imaging (MRI) are performed to exclude other abnormalities that are potentially amenable to surgical treatment, such as a tumor, hematoma, or hydrocephalus. However, in the recent practice parameter on the diagnosis of dementia, structural neuroimaging in the routine initial evaluation of patients with dementia is recommended as a guideline. Functional imaging provides insight into the operational aspects of the brain, and since it appears that brain pathology in dementia begins long before there is clinical evidence of disease, functional imaging is attractive for the early detection of dementia. Single-photon emission computed tomography (SPECT), positron emission tomography (PET), and functional MRI (fMRI) are becoming increasingly relevant to the study of dementia. To enhance their clinical implementation, operational definitions for the radiological part of the NINDS-AIREN criteria subsequently were defined (Table 1). To be considered as evidence in favor of VaD (probable VaD), the radiological findings should fulfill minimum standards of the NINDS-AIREN criteria for both severity and topography (large vessel and small vessel). Imaging appearance of vascular dementia can be broadly divided into: 1) large-vessel vascular dementia; 2) small-vessel vascular dementia and 3) microhemorrhage and dementia.

Conclusions
Cerebrovascular disease currently is viewed as a distinctly secondary cause of dementia that is of
uncertain importance. Although it is commonly cited as the second leading cause of dementia, a lack of well validated diagnostic criteria, makes accurate epidemiology difficult. Among the tools available to help clinicians diagnose and monitor VaD progression, neuroimaging is especially useful for confirming the diagnosis and identifying specific VaD subtypes.

KEYWORDS: Memory, MR Imaging/Diffusion

Table 1. Operational definitions for the radiological part of the NINDS-AIREN criteria (2003)

(A) Topography

**Large-vessel stroke**

- Large-vessel stroke is an infarction defined as a parenchymal defect in an arterial territory involving the cortical gray matter
  - ACA—Only bilateral ACA infarcts are sufficient to meet the NINDS-AIREN criteria
  - PCA—Infarcts in the PCA territory can be included only when they involve the following regions:
    - Paramedian thalamic infarct
    - Inferior medial temporal lobe lesions
- Association areas—MCA infarcts need to involve the following regions:
  - Parietotemporal lobe (e.g., angular gyrus)
  - Temporo-occipital cortex:
- Watershed carotid territories (between the MCA and PCA or the MCA and ACA)

**Small-vessel disease**

- Multiple basal ganglia and frontal white matter lacunes
- Extensive periventricular white matter lesions (leukoaraiosis)
- Bilateral thalamic lesions

(B) Severity

- Large-vessel disease of the dominant hemisphere
- Bilateral large-vessel hemispheric strokes
- Leukoencephalopathy involving at least 25% of the total white matter.
Fulfillment of radiological criteria for probable VaD

- Large-vessel disease—both the topography and severity criteria should be met (a lesion must be scored in at least 1 subsection of both topography and severity).

- Small-vessel disease—for white matter lesions, both the topography and severity criteria should be met

**Neurovascular Emergencies: The Usual, Unusual and Unbelievable**

J Cruz¹, J Gross¹, J Li¹, R Smith¹, B Devenney-Cakir¹

¹Albert Einstein Medical Center, Philadelphia, PA

**Purpose**

Neurovascular emergencies encompass a broad spectrum of pathology that can lead to significant morbidity and mortality. While many of these pathologies can have classic presentations, an atypical presentation or a complicated clinical course can make the diagnosis more challenging. Imaging plays a pivotal role in the diagnosis and management of neurovascular emergencies, and radiologists must be aware of the imaging findings of disease as well as possible complications. By reviewing a series of neurovascular emergencies from our institution, ranging from the common to the uncommon and frankly bizarre, we hope to enhance the radiologists' awareness of the spectrum of neurovascular pathologies to allow for prompt diagnosis and treatment.

**Materials and Methods**

A retrospective, pictorial review of a wide spectrum of neurovascular emergencies at our institution will be presented. We will categorize the different types of neurovascular emergencies into (1) anatomical/congenital, (2) traumatic (self-inflicted, iatrogenic), (3) neoplastic, and (4) nontraumatic/sequela of chronic disease. This exhibit will be a multimodality review, with emphasis on computed tomography (CT), MR imaging (MRI) and angiography.

**Results**

We will present a spectrum of neurovascular emergencies ranging from common entities, such as stroke and dissection, to rare pathologies including cervical dural AVFs and venous sinus thrombosis, to frankly bizarre cases including a self-inflicted cerebral nail gun injury. We also will present neurovascular complications of surgery including an ICA dissection with subsequent thrombosis and stroke following resection of a large carotid body tumor. Pre- and postoperative cross-sectional and angiographic imaging will be shown. An additional section will be dedicated to posttraumatic neurovascular emergencies including direct penetrating trauma to the neck and spine with resultant vascular injury and epidural hematoma. We also will delineate the anatomical considerations involved in some of these neurovascular emergencies including
hypertrophic olivary degeneration as a consequence of an acute pontine hemorrhage and hemiatrophy of the tongue as a consequence of an acute 12th nerve palsy following acute ICA dissection. Important diagnostic implications for treatment and management also will be described.

Conclusions

Neurovascular emergencies encompass a wide spectrum of pathology, from the usual, to the unusual, and frankly unbelievable. Radiologists are integral in the diagnosis of neurovascular emergencies, and having an awareness of common complications and common pitfalls can have an impact on prompt management and treatment.

KEYWORDS: Dissection, Iatrogenic, Venous Sinus Thrombosis

Not So Clueless: Differentiating Diseases Involving White Matter in Adults beyond Multiple Sclerosis (MS) and Small Vessel Disease (SVD).

T. Greenwood¹, M. Goyal¹, A. Radmanesh¹, T. Benzinger¹
¹Mallinckrodt Institute of Radiology/Washington University, Saint Louis, MO

Purpose

1. Categorize diseases that affect white matter in adults with MR imaging (MRI) using a systematic approach to narrow the differential diagnosis. 2. Show "clues" that suggest when white matter signal abnormalities are not typical for multiple sclerosis (MS) or small vessel ischemia.

Materials and Methods

> Discuss importance of characterizing white matter disease. > Describe imaging features suggesting diagnosis other than MS or small vessel disease (SVD): Pattern, Location, Signal Characteristics, Enhancement, Diffusion, Calcifications, Cysts, Atrophy, Susceptibility, and Clinical presentation. > Provide an algorithm for approaching white matter disease in adults. > Show case-based examples emphasizing differentiating features.

Results

Many of the following imaging features, while not be diagnostic for a signal diagnosis, can raise suspicion for certain entities and narrow the differential diagnosis. Examples of when these "clues" are helpful are listed: > Pattern: GBM, radiation, lymphoma, ADEM. > Location: Behcet, CADASIL. > Signal Intensity: Toxoplasmosis, Wilson's. > Enhancement: metastases, carbon monoxide, IRIS, TB. > Diffusion: Wernicke, Osmotic demyelination, PRES. > Calcifications: Fahr, thyroid disorders. > Cysts: Cryptococcus. > Atrophy: Wernicke, Marchiafava–Bignami syndrome. > Susceptibility: Cerebral Amyloid Disease, DAI. > Clinical: Lupus, HIV encephalitis.

Conclusions

Although it is true that multiple sclerosis and chronic small vessel ischemia dominate as the most prevalent entities affecting white matter in adults, suggesting alternative diagnoses based on imaging characteristics has an important impact on patient work up and care. Radiologists should have a systematic approach to interpreting white matter signal abnormalities and know when to be "clued-in" to alternative diagnoses.
Patterns of Bevacizumab (Avastin) Failure and Complications of Treatment

S Ali¹, Y Li¹, J Clarke¹, S Cha¹

¹University of California San Francisco, San Francisco, CA
Purpose
Bevacizumab (Avastin) is an angiogenesis inhibitor that blocks the action of vascular endothelial growth factor and frequently is used alone or in combination with radiation therapy or chemotherapy, for treatment of recurrent glioblastoma. The imaging features of tumor following bevacizumab therapy have been well described, with the most common findings being marked decrease in enhancement on contrast-enhanced MR images and decrease in vasogenic edema. It also has been suggested that bevacizumab may unmask the presence and extent of infiltrative disease best seen on FLAIR images. In this educational exhibit, we review our experience and demonstrate the major patterns of tumor progression and non-neoplastic complications following bevacizumab therapy.

Materials and Methods
We retrospectively reviewed MR imaging in 42 patients with suspected recurrent glioblastoma from 2006 to 2013 who underwent bevacizumab therapy and then had subsequent tumor recurrence and/or treatment complications. Serial MR imaging characteristics were analyzed while patients were on bevacizumab. Imaging patterns were analyzed for degree of enhancement, edema, infiltration, and presence of reduced diffusion within or remote from tumor.

Results
Four patterns of bevacizumab failure were identified: first, local tumor progression at site of original disease with enlarging area of reduced diffusion and FLAIR abnormality without much enhancement; second, development of diffuse tumor infiltration on FLAIR images in a gliomatosis-like pattern with minimal enhancement; third, decrease in FLAIR abnormality and enhancement at the site of original disease, but development of distant unifocal or multifocal enhancing tumor, either with or without subependymal spread; and fourth, continued progression of local or multifocal disease with increase in FLAIR and enhancement despite Avastin treatment. We also reviewed cases of diffusion abnormality in patients treated with Avastin, some of which represent ischemic injury, hypoxic or hypercellular tumor, or blood products.

Conclusions
In this educational exhibit we demonstrate imaging characteristics of recurrent glioblastoma following bevacizumab therapy with special emphasis on four imaging patterns suggestive of therapeutic failure. We also present bevacizumab-related complications with focal acute infarcts being the most common. Recognition of various imaging changes following bevacizumab therapy will be essential for assessment of therapy response and tumor progression in patients with recurrent glioblastoma.

Pearls and Pitfalls of Imaging in Neurodegenerative Disorders: What the Radiologist and Clinician need to know?

M Gul1, A Chaudhry2, D Franceschi3, R Peyster4, R Matthews4
1Winthrop University Hospital, Mineola, NY, 2Stony Brook University Medical Center, Westbury, NY, 3SUNY Stony Brook, Stony Brook, NY, 4Stony Brook University Medical Center, Stony Brook, NY
Purpose
1. Review the anatomy, pathophysiology, and imaging findings including PET-MRI, SPECT imaging (DATscan), PET-CT, CT, and MRI of various neurodegenerative disorders including Parkinson's disease, supranuclear palsy, Alzheimer's dementia. 2. Review pearls and pitfalls of various imaging techniques including PET-MR imaging, SPECT Imaging, PET imaging and susceptibility-weighted imaging (SWI).

Materials and Methods
1. Review study technique and clinical indications of various imaging modalities available to evaluate neurodegenerative disorders including PET-MRI, nigrostriatum I-123 Ioflupane imaging, SWI, etc. and approach to study interpretation. 2. Review characteristic imaging findings of various neurodegenerative disorders in the aforementioned modalities and their respective differential diagnoses. 3. Review radiological pitfalls and emphasize key points which can help in avoiding these pitfalls. 4. Review clinical and radiological pearls that can help narrow the differential diagnosis.

Results
1. Detailed physiologic and pharmacologic discussion of various PET and SPECT agents including I-123 ioflupane, 11C-PIB PET, etc. 2. Case-based discussion of clinical features, pathophysiology, histology features, imaging findings (SPECT, CT and/or MRI) highlighting radiological pearls, treatments and prognosis of various neurodegenerative disorders including Parkinson's disease, multisystem atrophy, progressive supranuclear palsy, vascular dementia, Alzheimer's dementia, Lewy body dementia, corticobasilar degeneration, etc. 3. Case-based discussion of various pitfalls of these imaging modalities will be discussed along with reviewing clinical and radiology findings that can help in arriving at the correct diagnosis.

Conclusions
Neuroimaging is key in diagnosis of various neurodegenerative disorders. Functional imaging obtained via PET-MRI, PET-CT, SPECT imaging, etc. play key role in conjunction with routine structural neuroimaging (CT and MRI) in accurately diagnosing patients and guiding proper patient management. Although the differential diagnosis is broad, it can be narrowed utilizing age, clinical findings and imaging characteristics on functional imaging. By the conclusion of this presentation, the viewer should have a better understanding of various movement disorders and know the appropriate imaging modalities that are most cost- and time-effective in diagnosing the patient.

Phase-Contrast Cerebrospinal Fluid (CSF) Flow Imaging: Basic Technique and Clinical Applications

A Agarwal¹, S Kanekar², K Thamburaj³
¹Penn State University, Hummelstown, PA, ²Penn State Milton S Hershey Medical Center, Hershey, PA, ³Penn State University, Hershey, PA

Purpose
During the last two decades, flow-sensitive MR imaging (MRI) techniques have been applied increasingly to quantitatively and qualitatively assess cerebrospinal fluid (CSF) flow dynamics. In this pictorial review, we emphasise phase-contrast (PC) MRI technique, CSF physiology and cerebrospinal space anatomy, congenital and acquired disorders that can alter the cerebrospinal fluid dynamics, and the use of PC MRI in the assessment of various central nervous system (CNS) abnormalities.

Materials and Methods
The PC MRI generates signal contrast between flowing and stationary nuclei by sensitizing the phase of the transverse magnetization to the velocity of motion. Two data sets are acquired with opposite sensitization, yielding opposite phase for moving nuclei and identical phases for...
stationary nuclei. Magnitude and phase images can be generated for anatomy and velocity information, respectively. The result is that the grayscale intensity of each pixel is related directly to the velocity of CSF. Caudal flow of CSF is conventionally represented as shades of white on phase images, whereas cranial flow is by shades of black. Since it reflects the phase shifts, PC velocity image is far more sensitive to CSF flow than is the magnitude image. Two series of PC imaging techniques are applied in the evaluation of CSF flow, one in the axial plane, with through-plane velocity encoding in the craniocaudal direction for flow quantification, and one in the sagittal plane, with in-plane velocity encoding in the craniocaudal direction for qualitative assessment.

Results
Cerebrospinal fluid flow MRI can be used to discriminate between communicating hydrocephalus and noncommunicating hydrocephalus, to localize the level of obstruction in obstructive hydrocephalus, to determine whether arachnoid cysts communicate with the subarachnoid space, to differentiate between arachnoid cysts and subarachnoid space, to discriminate between syringomyelia and cystic myelomalacia, and to evaluate flow patterns of posterior fossa cystic malformations. This imaging method also can provide significant information in pre-operative evaluation of Chiari 1 malformation and normal pressure hydrocephalus and postoperative follow up of patients with endoscopic third ventriculostomy (ETV) (Figure 1) and ventriculoperitoneal (VP) shunt.

Conclusions
Phase contrast cine MR is a useful imaging technique in evaluating CSF dynamics that affects various disease processes. In evaluation, follow up, surgical decision and postoperative survey of these disease processes, PC cine MR can provide valuable additional information to conventional MRI. Cerebrospinal fluid pulsatility and stroke volume through the aqueduct has been correlated with a positive response to shunting in patients with normal pressure hydrocephalus. Cerebrospinal fluid flow studies can be used to differentiate posterior fossa cystic malformations from each other. It also has a role in assessing the functioning of surgical interventions. Finally, pulsatile CSF flow within a cystic cord lesion may help to discriminate a syrinx from myelomalacia.

KEYWORDS: Cerebrospinal Fluid, Flow, Phase Contrast Imaging
Purpose
To provide a neuroimaging review of pineal region tumors and correlation with neuropathological findings to assist the radiologist in developing an appropriate differential diagnosis.

Materials and Methods
A retrospective review of the pineal region tumor cases discussed during the previous 10 years of brain tumor board at our institution. Analysis of neuroimaging findings is correlated with the neuropathological findings from a variety of pineal region tumors.

Results
Pineal region tumors, including primary tumors and metastases, constitute 1% of all central nervous system (CNS) tumors. Primary pineal region tumors generally fall into two categories: Germ cell origin and Pineal cell origin. Neuroimaging (mostly brain MRI) for each category of pineal region tumor will be present along with pathologic correlation. The cases will include:
germinoma, pineocytoma, pineoblastoma, yolk sac tumor, astrocytoma, teratoma, papillary tumor, lymphoma and metastases. All of the cases have neuropathologic correlation.

Conclusions
This pictorial review of the neuroimaging for a variety of pineal region tumors should help familiarize the radiologist with the differential diagnosis for pineal region neoplasms and their respective imaging characteristics.

KEYWORDS: Pineal Cell Tumor, Pineal Gland

A) Sagittal T1W without Gadolinium and B) Axial T1W with Gadolinium. These images demonstrate a tumor of the pineal region which is isointense on the precontrast T1 weighted image and demonstrates ring contrast enhancement. This is an unusual appearance as this tumor is typically characterized by increased T1 signal intensity according to the literature.

Predicting the Spread of Glial Tumors: Insights from “Gliography” of the Cingulate
Purpose
After studying >1000 cases of cerebral hemispheric diffuse gliomas (grade II-IV), our group observed that based on the locations of brain tumors there is asymmetric growth shaped by the underlying anatomy. We call this process "gliography" where numerous cases are put together to identify the interlocking three-dimensional shapes which form the basis of glial tumor spread. This technique is used for cingulate gliomas to better understand the anatomy and connections to other areas.

Materials and Methods
Preoperative Mr images (MRIs) from 65 cingulate gliomas were assessed by neuradiologist consensus for shape and position of bulk tumor. Additional cases involving the callosum and "supra-cingulate" neocortical areas were studied to show the gliographic borders from the other side. Cingulate was divided into 4 parts (Figure 1): Anterior (Brodman area [BA] 24,32, and 33) Subgenual (BA 25), Posterior (BA 23 and 31), and Retrosplenial (BA 28-30).

Results
Traditionally the cingulate forms a "C" shape in the sagittal plane around the callosum. However, cingulate tumors often form a "C" shape in a coronal (radial) plane, extending superficial to the cingulate sulcus while being contained laterally by the "C" shaped medial callosal fibers. When callosal invasion does occur, it is at the lateral ventricular margin where subcallosal fibers and vessels perforate the callosum. Tumor growth can lead to herniation (with a pushing border) rather than invasion through callosum, especially at the callosal isthmus. Spread to the supra-cingulate, superficial "neocortex" occurs via callosal more than cingulate connections. Supplementary motor and primary visual cortex do not connect to the cingulate directly. In the sagittal plane, the rostral and caudal ends of the cingulate are not bound by callosal fibers, allowing subgenual and retrosplenial cingulate tumors to wrap around the callosum or spread laterally. Within the cingulate itself, tumors rarely spread under the plane of the paracentral gyrus to cross between anterior and posterior cingulate (BA 23 and 24).

Conclusions
These observations have important implications for neurosurgical and radiation therapy planning by knowing the most likely and unlikely sites for invasion. For instance, it is important to carefully inspect the callosum at the lateral ventricular margin as this is the likely location of callosal invasion and the most common way to spread to the medial neocortex. Similarly extension to the caudal aspects of the cingulate can predispose for more lateral cerebral extension or subependymal/CSF spread (Figure 2). By understanding these patterns, neurosurgical approach and radiation plans can be altered to minimize morbidity while improving mortality. Several specific examples will be given. Knowing the shape and location of cingulate tumors reveals the pertinent underlying anatomy, with important implications for therapeutic planning.

KEYWORDS: Functional Brain Mapping, Glioma, Limbic System
Primary CNS lymphoma: What the radiologist needs to know.

A Zambrano¹, A Jay¹
¹Georgetown University Hospital, Washington, DC

Purpose
Primary central nervous system (CNS) lymphoma is the fourth most common primary CNS neoplasm and as such, its imaging findings are important for radiologists to know. Primary CNS lymphomas have wide ranging imaging features but also have characteristic imaging findings that help narrow the differential diagnosis and distinguish them from other masses. As the treatment for CNS lymphoma is nonsurgical, it is imperative that the neurosurgeon is aware that lymphoma is suspected so that the appropriate pre-operative counseling and planning can be performed. We aim to review both the common and atypical imaging features of primary CNS lymphoma.

Materials and Methods
The medical records, cross-sectional images and pathology reports were reviewed in patients with primary CNS lymphoma that were imaged at our institution over the past five years. The clinical presentation, and CT and MR imaging manifestations were reviewed retrospectively.

Results
Primary central nervous system lymphoma (PCNSL) is the fourth most common primary CNS neoplasm (following glioblastoma multiforme, meningioma and low grade CNS astrocytoma).
PCNSL is most frequently a diffuse large B cell lymphoma, composed of blue cells with a high nucleus to cytoplasm ratio packed tightly together in the perivascular (Virchow-Robin) spaces. This histology directly correlates with the classic imaging appearance of hyperdensity on noncontrast CT, hypointensity on T2-weighted images, and restricted diffusion on DWI. They also characteristically have solid enhancement and little mass effect for size of the lesions. There is a predilection for the periventricular region and if subependymal spread is present, lymphoma should be strongly suspected. In immunocompromised patients, the imaging appearance changes to reflect the increased incidence of necrosis, often appearing as ring-enhancing lesions. Multifocality is also more common in this patient population. Despite the typical imaging characteristics of primary CNS lymphoma, however, the radiologist also should be aware that hemorrhage, multifocality, and central necrosis can occur in immunocompetent patients.

Conclusions
Primary CNS lymphoma is not an uncommon primary brain neoplasm. It is important for the radiologist to be well versed in its typical and atypical imaging features so that the diagnosis can be suspected at presentation. We present a comprehensive review of the imaging features of primary CNS lymphoma that the radiologist needs to know.

KEYWORDS: Brain, Lymphoma, Primary CNS Neoplasms

Principles, Techniques and Clinical Applications of Phase Contrast MRI Cerebrospinal Fluid Imaging

T Alves¹, J Bapuraj¹, D Malyarenko¹, B Martin², A Srinivasan¹
¹University of Michigan Health System, Ann Arbor, MI, ²Director, Conquer Chiari Research Center, Akron, OH

Purpose
1. To understand the principles of cerebrospinal fluid (CSF) flow dynamics. 2. To learn the technical aspects, challenges and limitations of CSF flow studies. 3. To discuss alterations in CSF hydrodynamics in disease and explore clinical applications of CSF flow dynamics with illustrated examples.

Materials and Methods
Methods/Content organization: Normal CSF flow dynamics. • Intracranial, • Spine, • Bulk flow versus pulsatile flow. Principles of phase contrast MR imaging. Technical parameters and challenges of PC MRI. Clinical applications: • Normal pressure hydrocephalus, • Chiari I malformation, • Syringomyelia, • Endoscopic third ventriculostomy. CSF flow results from the complex distribution of hydrostatic and dynamic pressure acting within the ventricles and intracranial venous and arterial system. The resulting CSF flow can be quantified in terms of: 1) "bulk" CSF flow that is driven by hydrostatic pressure acting between the ventricles and arachnoid granulations and 2) "pulsatile" CSF flow that is primarily driven by cerebral blood pulsations due to the cardiac cycle and also influenced by unsteady intrathoracic pressures due to respiration that act on the epidural venous plexus. 2D Phase Contrast MR imaging (PC MRI) is a robust technique in measuring CSF flow and is dependent on the detection of moving spins by alteration of transverse magnetization to the velocity of motion. Single slice 2-D sequences in the
axial and sagittal planes are a standard for evaluation of CSF, especially at the aqueduct and the foramen magnum. CSF flow measurements typically are carried out for 14-16 phases of the Cardiac cycle timed retrospectively to coincide with the RR interval. Velocity is encoded in one direction (1D) within the measurement plane (2D), with a typical velocity encoding value of 10 and 20 cm/s for CSF flow at the foramen magnum and aqueduct of Sylvius, respectively. Research has shown that CSF flow within a region of interest, such as at the foramen magnum, can be heterogeneous with relatively small concentrated regions of elevated CSF velocities termed “jets”. Recent advances in MRI imaging technology have enabled quantification of the CSF flow field in 3D with respect to time over a volume of interest in what is called “Time-resolved 4D phase contrast MR imaging”.

Results
Clinical application of PC MRI in CSF alterations in disease will be discussed in the exhibit. • Chiari 1 malformation: Research has been conducted to investigate abnormal CSF flow patterns associated with tonsillar descent in addition to typically used morphometric parameters, such as the degree of tonsillar descent, associated with this malformation. Measurement and analysis of CSF velocities and flow at the foramen magnum and aqueduct is an ongoing theme for research. The outcome of decompression surgery and the techniques of decompression surgery also are being correlated with pre-operative CSF flow measurements. • Syringomyelia: Formation and extension of spinal cord cavities, or syrinx, is a fascinating aspect of CSF hydrodynamics in the spinal canal. Demonstration of pulsatile flow within a syrinx helps in defining a cyst from myelomalacia. 4D PC MRI in the spinal subarachnoid space is the basis of new research to understand CSF flow in the vicinity of syringes. • Endoscopic Third Ventrilostomy. Determination of patent alternate CSF pathways following endoscopic third ventriculostomy for the treatment of acquired and congenital third ventricular obstruction is best done by observation of pulsatile CSF flow at the site of the ventriculostomy, created in the floor of the third ventricle. • Normal Pressure Hydrocephalus: The evaluation of the pattern of CSF flow curves in this condition is a challenge. Increased pulsatility at the aqueduct is thought to indicate better response to shunting in these patients.

Conclusions
Phase-contrast MR imaging of CSF flow is a versatile, noninvasive technique to assess the pathophysiology of CSF hydrodynamics in the brain and spinal cord. Understanding the physical principles behind the technique helps in the tailored assessment of disorders of CSF flow and the results of the procedures used to treat them.

Recent advances of MR imaging in relation to phylogenetic anatomy of the cerebellum in spinocerebellar ataxia

K Sato1, K Kamagata1, H Terada2, S Aoki1
1Juntendo University School of Medicine, Bunkyo-ku, Tokyo, 2Toho University Sakura Medical Center, Saku ra, Chiba, Tokyo
Purpose
This presentation will review clinical presentations and imaging findings from conventional MR imaging (MRI) to advanced diffusion and volumetric imaging in relation to phylogenetic anatomy of the cerebellum among different types of spinocerebellar ataxia (SCA).

Materials and Methods
Spinocerebellar ataxia previously called hereditary spinocerebellar degeneration (SCD), is a progressive autosomal inherited disease that results in ataxia due to degeneration of the cerebellum, the brainstem, and the spine. Differential diagnosis is sporadic SCD such as multiple system atrophy, newly recognized as synucleinopathy, and cortical cerebellar atrophy. The main affected region is different depending on diseases or types of SCA. We will present imaging findings and symptoms of SCA in relation to phylogenetic anatomy which would help differential diagnosis of them.

Results
Spinocerebellar ataxia is an autosomal inherited disease associated with CAG repeat expansion. Thirty-six different types of SCA have been found. This study will describe the most common types including SCA1, 2, 3, 6, 8, and 31. The cerebellum has three regions derived from different phylogenetic origins (Fig. 1). They have connections with other regions of the brain and believed to have association with symptoms. The archicerebellum is the oldest region connected to the vestibular nuclei. The paleocerebellum have connections to the spine. The neocerebellum is the newest region and has cortico-ponto-cerebellar connections. MR imaging (MRI) is an excellent noninvasive tool to study SCA phylogenetic anatomy and to better understand the infratentorial neural networks involvement. We will discuss: (1) Pathogeneses of SCA; CAG repeat (polyglutamine expantion), RNA repeat, and conventional mutation (2) Conventional MRI and volumetric MRI findings among different types of SCA. (3) Advanced diffusion imaging including tractography and diffusion analysis.

Conclusions
This review would improve understanding of MR imaging in relation to phylogenetic anatomy of the cerebellum in SCA, a progressive neurodegenerative disease that is found to have increased number of diagnosis in recent years.

KEYWORDS: Cerebellum, Diffusion Tensor Image, Spinocerebellar Ataxia Type
Fig. 1 Phylogenetic anatomy of the cerebellum. The cerebellum has three regions derived from different origins, the archicerebellum, the paleocerebellum, and the neocerebellum.

Simple Breath-holding Task for Cerebrovascular Reactivity Scans in Clinical fMRI

J Peacock¹, D Black², D DeLone², K Welker²
¹Mayo Clinic College of Medicine, Rochester, MN, ²Mayo Clinic, Rochester, MN

Purpose
Functional MR imaging (fMRI) is a powerful tool for presurgical mapping of cerebral language and motor activity. The technique is based on local augmentation of cerebrovascular perfusion in response to increased neuronal metabolism, creating a rise in blood oxygenation level dependent (BOLD) T2* signal. However, the link between neuronal activity and BOLD signal can be
severed by cerebral pathology that causes neurovascular uncoupling (NVU) or by local magnetic susceptibility artifact. To correctly interpret clinical fMRI studies, it is important to know if all brain regions are capable of vasoreactivity and free of signal-altering magnetic susceptibility. Simple breath-hold scans provide an excellent means to assess one's ability to detect BOLD signal throughout the brain. During breath holding, carbon dioxide buildup in the blood leads to a global increase in cerebral vasodilatation. Consequently, brain cortical regions that do not demonstrate elevated BOLD signal during a breath-hold task are concerning for sites of potential NVU or altered magnetic susceptibility. We have developed and report on a simple breath-holding fMRI task that allows for consistent mapping of cerebrovascular reactivity during clinical fMRI studies.

Materials and Methods
The visually presented block design task interleaves a series of six 21 second normal breathing periods, with five 21 second periods of breath holding. Patients are instructed to transition between the breathing and breath-holding blocks without taking abnormally deep inspirations. A respiratory belt monitors inspiratory movements to ensure patient compliance. Functional MRI is performed using an EPI/GRE technique with a TR/TE of 3000/25, flip angle 90, 20 cm x 20 cm FOV, 5 mm slice, and 64 x 64 matrix. For analysis, the first 21 sec period of normal breathing is discarded. The data can be processed with any number of statistical methods including simple t-test or correlation analysis. However, during statistical processing the lengthy hemodynamic lag between the onset of breath holding and the onset of cerebral vasodilatation must be accounted for in the statistical model design. BOLD signal peaks about 30 seconds after initiation of a 21 second breath hold, compared with a delay of about 6 seconds for a nonrespiratory stimulus.

Results
Normal patients demonstrate a global, uniform distribution of BOLD signal throughout the cortex with the exception of signal drop out near the skull base consequent to magnetic susceptibility from the petrous bones and sinuses. Some tumors and arteriovenous malformations may be associated with regions of absent or negative BOLD signal, indicating potential NVU (Figure 1). Similarly, cerebrovascular diseases can cause regions of absent or altered cerebral vasoreactivity. These cerebrovascular reactivity maps then can be used to assess for sites of potential false-negative BOLD activation during routine fMRI tasks.

Conclusions
Breath-hold tasks are a useful adjunct to any fMRI study given that they provide insight into the cerebrovascular substrate that influences the interpretation of routine fMRI tasks. The method described previously provides a simple means of introducing this technique into a clinical fMRI practice.

KEYWORDS: BOLD FMRI, FMRI, Postprocessing
Spectrum of Imaging Manifestations of Melanoma in the Central Nervous System
Purpose
Melanoma accounts for less than 5% of skin cancer cases, but the vast majority of skin cancer deaths. It is the only cancer among top seven whose incidence is increasing by 1.9% annually. The USA holds the third highest national rate for melanoma only after Australia and New Zealand. Because of aggressive nature it has widespread metastatic potential with central nervous system (CNS) being the fourth most common metastatic site after lymph node, lung and liver. It also accounts for the third most common metastasis to brain in U.S. after lung and breast. Despite its distinctive imaging features, the presentation of melanoma within the central nervous system is variegated and seemingly boundless. This exhibit will review the spectrum of imaging findings of both common and uncommon presentations of melanoma in the central nervous system, primary and metastatic.

Materials and Methods
Various presentations of central nervous system melanoma will be reviewed in a multimodality case-based format (CT, MRI and PET) with emphasis on advance imaging techniques. Cases will be grouped and presented according to anatomical location.

Results
Cases will include the following neuroimaging presentations of melanoma: Head: 1. Parenchymal. 2. Leptomeningeal/pachymeningeal. 3. Extracranial. Face and Neck: 1. Nodal. 2. Orbits. 3. Perineural spread. 4. Paranasal sinuses. 5. Spine: 1. Vertebral body metastasis. 2. Intramedullary. 3. Extramedullary intradural. Three different recognized MRI intensity patterns will be shown: 1. Melanotic. 2. Amelanotic. 3. Hemorrhagic. Histopathological and imaging correlation will be done for different types. A brief discussion will be made on mimics.

Conclusions
After reviewing this exhibit, radiologists will: 1. Identify the imaging findings of melanoma in the central nervous system on CT scans and MR images and provide a valid differential diagnosis using a pattern-based approach. 2. Recognize the appearance and locations of lesions in the spectrum of presentations of melanoma. 3. Integrate these concepts into practice through review of multiple representative cases. 4. Able to utilize the advanced imaging techniques in clinical practice.

KEYWORDS: Leptomeningeal Disease, Melanoma, Metastases
SUSCEPTIBILITY WEIGHTED IMAGING OF CEREBRAL SINUS THROMBOSIS

K Thamburai¹, A Agarwal², P Kalapos³, D Nguyen³
¹Penn State University, Hershey, PA, ²Milton S Hershey Medical Center, Hershey, PA, ³Penn State Milton S Hershey Medical Center, Hershey, PA

Purpose
Imaging plays a dominant role in the diagnosis of cerebral sinus thrombosis. Yet, it is one of the well known conditions often overlooked on imaging. Generally, a combination of MR sequences is utilized to diagnose cerebral sinus thrombosis. Susceptibility-weighted imaging (SWI) is a 3D high resolution gradient sequence with higher sensitivity to detect clot in vessels and hemorrhage in the brain and cerebrospinal fluid (CSF) spaces. Familiarity with the imaging features of cerebral sinus thrombosis on SWI sequence can help improve the diagnosis of this condition.

Materials and Methods
Imaging anatomy of the venous system and variants will be used to understand the imaging features of cerebral sinus thrombosis. A basic physics of susceptibility-weighted imaging will be highlighted to enhance the understanding of the appearance of normal brain and venous signals. The pathophysiology of cerebral sinus thrombosis will be discussed. Relevant clinical cases will be used to emphasize the imaging features of cerebral sinus thrombosis in various locations and the associated secondary changes including venous collaterals and hemorrhagic changes in the brain and sulci.

Results
Cerebral sinus thrombosis in acute stage contains deoxyhemoglobin and can be identified with higher sensitivity on susceptibility-weighted imaging in the cerebral sinuses. The cortical veins with clot will show blooming effect and tend to appear larger in caliber than normal cerebral veins. Further, the collateral venous channels can be recognized on SWI. Underlying parenchymal changes particularly the hemorrhagic venous infarct can be identified with higher sensitivity and attention to the distribution of these parenchymal changes can aid the diagnosis and management of cerebral sinus thrombosis. Also, secondary changes in the CSF spaces such as subarachnoid hemorrhage can be identified with higher sensitivity with susceptibility-weighted imaging.

Conclusions
A review of the exhibit will help one to understand the physics of susceptibility-weighted imaging and its utility in the diagnosis and management of cerebral sinus thrombosis.

KEYWORDS: Susceptibility-Weighted Imaging, Venous Sinus Thrombosis

Thalamo-amygdala and subthalamo-amygdala connections of the human brain using high resolution diffusion tensor tractography on 3T.
A Kamali\textsuperscript{1}, P Adapa\textsuperscript{2}, E Motuzko\textsuperscript{1}, S Jasti\textsuperscript{1}
\textsuperscript{1}University of Medicine and Dentistry of New Jersey Cooper University Hospital, Camden, NJ, \textsuperscript{2}University of Nebraska Medical Center, Omaha, NE

Purpose

Hippocampal-hypothalamic pathway is part of stria terminalis and limbic system of the human brain which play an important role in emotion, behavior and long-term memory. Lack of adequate neuroimaging sensitivity and spatial resolution, so far, impeded depiction of small limbic structures such as hippocampal-hypothalamic and fornix trajectories within the human brain. The purpose of the current study is to demonstrate the feasibility of parcellation and quantification of different limbic structures (fornix, cingulum, stria terminalis) in relation to the gray matter nuclei (amygdala, hippocampus, and hypothalamus) using fiber tractography by deterministic approach and high spatial resolution diffusion tensor imaging (DTI) data on 3 T.

Materials and Methods

Subjects: Five healthy men (age range 24-37 years) were studied and written informed consent was obtained from all subjects. Conventional and DT-MRI Acquisition: Data were acquired using a Philips 3.0 T Intera system using a SENSE receive head coil. Diffusion-weighted image (DWI) data were acquired axially using single-shot multi-slice 2-D spin-echo diffusion with the balanced Icosa21 tensor encoding scheme. The $b$-factor = 500 sec mm$^{-2}$, TR/TE = 14460/60 msec, FOV = 256 mm x 256 mm and slice thickness / gap / #slices = 1 mm/0 mm/120. The EPI phase encoding used a SENSE k-space undersampling factor of two, with an effective k-space matrix of 112x112 and an image matrix after zero-filling of 256x256. Fiber Tracking: We used the FACT algorithm (DTIStudio) to reconstruct limbic structure fiber tracts with a fractional anisotropy (FA) threshold of 0.22 and angle threshold of 60 degrees.

Results

To our knowledge, the current study is the first to present the whole limbic structures using high spatial resolution DTI measurements on 3 T. The fornix and hippocampal-hypothalamic tracts are clearly distinguishable in relation to the amygdala, hypothalamus, and hippocampus nuclei. Using high spatial resolution specially reduced slice thickness (1mm) in this study reduced the partial volume effect as well as incoherence due to the fiber intercrossings within each voxel and we were able to reconstruct and show even the small limbic trajectories such as hippocampal-hypothalamic and the whole fornix structures using deterministic approach. In our experiment the high resolution DTI method increased the detectable anisotropy within the gray matter structures and helped to trace the thin white matter fibers passing through the hippocampus and hypothalamus nuclei.

Conclusions

In this report we demonstrate for the first time, in vivo 3D reconstruction of the major limbic circuits using high resolution diffusion tensor tractography on 3 T.

KEYWORDS: Brain Mapping, Diffusion Tensor Image
The application of 18 F FDG PET in the diagnosis of Alzheimer disease: A practical guide for the neuroradiologist.

L Lavelle¹, D McWeeney¹, S McEvoy¹, R Killeen¹
¹St. Vincent's University Hospital, Dublin, Ireland

Purpose
The purpose of this poster is to illustrate the imaging appearances of Alzheimer disease (AD) and other common dementias on FDG PET so that they may be recognized and differentiated from one another by a neuroradiologist in practice.

Materials and Methods
The current literature in AD will be reviewed with regard to the accuracy of clinical diagnosis and the utility of FDG PET in identifying patients with AD. Examples from our own practice will be used to illustrate the different patterns that are seen on FDG PET in AD and the other common dementias including dementia with Lewy bodies, frontotemporal dementia and corticobasilar degeneration with MR correlation where applicable.
Results
Alzheimer disease (AD) is the fourth leading cause of death in persons over 65 years of age and is characterized by a progressive decline in memory. Apraxia, agnosia and aphasia are also features. Clinical diagnosis of AD often is made using scoring systems such as the National Institute of Neurologic and Communicative Disorders and Stroke-Alzheimer Disease and Related Disorders Association criteria. In patients with 'probable' AD based on clinical scoring systems the sensitivity has been reported to be 80% but with a specificity of 70%. In those labelled 'possible' AD the sensitivity was 93% but the specificity was 48%. Thus, the clinical diagnosis of AD is an imperfect tool. Functional imaging of the brain shows great promise with marked reduction in brain glucose utilization in specific regions of the brain noted in patients with AD using FDG PET. A recent metaanalysis has reported the overall accuracy of FDG PET in differentiating AD from healthy subjects at 93% with sensitivity 96% and specificity of 90% (Figure 1). Figure 1 Axial (A) and sagittal (B) FDG PET from a 57-year-old male with progressive cognitive decline shows reduced FDG uptake within the parietal lobes bilaterally (A) and throughout the temporal lobes (B, right side shown) with sparing of the frontal and occipital lobes. This pattern is typical of AD.

Conclusions
FDG PET is a useful imaging tool for the identification of AD in patients with cognitive decline and for the differentiation of AD from other neurodegenerative disorders.

The Faces of CNS Lymphoma

M Broadbent¹, P Mehta², N Supakul², I Wu²

¹Indiana University School of Medicine, Avon, IN, ²Indiana University School of Medicine, Indianapolis, IN

Purpose
Central nervous system lymphoma (CNSL) presents a diagnostic challenge to both radiologist and clinicians, as its imaging appearance and symptoms often are nonspecific. On imaging, it is often difficult to distinguish CNSL from a variety of infectious, demyelinating, and other neoplastic entities. Also, its variable appearance is further complicated by such factors as the patient's recent treatment (e.g., steroid) and immunocompetence. This can leave the radiologist unsure of when to appropriately include CNSL in the differential diagnosis, and can potentially lead to delays in work up, diagnosis, and treatment. This electronic educational exhibit provides an overview of the typical and various atypical presentations of CNSL. Additionally, it includes an interactive quiz that emphasizes key imaging findings which can aid in distinguishing CNSL from its common mimics. The goal is to improve the viewer's understanding of the highly variable appearance of CNSL, and to assist them in including this entity in a concise differential diagnosis when appropriate.

Materials and Methods
Images from biopsy proven cases of CNSL are identified by retrospective case review of a large tertiary referral center and its network hospitals. Of these, cases are selected that represent the breadth of appearance of CNSL in both immunocompromised and immunocompetent patients. From these cases, a PowerPoint presentation is generated that provides a pictorial review of both the typical and atypical appearances of CNSL, in addition to other CNS lymphoproliferative disorders such as posttransplant lymphoproliferative disorder. Additionally, comparison cases of disease entities that closely resemble CNSL are included for the interactive quiz.

Results
After viewing this presentation, the viewer will have greater familiarity with the various presentations of CNSL, and of the imaging features that can aid in distinguishing it from common mimics. The viewer will also have greater ability to appropriately include or disclude CNSL in the differential diagnosis when imaging findings are nonspecific.

Conclusions
Central nervous system lymphoma is diagnostically challenging. By reviewing this exhibit, the viewers will become more familiar with its "classic" and other potential appearances. The goal is to assist the viewers in including CNSL in a concise differential diagnosis when appropriate.

The Human Connectome Project and the Promise of High B-value Imaging

M Borja¹, D Boulter¹, A Nummenmaa², S Stufflebeam², T Witzel², S Huang¹, L Wald², O Rapalino¹

¹ 6:30AM - 9:00PM
Purpose
The purpose of this education exhibit is: - To increase radiologists' understanding of the Human Connectome Project (HCP) and associated technical advances. - To describe current research applications of high b-value imaging techniques. - To explore the role of high b-value imaging with the HCP. - To review potential future clinical and research applications of high b-value diffusion imaging.

Materials and Methods
The objectives of the HCP, as well as the current progress and associated technological advances will be reviewed. High b-value diffusion imaging and its role in the HCP will be described. Representative images obtained with high b-values will be shown to illustrate the advantages of this technique. The current clinical and research applications, future prospects, and limitations of high b-value imaging will be discussed.

Results
The HCP intends to map the complete structural and functional neural connections of the human brain in vivo. With data from 1200 healthy individuals, comprehensive structural connection data sets will be created to enhance the understanding of neuronal connections and the relationship between structural and functional connectivity. In the future, this information will serve as a model to study the evolution and disease of connectomes. With the primary goal of optimizing the available technology to enhance the HCP, great advances in imaging and research technology have been attained. One of the most significant advances is that of high b-value diffusion imaging (>1900 s/mm2). The higher the b-value, the stronger the diffusion weighting and the greater the tissue contrast will be. This increased sensitivity also permits exceptional neuroanatomical resolution of white matter tracts, which is crucial for mapping structural connectivity. Although primarily envisioned for the HCP, high b-value diffusion imaging also could be applied to traumatic brain injury, vascular disorders, epilepsy and inflammatory brain disorders, among others.

Conclusions
The HCP is a collaborative study which aims to map the structural and functional connectivity of the human brain, and will serve as the structural basis for the study of brain function in health and disease. Numerous technological advances have arisen from the project. High b-value diffusion imaging allows depiction of neuroanatomical structures with exceptional resolution, which is critical for the HCP. The applications of high b-value imaging, however, go far beyond the HCP and appear promising in other fields such as trauma, epilepsy and vascular disease.

Title: The diagnostic challenge of diffuse axonal and cerebral fat embolic injuries: overlapping imaging findings and features.

M. Wetzel¹, G. Lorenzo¹, B. Hart¹
¹University of New Mexico, Albuquerque, NM

Purpose
Diffuse axonal injury (DAI) and cerebral fat emboli (CFE) syndrome often demonstrate overlapping imaging findings by MR imaging (MRI) including restricted diffusion and/or foci of susceptibility signal. The purpose of this exhibit is to compare and contrast the varying imaging features of DAI and CFE and highlight the differentiating features.
Materials and Methods
We retrospectively reviewed all MRI studies at our institution for the last two years where DAI and/or CFE were diagnosed.

Results
Diffuse axonal injury and CFE can have overlapping imaging findings including restricted diffusion and foci of susceptibility signal. While restricted diffusion in the setting of DAI characteristically involves the gray/white matter junction and that of CFE tends to involve the white matter either in a confluent or "starfield" pattern, we note that involvement of the corpus callosum can make this differentiation difficult, given that shear injury along the falx and early cytotoxic edema in CFE both present in this location. Foci of susceptibility signal can help differentiate these entities if there is a clear pattern of gray/white matter or white matter involvement thereby indicating DAI or CFE respectively. However, the differentiation can be particularly difficult when susceptibility signal is not present in a patient presenting with long bone fracture and other traumatic brain injuries. In addition, these two entities are not mutually exclusive and can be found in the same patient. We found the clinical presentation to be important discriminator given that patients with DAI are obtunded at initial presentation whereas CFE patients often develop neurologic symptoms after admission.

Conclusions
Diffuse axonal injury and cerebral fat embolism syndrome can demonstrate overlapping imaging features in severely traumatized patients. The various patterns of DAI and CFE and their overlap will be reviewed.

Trapped in a Tunnel!! - MR Neurography Technique and Imaging Approach to Peripheral Nerve Entrapment

K Sharma¹, A Varma,¹ Z Rumboldt¹, M Vittoria-Spampinato¹
¹Medical University of South Carolina, Charleston, SC

Purpose
Most peripheral nerves pass through anatomically confined fibro-osseous and fibro-muscular tunnels along their course. At these sites the nerves are particularly susceptible to entrapment and compressive neuropathy. Peripheral nerve entrapment syndromes are characterized by distinct motor and sensory neuropathy; however, on many occasion the clinical and electrophysiological findings are inconclusive. High resolution MR neurography (MRN) is an excellent adjuvant tool that allows for accurate anatomical localization of the entrapment site and assessment of the underlying cause of neuropathy. We will illustrate MRN technique, MR imaging anatomy of the common sites of nerve entrapment and the MRN appearances of nerve entrapment in various upper and lower extremity fibro-osseous and fibro-muscular tunnels.

Materials and Methods
Our presentation will be a didactic electronic exhibit that will include an introductory section on MRN technique, followed by a discussion of the pathophysiology of nerve entrapment syndrome, an overview of direct and indirect MR imaging features of entrapment neuropathy,
and finally MRN cases demonstrating common upper and lower extremity sites of entrapment neuropathy.

Results
The MRN images will illustrate common anatomical sites of nerve compression in upper and lower extremity, such as radial tunnel, cubital tunnel, Guyon's canal, carpal tunnel, peroneal tunnel, tarsal tunnel. We will demonstrate MRN characteristics of the entrapped nerve as well as the secondary denervation changes in specific group of muscles that are useful in identifying and localizing peripheral nerve lesions.

Conclusions
The teaching point of the exhibit is to demonstrate how the understanding of imaging anatomy of common fibro-osseous and fibro-muscular upper and lower extremity tunnels along with knowledge of the normal and abnormal appearances of the peripheral nerves on MRN enables accurate diagnosis of entrapment neuropathy.

KEYWORDS: MR Neurography, Neurography

Traumatic Brain Injury (TBI) Re-visited: A Pictorial Review

C Pluguez-Turull\textsuperscript{1}, W Rivera\textsuperscript{1}, J Lara\textsuperscript{2}, S Baussan\textsuperscript{2}, S Maldonado\textsuperscript{1}, C Quintero-Estades\textsuperscript{1}, J Quintero-Estades\textsuperscript{3}, E Labat\textsuperscript{1}

\textsuperscript{1}University of Puerto Rico - Medical Sciences Campus, San Juan, PR, \textsuperscript{2}University of Puerto Rico, San Juan, PR, \textsuperscript{3}San Juan City Hospital, San Juan, PR

Purpose
Traumatic brain injuries (TBIs) are a very common cause of hospital admission following trauma, and are associated with significant long-term morbidity and mortality. Every year, at least 1.7 million TBIs occur either as an isolated injury or along with other injuries. In addition, TBI contributes as much as a third (30.5%) of all injury-related deaths in the United States. This educational exhibit will review the pathophysiology, mechanism of injury (MOI), characteristic imaging findings, management strategies and classic signs of traumatic brain injuries by examining computed tomography (CT) and MR imaging (MRI) findings in patients at our institution. We also will provide a review of the indications for radiological evaluation and the most common associated complications of brain trauma.

Materials and Methods
We extracted all CT and MR images from PACS station with relevant clinical information extracted from our MEDITECH\textsuperscript{TM} integrated healthcare system at Puerto Rico's Trauma Center. Images were retrieved for recent brain imaging studies to review a wide spectrum of the major intracranial pathologies found in patients admitted for trauma.

Results
In this educational exhibit we intend to review a wide range of intracranial pathologies encountered in brain trauma patients at our institution to include, but not limited to: subarachnoid hemorrhage, diffuse axonal injury, epidural hematoma, subdural hematoma, contusion, intraventricular hemorrhage, penetrating brain injury, depressed fractures, microhemorrhages, etc. Secondary effects of TBI also will be presented. Particular attention was paid to noncontrast
head CT and MRI findings as this is usually the most appropriate study in this setting. Discussion of pathophysiology, MOI, classic signs, management, common complications and characteristic imaging findings with pertinent radiological illustrations will provide adequate exposure to the most commonly encountered and some less common scenarios in TBI. Conclusions

TBIs are a very common cause of hospital admission following trauma, and are associated with significant long-term morbidity and mortality. Reviewing the pathophysiology, MOI, classic signs, management, common complications, indications for radiological evaluation and characteristic imaging findings of TBIs will help improve the outcome of patients presenting with acute head trauma.

KEYWORDS: Brain, Brain Hemorrhage, Brain Trauma

Uncommon and Unusual Lesions of the Pineal Region

G de la Vega1, R Bhatia2, G Saigal3
1University of Miami Miller School of Medicine, Miami, FL, 2Jackson Memorial Hospital/University of Miami, Miami, FL, 3Jackson Memorial Hospital/University of Miami Miller School of Medicine, Miami, FL

Purpose

- Discuss the differential diagnosis of lesions in the pineal region focusing on uncommon and unusual masses encountered in this region.
- Describe the salient imaging findings of uncommon pineal region lesions.
- Review the literature in regard to CT and MR imaging (MRI) findings associated with the pineal region masses discussed.

Materials and Methods

A retrospective review of pineal region lesions in adults and children in our institution was performed, spanning a time range of approximately 10 years. Their respective pathologies were ascertained and catalogued. Finally, the associated CT and MRI imaging findings were reviewed and compared with those previously described in the literature in each instance.

Results

Lesions of the pineal region include a diverse variety of histologies and vary widely in behavior, from the benign, such as pineal cysts to the highly malignant, like the pineoblastoma. The most common of these are the germ cell tumors, in particular the germinomas which typically present as a solid or partially cystic mass, with central calcifications, avid enhancement and, in some cases, restricted diffusion. Teratomas also are commonly encountered and classically demonstrate foci of fat, calcifications, cystic areas as well as avid enhancement of the soft tissue components. The neoplasms arising from the pineal parenchyma are seen less frequently and include the low-grade pineocytoma, pineal parenchymal tumor of indeterminate differentiation, and the pineoblastoma. It is impossible to differentiate theses masses solely based on imaging due to the significant overlap of their findings. Nonetheless, they typically are noted to contain peripheral calcifications giving the gland an "exploded" appearance. Uncommon lesions also are encountered in the pineal region such as the papillary tumor of the pineal region, a rare neuroepithelial neoplasm without a histologic grading criterion, likely due to its rarity. Other rare
lesions such as arachnoid cysts, trilateral retinoblastomas, and atypical teratoid-rhabdoid tumors also may be encountered and should be kept in mind. In addition, neoplasms also may arise from the structures in the vicinity of the pineal gland, such as tectal gliomas and pilocytic astrocytomas, and may thus mimic pineal gland masses. Furthermore, metastases to the pineal gland are seen in up to 5% of patients referred for surgical management. Therefore, due to the variety of lesions that can be encountered in the pineal region, it is important for the radiologist to be cognizant about the common and uncommon etiologies of these lesions and their imaging characteristics in order to optimize patient management and avoid unnecessary interventions.

Conclusions
The exhibit demonstrates the imaging characteristics of lesions in the pineal region with special emphasis on uncommon and unusual masses which may be encountered. It is clear that the possible etiologies are numerous and their imaging characteristics often overlap. In addition, lesions in the vicinity of the pineal gland also may mimic pineal gland masses further confounding the differential diagnosis. Therefore it is important to possess a working familiarity with these entities since it can greatly inform the appropriate subsequent management of the patient and even help prevent unnecessary procedures in certain cases.

KEYWORDS: Pineal Gland
Sagittal contrast enhanced T1 weighted MR image of a 12 y/o male patient who presented with recurrent headaches and visual disturbances, demonstrates an enhancing large lobulated pineal region mass which is encasing the interthalan cerebral veins and demonstrates isointense signal on T1 and FLAIR and associated mild restricted diffusion (not shown). Pathology confirmed that this was a metastatic rhabdomyosarcoma.
Vascular Causes of Ischemic Stroke in the Young Adult: A Pictorial Review

D Boulter¹, P Schaefer¹
¹Massachusetts General Hospital, Harvard Medical School, Boston, MA

Purpose
1. To review the arterial causes of ischemic stroke in young adults. 2. To discuss clinical and radiological features that help narrow the differential diagnosis. 3. To present representative stroke cases which highlight the range of vascular etiologies.

Materials and Methods
A search of the electronic medical record identified cases of ischemic stroke in young adult patients that best demonstrate the range of vascular etiologies and associated imaging findings. Representative cases are presented in an educational format with an emphasis on differentiating clinical and radiographic features.

Results
Approximately 15% of strokes occur in adults under the age of 45. Ischemic stroke etiology in the young is heterogeneous, with higher frequency of causes that are uncommon in the general adult population. Nonatherosclerotic arteriopathies are collectively among the most common causes of ischemic stroke in young adult patients. These can be subdivided into cerebral artery dissections, reversible cerebral vasoconstriction syndromes, moyamoya disease and syndrome, illicit drug abuse, radiation-induced arteriopathy, infectious arteritis, inflammatory or immunologic vasculitis, and genetic or inherited vasculopathies. Many of these disorders have characteristic patterns of arterial involvement and stroke topologies that can help narrow the differential diagnosis.

Conclusions
Nonatherosclerotic arteriopathies are a more frequent cause of ischemic stroke in young adults relative to the general adult population. Although a heterogeneous group of disorders, the correct diagnosis often can be suggested on imaging by considering the stroke topology and pattern of vascular involvement.

KEYWORDS: Arteriopathy, Stroke

Vascular diseases of the head and neck for the non-interventional Neuroradiologist.

M Trelles de Belaunde¹, T Saam²
¹UTMB Health, Galveston, TX, ²Ludvik Maximillian Universitat, Munich, Germany

Purpose
Vascular pathology is initiated at the vessel wall. Stroke is the main clinical outcome of all vascular illnesses in the central nervous system. Stenosis is the end-stage finding and can be
evaluated easily using angiographic methods. However, such luminographic methods often are insufficient to identify or differentiate vascular diseases. This exhibit will review the supra-aortic arteriopathies with an emphasis on the use of black blood MR imaging (MRI) for vessel wall imaging.

Materials and Methods

Results

Traditional noninvasive luminographic methods such as CTA and conventional MRA are optimized to demonstrate the vessel lumen and try to copy digital subtraction angiography results. Newer methods such as black blood imaging permit imaging and visualization of the vessel wall allowing further characterization of disease processes affecting vessels. Two major breakthroughs in this area include the ability to characterize atherosclerotic plaque in the carotid bulb and the ability to differentiate inflammatory from noninflammatory causes of vessel stenosis in the remaining of the circulation by evaluation of contrast enhancement. Future developments likely will be targeted at the evaluation of nonstenotic vascular disease which may permit earlier diagnosis and higher resolution which will permit the study of smaller, more distal vascular beds.

Conclusions

The objective of this exhibit is to improve the noninterventional neuroradiologist's understanding of arteriopathies affecting the supra-aortic vessels with emphasis on the use of black blood MRI to assess vessel wall composition and enhancement.

What you need to know to go with the flow: A primer on MR perfusion

E Dickerson¹, G Fatterpecker², A Srinivasan¹
¹University of Michigan Health System, Ann Arbor, MI, ²New York University School of Medicine, New York, NY

Purpose

1. To describe the technical aspects, postprocessing techniques and challenges of MR perfusion imaging. 2. To present clinical examples of application of MR perfusion imaging in stroke, brain tumors and head and neck cancer.

Materials and Methods

• Principle of MR perfusion. • Technical aspects and challenges of MR perfusion: o Dynamic susceptibility contrast, o Dynamic contrast-enhanced, o Arterial spin labeling. • Clinical applications: Acute ischemic stroke, Brain tumors. o Identification of optimal site for biopsy. o Differentiation of radiation necrosis from recurrent brain tumor. o Identification of pseudoprogression and pseudoresponse. o Grading of brain tumors. • Head and neck cancer: o
Differentiation of malignant from nonmalignant lesions. o Differentiation of recurrent tumors from post-therapy changes. o Monitoring and prediction of response to therapy.

Results
MR perfusion is being employed increasingly across various institutions, especially in the setting of acute ischemic stroke and evaluation of brain tumors. A thorough understanding of the principles of MR perfusion as well as the differences and similarities between the different techniques of acquiring MR perfusion data is essential for proper integration of perfusion data into the clinical context. In this exhibit, we discuss the technical aspects, challenges and clinical application in brain, and head and neck imaging. We will elaborate on each clinical application and present illustrated examples to emphasize the concept.

Conclusions
The radiologist should be aware of the benefits, challenges and limitations of MR perfusion imaging in order to incorporate pertinent information into their clinical interpretation and provide a comprehensive evaluation.

KEYWORDS: MR Perfusion-Weighted Imaging
What’s DaTscan all about?: Review of Ioflupane I-123 DaTscan Brain Imaging.

W Altmeyer¹, D Metter¹, A Schneider¹, B Winegar¹, A Singh¹

¹University of Texas Health Science Center at San Antonio, San Antonio, TX
Purpose
Purpose: - Review ioflupane I-123 (DaTscan) SPECT brain imaging technique. - Discuss current clinical application and utility of DaTscan imaging. - Illustrate DaTscan interpretation method.

Materials and Methods
The educational exhibit starts with a discussion of pertinent basal ganglia anatomy and physiology with an emphasis on the coordination of body movement. Normal and pathologic dopamine physiology will be reviewed. We will discuss the biodistribution of the radiopharmaceutical ioflupane I-123 and basics of DaTscan SPECT brain imaging technique. Finally, the educational exhibit will explain Ioflupane I-123 scintigraphy interpretation method and the role of imaging in the diagnosis of Parkinsonian syndromes. The exhibit will utilize clinical vignettes with examples of both normal and abnormal ioflupane I-123 scintigraphy to help emphasis the clinical utility of scintigraphy in the evaluation of movement disorders.

Results
Ioflupane I-123 (DaTscan) brain imaging is an emerging technology for the imaging of movement disorders. FDA approval for ioflupane I-123 scintigraphy was obtained in early 2011. Often, it can be difficult for clinicians to diagnosis the etiology of tremor, particularly early in the course of the disease. Ioflupane I-123 can be helpful in differentiating Parkinson's disease from other causes of movement disorder (especially essential tremor).

Conclusions
Our educational goal is to provide a concise and informative review of Ioflupane I-123 (DaTscan) imaging technique, clinical application and interpretation with imaging correlation.

Where's the Stroke? What's the Deficit?
Purpose
To demonstrate functional brain anatomy and deficit localization through cross-sectional imaging of stroke, using an interactive quiz and discussion format.

Materials and Methods
An interactive quiz and discussion format is used to teach localization of brain deficits, reinforced by two complementary approaches. In part 1, CT brain studies with difficult to visualize strokes are presented for review, followed by clinical descriptions of associated neurological deficits. Multiple questions provide choices for the location of vascular insults, followed by MRI confirmation and discussion of relevant brain functions and dysfunctions. In part 2, the clearly visible locations of strokes at CT and/or MRI are presented. Multiple questions provide choices of expected neurological deficits based on stroke location, followed by discussions of relevant brain functions and dysfunctions.

Results
With development of the electronic medical record, neuroradiologists now more than ever have access to clinical deficits associated with stroke. Consequently, an understanding of stroke deficits and associated locations within the brain can be reinforced day-to-day in clinical practice. Studying deficits associated with localized strokes of gray and white matter structures can provide significant insights into brain function and dysfunction. The interactive quiz and discussion presented here bridges educational and clinical aspects of brain imaging. The exhibit seeks to educate neuroradiologists to the locations of neurological brain deficits, and while doing so reinforce an understanding of normal brain functions and dysfunctions. The educational approach also should help to improve search patterns for detecting subacute strokes when interpreting CT brain imaging. Moreover, the knowledge gained from the exhibit will provide a more sophisticated understanding of deficits associated with other brain diseases, as well as discussions with referring clinicians.

Conclusions
A thorough understanding of deficit location within the brain can improve search patterns, provide more sophisticated understanding of brain diseases, and promote more effective communication with referring clinicians. Such an understanding is within the domain of neuroradiology, and once learned can be reinforced in daily practice.

"Little Brain": Evaluation of Sporadic Cerebellar Atrophy

D Pechersky¹, D Reede², W Smoker³, J Nath¹
Purpose
1. Review the function and normal anatomy (gross and imaging) of the cerebellum. 2. Learn the sporadic causes of cerebellar atrophy and their clinical manifestations. 3. Discuss etiologies based on the location of findings in the cerebellum and other associated imaging findings.

Materials and Methods
Cerebellar atrophy often is encountered on imaging incidentally or in the evaluation of ataxia. After a discussion of the normal anatomy and function of the cerebellum, cases are presented in a quiz format. Common sporadic causes of cerebellar atrophy, as well as their relevant clinical histories are discussed. Etiologies include alcoholic degeneration, toxicity from medications, paraneoplasia, multiple system atrophy-cerebellar predominant (MSA-C), and age-related atrophy. Cases are organized based on the location of cerebellar atrophy (focal versus global) and presence of additional associated imaging findings (brainstem, cerebral hemisphere, basal ganglia, and calvarium).

Results
The cerebellum ("little brain" in Latin) plays an important role in movement and motor coordination. Special attention to this region is required in the work-up of ataxia. Familiarity with different atrophy patterns, associated imaging features and clinical findings can aid in the development of an appropriate differential diagnosis.

Conclusions
Cerebellar atrophy may be an incidental finding or clinically suspected. An algorithm is provided using atrophy patterns, clinical presentation, and other associated imaging findings to aid in determining the etiology of cerebellar atrophy.

KEYWORDS: Alcohol, Cerebellum, Drugs
Phenytoin

Axial and sagittal T1-weighted images demonstrate global cerebellar atrophy, as demonstrated by enlargement of the fourth ventricle, interfolial spaces and supracistern. There is no significant involvement of the brainstem or cerebellar hemisphere. Additional finding of bone marrow expansion is noted (white arrow).

J Nair¹, J Chankowsky², C Torres², R del carpio³
¹McGill University Health Centre, Montreal, Quebec, Canada, ²Montreal General Hospital, McGill University Health Centre, Montreal, Quebec, Canada, ³Montreal General Hospital, McGill University Health Centre, Montreal, Quebec
Purpose
To highlight rare but increasingly recognized causes of neck pain, backache and progressive myelopathy of the spinal cord commonly misinterpreted due to ignorance of the entities. To review the characteristic CT/ MRI findings and salient features which should raise suspicion on imaging.

Materials and Methods
PACS search will be undertaken to identify selected cases. Using an interactive model, representative images and multiple choice questions an attempt will be made to familiarize with the not so frequent but important spinal lesions/pathologies on imaging.

Results
We shall use a case-based approach focused on clinical impression, CT and MR imaging (MRI) to discuss unusual cases like calcific tendinitis of the longus colli muscle, Spontaneous spinal cord herniation, Hirayama disease, extramedullary hematopoiesis, epidural hematoma and Guillain-Barre syndrome (amongst others). Salient features of two of the pathologies are described below: 1) Spontaneous spinal cord herniation: Mainly, thoracic spinal cord dural defect (congenital/acquired), Prolonged CSF pulsations cause the herniation, Unusual case of progressive myelopathy, Arachnoid cysts associated. 2) Guillain-Barre syndrome: Thickening of spinal nerve roots along the length of the cauda equina. Enhancement of anterior spinal nerve roots on postcontrast study (posterior roots also may be involved), Cranial nerve involvement-Children. Most common abnormal findings: Laboratory findings, Elevated CSF protein level without cells (pleocytosis), Electrophysiological findings, Nerve conduction slowing.

Conclusions
Knowledge of the characteristic imaging findings of these uncommon spinal abnormalities would help in early and correct diagnosis allowing prompt treatment. Ignorance to these entities re-emphasis the fact "The Eyes See Only What The Mind Knows".

3D Interactive and Stereotactic Atlas of the Skull Base Region: Bone, Vessels, Cranial Nerves, and Head Muscles

W Nowinski¹, B Chua¹, S Hnin Wut Yi¹, G Qian¹, T Shoon Let Thaung¹, Y Yang¹, N Nowinska¹, R Chrzan², A Urbanik²
¹ASTAR, Singapore, Singapore, ²Jagiellonian University, Cracow, Poland

Purpose
The skull base region is anatomically complex. Our objective is to construct a three-dimensional (3D), interactive, stereotactic, detailed and parcellated atlas of the skull base region correlated spatially with the existing brain atlas which comprises structure, vasculature, cranial nerves and head muscles, among others. This atlas allows the user to explore any region of interest along with its surroundings with just a few clicks.

Materials and Methods
We had previously developed a 3D brain atlas (1) from 3/7 T multiple in vivo scans (MPRAGE,
TOF, SPGR and SWI) of a single brain specimen with a virtual cerebral model containing structure (2), vasculature (3) (presented at ASNR 2009), cranial nerves and nuclei (4), and muscles (5). A high resolution spiral CT scan (526 slices of 0.75 mm thickness, 0.5 mm increment; 512 x512 matrix) of the same specimen was acquired. The skull and vertebrae were segmented, parcellated, reconstructed in 3D, and spatially registered with the cerebral model. A user friendly and efficient application was developed with functions for structure selection (brain, neck and/or head compositing and decompositing), spatial manipulation (rotate, zoom, pan and set view), identification (3D labeling and component highlighting), context exposure (3D virtual model cutting and MR triplanar display), quantification (distance measurement and stereotactic coordinates) and presentation (image saving).

Results
This atlas is rich in content (about 2,400 components) with all 3D structures labeled with names and, in addition, diameters for the vessels. It also provides powerful tools for studying and understanding the skull base and surrounding anatomy. A real-time manipulation with rotate, zoom, pan, set view and 3D cut facilitates a user-friendly exploration of the anatomy with a few clicks. A cutting plane technique along with texture mapping allows combining surface and sectional anatomy. Measurement of 3D distances and stereotactic coordinates enable quantitative analysis.

Conclusions
This novel atlas is valuable to medical students and residents to easily get familiarized with the skull base and surrounding anatomy with a few clicks. The atlas also is helpful to educators to prepare teaching materials. It may potentially serve as a reference aid in the reading room.

A Method to Detect M2 Branch Occlusion Using Axial Time-of-Flight Source Images – The Empty Dot Sign

J Lee1, B Yoo1, N Salamon1
1David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA

Purpose
Time-of-flight (TOF) MR angiography commonly is used to detect thrombotic occlusion of the Circle of Willis in the setting of acute stroke. Proximal occlusions of the M1 segment of the middle cerebral artery (MCA) are detected readily by rotational 3-D maximal intensity projection (MIP) images. However, detection of distal M2 branch occlusions can be both subtle and challenging. The aim of this study is to review M2 branch anatomy. There will be a specific focus on the M2 anatomy within the Sylvian fissure, and we will illustrate a novel technique that quickly and accurately identifies the common M2 branches using axial TOF MRA source images to assess for thrombotic occlusion (“the empty dot sign”).

Materials and Methods
A multimodal, pictorial review of M2 branch anatomy will be performed, illustrating the 12 major M2 branches supplying the MCA territory. The territories supplied by each M2 branch will be depicted and specific anatomical landmarks and associated clinical deficits for each
territory will be displayed. A particular focus will be placed upon anatomical opercular landmarks in relation to the major M2 branches normally seen in the Sylvian fissure. We will illustrate a novel technique to quickly assess the patency of the five major M2 branches in the Sylvian fissure, by counting from anterior to posterior the presence of five hyperintense "dots" on axial TOF MRA source images, corresponding to the prefrontal, precentral, central, angular, and parietal M2 branches. The absence of flow-related signal in one of the 5 "dots" indicates M2 branch occlusion ("the empty dot sign").

Results
Representative examples of different M2 branch occlusions on axial TOF source images in the Sylvian fissure will be presented, using the technique described above. Diffusion-weighted images (DWI) will be presented to demonstrate the area of infarction. Perfusion-weighted images (PWI) will be shown to illustrate specific M2 branch vascular territories. Corresponding angiographic images also will be provided. Examples of M2 branch occlusion recanalization after thrombolytic treatment also will be presented.

Conclusions
Evaluation of distal MCA branches can be challenging. A knowledge of MCA branch anatomy and use of the "empty dot" sign potentially can be useful to quickly assess the patency of M2 branches in the setting of stroke, and have important implications on therapeutic decisions.

A Pattern Based Approach to Pathology on Susceptibility Imaging

M Mabray, J Villanueva-Meyer, A Kansagra, S Cha

University of California San Francisco, San Francisco, CA

Purpose

Susceptibility imaging sequences are powerful clinical tools that are sensitive to deoxygenated blood products and detect pathology in an increasing number of conditions. The purpose of our exhibit is to present a pictorial review of the large number of clinical conditions with findings on susceptibility imaging and to group these conditions into a framework of common patterns.

Materials and Methods

MR imaging including susceptibility sequences will be presented from a large number of cases depicting a variety of clinical conditions, some of which have not been reported previously or frequently in the literature. Relevant case history, pathology, and follow up will be provided as well as a review of the depicted clinical entity. We will present a pattern-based approach to thinking about the pathology depicted on susceptibility imaging and will attempt to group imaging findings and conditions accordingly.

Results

Susceptibility sequences depict findings in a large and expanding number of clinical conditions. While there is some overlap it is useful to arrange these conditions into common and rare conditions and to consider the following patterns: 1. Innumerable scattered foci, 2. Few to multiple scattered foci, 3. Linear/branching vascular lesions, 4. Other. Conditions that tend to demonstrate the innumerable scattered foci of susceptibility pattern include coagulopathy, DIC, thrombocytopenia, fat emboli, cerebral malaria, hemorrhagic encephalitis, sickle cell anemia, severe hypertension, and PRES. These tend to be diffuse processes that produce tiny petechial hemorrhages. Conditions that tend to demonstrate the few to multiple scattered foci of susceptibility pattern include amyloid angiopathy, axonal shear injury, prior radiation, prior lacunar infarct hemorrhage, dystrophic calcification, cavernous malformations, and prior hypertensive or traumatic hemorrhage. These are conditions that are less diffuse and may have single to multiple lesions or time points of the same process. Conditions that demonstrate linear and/or branching susceptibility characteristic of blood vessels include developmental venous anomalies, capillary telangiectasia, AV malformations, Sturge-Weber, CNS angiitis, arterial thrombus, and venous thrombus. Susceptibility imaging powerfully depicts the vascular nature and anatomy of these lesions. Conditions that depict other characteristic patterns based upon their location and clinical situation include superficial siderosis, pneumocephalus, mineralization, and hemorrhages related to tumor, infarction, aneurysms, and trauma.

Conclusions

Susceptibility sequences depict pathology in a large and expanding number of clinical
conditions. A pattern-based approach to forming a differential diagnosis is a useful framework for thinking about these entities and arriving at the correct diagnosis. Attendees will become familiar with the patterns of pathology on susceptibility sequences and the respective differential considerations after reviewing this exhibit.

**A Pictorial Review of Intrathecal Pump Assessment and Complications: A Radiologist's Guide**

M Seymour¹, M Mullican¹, H Scott¹, E Stehel¹

¹University of Texas Southwestern Medical Center, Dallas, TX
Purpose
Rising numbers of imaging requests for evaluation of intrathecal pumps within our radiology department has encouraged collaboration between our neuroradiologists, general radiologists, and referents. This collaboration has been the impetus for multidisciplinary education regarding the best way to assess these pumps by imaging. The purpose of this educational exhibit is to share our experiences and current management of potential pump malfunction in an image rich format. We will show numerous examples of intrathecal pump complications.

Materials and Methods
Retrospective review was performed of patients who have undergone imaging assessment of intrathecal pumps at University of Texas Southwestern Medical Center. Select cases best depicting normal appearance, specific complications, and pitfalls were selected for inclusion in this educational exhibit.

Results
Our routine imaging assessment of a malfunctioning intrathecal pump begins with radiographs. Radiographs can depict numerous abnormalities of the pump system, including nonrotation of the pump motor, flipped or "twiddled" pumps, kinked catheters, catheter disconnections, and catheter discontinuity. Radiographic assessment often can be challenging due to prior spinal fusions, concurrent spinal stimulators, and difficult to visualize Ascenda catheters. If radiographic assessment is unrevealing, we proceed to fluoroscopically guided injection of the pump via the catheter access port immediately followed by CT. Fluoroscopy demonstrates flow of contrast through the tubing, identifying focal areas of obstruction or catheter discontinuity. Following the intrathecal contrast injection, CT is helpful to detect subtle contrast leaks, potential epidural placement of the catheter, radiographically occult catheter kinking, and filling defects which can suggest granuloma formation. MR imaging (MRI) also is included occasionally in the work up, such as when patients develop changes in their neurologic status or have an atypical presentation which could overlap with pump malfunction. MR imaging can show granulomas and other potential disk or cord abnormalities.

Conclusions
Increasing numbers of imaging studies to evaluate intrathecal pumps has required educating both our radiologists and referents about the appropriate workup for potential pump malfunctions. Through our experience, we have gathered numerous cases of intrathecal pump-related complications that we believe are beneficial for the neuroradiologist to review.

A Radiologic Tour of the Brainstem with Pathology Correlation

B Connolly, T Roberts, D Green, A Tarabishy, J Hogg
West Virginia University, Morgantown, WV

Purpose
This electronic educational exhibit provides a review of the radiology of the brainstem including the relevant anatomy, appropriate clinical context, and pertinent imaging findings. The approach is based on anatomical localization using high quality computed tomographic and magnetic
resonance images. Each radiographic image of the basic anatomy will be accompanied by the corresponding gross pathologic imaging findings for correlation. This exhibit is targeted to both practicing radiologists and those in-training for board exams and re-certification.

Materials and Methods
This electronic educational exhibit provides a review of the radiology of the brainstem including the relevant anatomy, appropriate clinical context, and pertinent imaging findings. The approach is based on anatomical localization using high quality computed tomographic and magnetic resonance images. Each radiographic image of the basic anatomy, including white matter tracts, will be accompanied by the corresponding gross pathologic imaging findings. Pertinent clinical cases will conclude the exhibit for reinforcement and will include the pathologic correlate. A few examples of specific pathologic cases include: brainstem infarction, neoplastic disease, white matter disease, and sequelae of metabolic derangement.

Results
The audience of this poster will gain or refresh information about the anatomy of the brainstem with using high quality imaging with gross and microscopic pathologic correlation. Clinically relevant case material from a tertiary referral center to highlight more common brainstem pathology will reinforce learning for clinical practice and board certifying examinations.

Conclusions
The audience of this poster will gain or refresh information about the anatomy of the brainstem with using high quality imaging with gross and microscopic pathologic correlation. Clinically relevant case material from a tertiary referral center to highlight more common brainstem pathology will reinforce learning for clinical practice and board certifying examinations. An emphasis on the anatomy and clinical context will assist the radiologist in arriving at an appropriate differential diagnosis.

Added Value of Coronal and Sagittal Reformations on Routine Non-contrast CT of the Head - Initial Experience from an Academic Center

W Moore¹, M Fiesta¹, D Chason², R Suss², A Whittemore², M Pinho²
¹University of Texas-Southwestern, Dallas, TX, ²University of Texas-Southwestern Medical Center, Dallas, TX

Purpose
To illustrate the added value of coronal and sagittal reformations over axial imaging alone on noncontrast CT of the head with specific case examples in a pictorial review.

Materials and Methods
Beginning Fall 2012, we began reformatting all noncontrast CT head examinations in the coronal and sagittal planes, and sending them to PACS for review in addition to the industry standard routine axial images. Over this time period, it has been our experience that these additional reformatted images have at times added valuable information for image interpretation. We have accumulated cases and classified them into three main scenarios: (1) increase in absolute sensitivity for lesion detection, (2) increase in diagnostic confidence and characterization of axial
findings, (3) decrease in false positive findings including artifact identification (i.e., increased specificity).

Results
Historically, noncontrast CT imaging of the head has relied essentially on interpretation of sequential axial images. With the advent of volumetric helical acquisitions, raw imaging data can be reconstructed in multiple planes with no additional scanning time, cost, or radiation exposure. Multiplanar interpretation has become incorporated into clinical practice on CT for most body regions, with the notable exception of the head at most institutions, despite some available published data demonstrating added value in some clinical scenarios such as trauma (1, 2). We have recently modified our routine protocol to include those reformats, and our initial experience is favorable, especially for identification of normal and abnormal structures near the vertex, extra-axial spaces, brain/bone interface at the skull base and midline structures. In locations such as these, subtle abnormalities on axial images are often more obvious on an orthogonal plane, which may be invaluable to increase sensitivity and add diagnostic confidence, especially for less experienced readers in the academic training setting. Reduction of false positives is another important advantage, and we have encountered several situations in which reformats have improved the prospective identification of image artifacts and other pitfalls, avoiding additional imaging or follow up and potentially decreasing health care costs and patient radiation exposure.

Conclusions
Multiplanar reformats for noncontrast head CT studies can be instrumental at improving diagnostic confidence and accuracy with no added cost or radiation burden. We plan to demonstrate our preliminary experience with a pictorial presentation, focusing on potential benefits to patients. Further cost-effectiveness research is being implemented at our institution to compare the potential clinical and management benefits versus possible costs of increased interpretation times and data storage requirements.

KEYWORDS: CT, Postprocessing
Small subdural hematoma confirmed on coronal images: a. Axial CT in brain window. b. Coronal CT in brain window. Subtle peripheral hyperdensity (arrow) seen only on one axial slice raises question for extra-axial hemorrhage. Coronal reformat clearly demonstrate the shape an extent of a subdural hematoma, increasing diagnostic confidence.

6:30AM - 9:00PM

Anomalies and Variations of Intracranial Circulation Demonstrated on MR Angiogram

S Patro¹, R Glikstein¹, C Torres¹, P Hanagandi², T Almansoori¹, N Coffey¹
¹The Ottawa Hospital, Ottawa, Ontario, Canada, ²The Ottawa Hospital, University of Ottawa, Ottawa, Ontario, Canada

Purpose
The aim of this educational exhibit is to: 1. To present various anomalies and variations of the intracranial circulation demonstrated on MR angiogram. 2. To discuss these anomalies and their clinical significance.

Materials and Methods
We reviewed all the MR angiograms of the intracranial circulation performed at our institution
within the last five years and assessed the various anatomical variants present in these angiograms.

Results
Magnetic Resonance (MR) angiogram is a frequently used imaging technique in most of the centers for evaluation of the intracranial circulation. Three-dimensional time-of-flight (TOF) sequence is the preferred and most commonly used MRI technique. This study covers the circle of Willis as well as the distal vessels, allowing the identification of most of the vascular abnormalities and anatomical variants. Normal variations of the cerebral circulation are not uncommon. Knowledge and understanding of these variations such as aplasia/hypoplasia, agenesis, duplication, fenestration and persistent fetal arteries plays an important role in endovascular or surgical management of patients with stroke and subarachnoid hemorrhage. The significance of various anomalies differs with respect to its clinical presentation, for example, the fenestration and persistent fetal arteries are commonly associated with increased risk of aneurysm formation.

Conclusions
It is important to identify and report various normal anatomical variants and anomalies while evaluating the cerebral circulation using MR angiogram. Knowledge of the anatomical variations is important since it can influence surgical and interventional procedures.

KEYWORDS: Anatomical Variation, Fenestration, Variants

eEdE-100

Case-Based Review: Differential Diagnosis for Commonly Encountered Lesions of the Pons.

F Gonzalez¹, L Gillihan¹, K Gandhi¹, A Steven¹
¹University of Maryland, Baltimore, MD

Purpose
The pons is the largest portion of the brainstem responsible for both relaying information and controlling a number of essential functions. It is also a common location for a variety of pathologic entities to present, from ischemia and inflammation to neoplasm and vascular malformations. While there is considerable overlap in the imaging characteristics of these entities, certain findings and clinical information may be employed to narrowing the differential and often make a specific diagnosis. The purpose of this exhibit is to offer the radiologist an approach to these lesions, and help guide the diagnostic work up and management of these patients.

Materials and Methods
A menagerie of cases were collected over a one-year time frame at the University of Maryland Medical System. In addition to cases encountered during typical day-to-day proceedings, a radiology search engine was utilized to identify additional rare and unusual entities. Approximately two dozen example cases were collected, which includes both classic and atypical presentations of disease.

Results
Following a brief illustrated discussion of the anatomy and of the function of the pons, we
review the identification and differential diagnosis for commonly encountered pontine lesions. Pathologic entities presented in a case-based format include acute and chronic ischemia, hemorrhagic lesions, infectious and inflammatory entities, demyelinating disease, toxic-metabolic derangements, neurodegenerative disorders, anatomical variants, vascular malformations and neoplasms. The imaging features for each entity are reviewed, with an emphasis on specific distinguishing features that may be used to differentiate among these entities. When possible, advanced imaging techniques including MR spectroscopy (MRS) and diffusion tensor imaging (DTI) are employed. For lesions without specific imaging features, the clinical history and laboratory data required for patient management are reviewed.

Conclusions
A wide variety of lesions, both aggressive and benign, may be encountered in the pons with a number of possible clinical presentations. This brief review should increase familiarity with and diagnostic confidence for these entities for any practicing radiologist.

KEYWORDS: Adult Brain, Arteriovenous Malformation, Central Pontine Myelinolysis

CAT Lesions: When Pathology Involves the Caverno-Apical Triangle

C Glastonbury¹, J Narvid¹, J Talbott¹
¹University of California, San Francisco, San Francisco, CA

Purpose
1. To examine the anatomical contours that define the caverno-apical triangle (CAT). 2. To demonstrate the most important and unusual pathologies that may involve the caverno-apical triangle and the implications for the surgeon and oncologist.

Materials and Methods
Through high-resolution CT and MR images and with PET and pathologic correlation, we present a detailed anatomical study of the contours that define the caverno-apical triangle and the key and unusual pathologies that may be found here.

Results
The caverno-apical triangle is a small triangular-shaped area at the junction of the anterior and middle cranial fossae where the anterolateral aspect of the cavernous sinus meets the orbital apex and superior orbital fissure. This area can harbor pathology which is subtle on imaging but because of the intimate anatomical relations can result in significant morbidity and be difficult to access surgically for biopsy.

Conclusions
The caverno-apical triangle has been described poorly in the literature and because of its small size may be readily overlooked on imaging. The clinically important anatomical relations mean that pathology in this area may result in high morbidity and surgical access is difficult for diagnosis. This area should be carefully evaluated on CECT or MRI particularly when patients have symptoms of CN3, 4 or 6 neuropathy, orbital pain or altered visual acuity.

Clinical Utility of Susceptibility Weighted Imaging

M Gul1, A Chaudhry2, L Gerges3, A Chaudhry4, J Dunkin5
1Winthrop University Hospital, Mineola, NY, 2Stony Brook University Medical Center, Westbury, NY, 3Stony Brook University Medical Center, Bellport, NY, 4St Johns University, Westbury, NY, 5Stony Brook University Medical Center, Stony Brook, NY

Purpose
Susceptibility-weighted imaging (SWI) utilizes flow/velocity compensated long echo, RF spoiled, gradient recalled echo pulse to obtain MR images. It has been used traditionally in evaluation of large-vessel flow quantification or for use in inversion recovery sequences. Recently, there has been marked interest in the information provided by SWI at tissue interface especially about local tissue susceptibility changes that can arise from presence of ferromagnetic agents such as iron and other substances that change the local field. We aim to review basic concepts of SWI with a case-based discussion highlighting the origins of low signal on SWI and the significance of high-pass filtered phase images in distinguishing hemorrhage from other causes of low signal on SWI. By the conclusion of this presentation, the radiologist should have a better understanding of various clinical presentations of granulocytic sarcoma and relevant imaging and pathologic findings.

Materials and Methods
We present a case-based review highlighting basic concepts of various SWI (T2*WI versus SWI, magnitude and high-pass filtered phase images, minimum intensity projection SWI, QSM) and various causes of low signal on SWI (diamagnetic versus paramagnetic causes) using MR images, flow-chart and/or cartoons. The exhibit will include clinical image examples of SWI including trauma, neoplasm, vasculopathy, neurodegenerative diseases, inflammatory and infectious diseases. Emphasis will be on key points that help differentiate low signal high-pass filtered phase images and how certain patterns can help differentiate between diamagnetic versus paramagnetic substances. We also will discuss common pitfalls of SWI including orientation within main magnetic field, chemical shift artifacts, etc.

Results
We will give an image-rich overview of physical principles of SWI and how these principals can be used to aid in image interpretation. Following this, there will be case-clinical image examples of SWI including trauma, vasculopathy, and neurodegenerative diseases. Emphasis will be on key points that help narrow the differential diagnosis. Case examples also will highlight utility of SWI in neonatal imaging (hydrocephalus, hypoxic encephalopathy, CVAs, etc.), role of SWI in dymelinating diseases (MS, NMO), neoplasms (primary CNS and metastases (hemorrhagic versus nonhemorrhagic), lymphoma, hemangiopericytoma and malignant fibrous histiocytoma), infection (tuberculosis, pyogenic abscess, neurocysticercosis, nocardia, aspergilloma, cryptococcosis, etc.), and inflammatory conditions (neurobehcet's, sarcoidosis, lupus, CLIPPERS, etc).

Conclusions
Susceptibility-weighted imaging is a key diagnostic MR imaging tool which combines phase and magnitude information to detect magnetic susceptibility differences between adjacent tissues. Because of its ability to detect paramagnetic and diamagnetic substances (e.g., iron deposits,
calcifications, blood degradation products, etc.) with high sensitivity, it provides clinically useful information in the evaluation of various disorders including traumatic brain injury, neonatal brain, vasculopathy, neurodegenerative disorders, neoplasms, etc. By the conclusion of this presentation, the viewer should be familiar with principals behind SWI, characteristic SWI patterns of the aforementioned clinical entities and beware of the common pitfalls of SWI.

KEYWORDS: Neuro-Behçet, Neurosarcoidosis, Susceptibility-Weighted Imaging

eEdE-111

Cranial Nerve Anatomy as Illustrated by Schwannomas

M McCrary¹, K Baugnon¹
¹Emory University School of Medicine, Atlanta, GA

Purpose
A firm understanding of cranial nerve anatomy and function is necessary for the interpretation of examinations that include the skull base or head and neck. Particularly, in the evaluation of patients with cranial neuropathies, it is imperative for the radiologist to assess for pathology along the entire course of the cranial nerve, from nucleus to end organ. Cranial nerve schwannomas are benign nerve sheath tumors that can be seen along the intracranial and extracranial course of cranial nerves III-XII. The aim of this pictorial essay is to refresh the expert and educate the novice imager about cranial nerve anatomy and function using schwannomas to illustrate key points.

Materials and Methods
Patients undergoing MR imaging (MRI) or CT imaging for the workup of cranial neuropathies will be included in this pictorial essay. Normal anatomy of the cranial nerves will be depicted on MRI images, from nucleus to end organ, and CT images will be used to demonstrate the normal and abnormal appearance of the skull base foramina. Multiple cranial nerve schwannomas will be presented to emphasize this anatomy along the course of each nerve.

Results
With an emphasis on MRI, techniques and relevant physics for imaging the cranial nerves will be reviewed. For each individual cranial nerve, a discussion of function will be included. Next, imaging anatomy will be demonstrated including nuclei and major branches. Clinically relevant anatomical relationships along the course of each cranial nerve with adjacent structures will be stressed. Schwannomas will serve to facilitate understanding of these anatomical and functional concepts. Finally, various clinical presentations of cranial nerve dysfunction also will be discussed. A systematic approach for the assessment of the cranial nerves will be presented.

Conclusions
For every radiologist whose practice includes neuroimaging, intimate knowledge of cranial nerve anatomy, function, and presentations of dysfunction is a must. A CT and MRI review of cranial nerve anatomy presented here aims to illustrate this intricate anatomy using cranial nerve schwannomas for emphasis.

Crossroads for Head and Neck Cancer: Critical Imaging Findings that Alter Management of Squamous Cell Carcinoma of the Head and Neck

B Garvey¹, W Moore¹, M Fiesta¹, C Perez¹, L Nedzi¹, M Pinho²
¹University of Texas Southwestern, Dallas, TX, ²University of Texas Southwestern Medical Center, Dallas, TX

Purpose
The aim of this exhibit is to familiarize radiologists with the staging principles for squamous cell carcinoma (SCC) of the head and neck at multiple primary sites, with a focus on key cross-sectional imaging findings that directly impact prognosis and patient management. After exploring this exhibit, participants will become more comfortable interpreting cross-sectional studies due to a better understanding of staging principles and how these affect treatment options.

Materials and Methods
We will revisit the newest edition of the American Joint Committee on Cancer (AJCC) Cancer Staging Manual, and provide a pictorial review of head and neck SCC staging, including lesions of the lip and oral cavity, oropharynx, nasopharynx, larynx, hypopharynx and nasal cavity/paranasal sinuses. The review will discuss key imaging findings that help determine tumor stage and how this information influences clinical decision making, including a summary.
discussion of updated treatment options for each stage of disease. An interactive quiz will be available at the end of the exhibit, allowing participants to test their knowledge by searching for key imaging findings on unknown cases, with explanations of how the findings affect clinical management and prognosis.

Results
In an era that increasingly emphasizes the added value of radiology, it is crucial for radiologists to possess an understanding of how imaging findings influence clinical management. Due to the complex anatomy of the head and neck, staging of head and neck SCC can be a daunting task. However, by adhering to guidelines set forth by the AJCC, becoming familiar with key imaging findings that influence cancer stage and building a solid search pattern, radiologists often can play a decisive role at the crossroads of integrating clinical and imaging findings to determine prognosis and best strategies for patient care.

Conclusions
Radiology training is undergoing changes as the specialty evolves into a more patient-centered practice and radiologists participate more directly on treatment decisions. To be seen as important members of a multidisciplinary head and neck cancer group, radiologists need to be familiar with key staging and treatment principles adding greater value to patient care.

KEYWORDS: Cancer, Head And Neck, Staging

56 y/o female smoker with 4 month onset hoarseness and 30 lbs Contrast enhanced CT of demonstrates a supraglottic inf with extralaryngeal extension (T4 IVa). Stage IVa disease is moderately advanced and patient eligible for partial laryngeal laryngectomy is an option but functional organ preservation concurrent chemoradiation is chemotherapy option of laryngectomy for local fi
Purpose
To study the embryology, bony and ligamentous anatomy and topographic relationship of craniovertebral junction on imaging. To understand imaging features of various craniovertebral junction abnormalities on CT and MRI.

Materials and Methods
Computed tomography was performed on Philips 40-slice multidetector scanner (Brilliance). Helical acquisition was used with multidetector computed tomography, and thin slices of 0.5 to 1 mm from clivus to lower end of C2 vertebral were acquired. MR imaging was performed using Siemens 1.5 T MR system (Magnetom Symphony) with a phased array spinal coil. The examination was conducted in a nonemergent (nonacute) setting. Sedation (oral or intravenous) if required was given. Axial T1, T2 and gradient echo. Coronal T2, STIR. Sagittal T1, T2, gradient echo and STIR. Postcontrast, dynamic flexion/extension studies and 3D TOF angiography were done wherever required/possible.

Results
Study included 30 males and 18 females. Patients between 18 to 40 years of age constituted the largest group. Congenital abnormalities were seen in 39 (81%) cases and were found to be more common than acquired abnormalities which were seen in nine (19%) cases. Among the acquired abnormalities cases of trauma were seen in four (9%), infective etiology (tuberculosis) in two (4%), tumors in two (4%) and inflammatory in one (2%). Out of 39 patients of congenital cases, atlanto-axial dislocation was the most common bony abnormality in 74.3% followed by basilar invagination in 64.1%, occipitalization of atlas in 35.9%, dens dislocation in 23%. Other bony abnormalities seen were platybasia (25.7%), os odontoideum (15.4%), segmentation anomalies (17.9%), rachischsis and condylus tertius in 5.2% each, split atlas, foramen magnum stenosis, dens aplasia and os terminale in 2.5% each. Out of 39 patients of congenital abnormalities increase in predental soft tissue was the most common soft tissue abnormality seen in 56.4% cases, followed by ligament thickening seen in 23.77% cases, syrinx in 17.8% and cerebellar herniation in 10.25% of cases. CT could detect 100% of the congenital bony abnormalities. However, MRI could detect 86.27% atlantoaxial dislocation, 88% of basilar invagination, 78.5% atlantooccipital assimilation, 88.8% of dens subluxation, 90% platybasia, 66.6% os odontoideum. 28% cases with syrinx were detected on CT, whereas MRI detected all the cases with syrinx. In the four cases of trauma involving CVJ, CT detected all of atlas and axis fractures. MRI detected 75% of fracture and 100% of the cord and ligamentous injuries while CT detected 50% of cord and none of ligamentous injuries. 2 cases of CVJ tuberculosis seen, which revealed bony destructive lesions, atlanto-axial dislocation, dens subluxation, prevertebral abscess, epidural extension and cord changes. Two cases of CVJ tumors seen, one was meningioma and other was giant cell tumor of clivus.
Conclusions
An understanding of embryology and knowledge of the wide spectrum of pathology and its clinical presentation combined with imaging findings allows the radiologist to play a key role in the presurgical evaluation and treatment planning for the neurosurgeon. Though CT has a role in demonstrating bony abnormalities, MR imaging provides multiplanar images, and is proved to be superior soft tissue characterization, comprehensive anatomical definition and topographical relationships of the craniovertebral junction which is useful for surgical planning and prognostication. This ability makes MR imaging the primary imaging modality in the evaluation of the CVJ.

(Filename: TCT_eEdE-132a_Slide1.jpg)
A Singh¹, W Smoker², M Chen¹
¹University of Texas Health Science Center San Antonio, San Antonio, TX, ²University of Iowa Hospitals and Clinics, Iowa City, IA

Purpose
The purpose of this exhibit is to review various congenital and developmental anomalies of the occiput, atlas, and axis (craniovertebral junction) in an interactive format.

Materials and Methods
We retrospectively reviewed teaching files from two institutions for congenital and developmental anomalies of the craniovertebral junction (CVJ). Representative cases were used for this exhibit.

Results
The occiput, atlas and axis comprise the craniovertebral junction (CVJ). Imaging plays a key role in identification of CVJ anomalies. Anatomy of CVJ with relevant embryology is discussed with normal imaging features. Anomalies of the CVJ can result in underlying cervicomedullary compression and, therefore, are important to recognize. These anomalies can be categorized based on the anatomical location (occiput, atlas and axis). Occiput anomalies included are basioccipital and occiput hypoplasia (and resultant basilar invagination), incorporation of the proatlas to the basiocciput, and various atlantooccipital assimilations. Atlas anomalies include split atlas and posterior arch anomalies (Keller aplasia, arch hypoplasia/aplasias, rachischesis) and persistent epicondylar process. Axis anomalies include os odontoideum, odontoid hypoplasia, and C2 spondylolysis. Figure shows nonfusion at the anterior and posterior arches of atlas consistent with split atlas.

Conclusions
It is important to be aware of the imaging appearance of the various CVJ anomalies due to their significant clinical implications. The knowledge of normal imaging anatomy and parameters is crucial for the recognition of these anomalies. We present an interactive tutorial on CVJ anomalies. After reviewing this exhibit, the viewer should develop a practical approach for these lesions.

Detecting the Dots- MRI in Spinal Dural ArterioVenous Fistulas with Angiographic Correlation.

S Kumar¹, F Hui¹
¹National Neuroscience Institute, Singapore, Singapore

Purpose
Spinal dural arteriovenous fistula (SDAVF) is an uncommon but treatable cause of myelopathy with nonspecific clinical presentation. If left undiagnosed and untreated, it can result in significant morbidity. It is important for the neuroradiologist to be familiar with the appearance of SDAVF and suspect the diagnosis on the initial MR imaging (MRI). The purpose of this exhibit is to describe the MRI findings of SDAVFs with angiographic correlation.

Materials and Methods
We describe the normal blood supply of the spinal cord and types of SDAVFs. We describe the
findings on MRI of the spine and correlation with spinal angiogram, which is considered the gold standard for the diagnosis of SDAVF.

Results
MR imaging of the spine is the first line of investigation in patients presenting with symptoms referable to the spinal cord. T2-weighted images show hyperintensity in the central cord due to venous hypertension resulting in edema/ischemia. This may be at the level of the fistula or remote from it. It is important to examine the entire cord and look for flow voids on the surface of the cord, which represent the dilated perimedullary veins. Postcontrast T1-weighted images may show enhancement within the cord showing T2 prolongation, due to venous ischemia. Enhancing serpigenous vessels can be seen on the surface of the cord. Selective spinal angiogram should be performed in suspected cases to confirm the diagnosis, localize the fistula, demonstrate the feeding artery and the venous drainage. PC-FIESTA MR imaging has been described to be useful in elderly patients in whom spinal angiography is difficult due to tortuosity of vessels or shunting is limited due to venous hypertension.

Conclusions
Spinal dural arteriovenous fistula is a treatable cause of myelopathy and a neuroradiologist may be the first clinician to suspect it. MR imaging findings of T2 prolongation within the cord along with presence of flow voids and/or presence of serpigenous vascular enhancement on the surface of the cord should prompt spinal angiography. Selective spinal angiogram may localize the fistula remote from the site of cord signal abnormality and demonstrate the feeding artery and venous drainage.

Diffusion MRI-Tractography of the Temporal Stem: A Pictorial Review of Fiber Tract Anatomy

O Clerk-Lamalice¹, J Houde², M Descoteaux²
¹Université de Sherbrooke, Sherbrooke, Quebec, Canada, ²Sherbrooke Connectivity Imaging Lab – Université de Sherbrooke, Sherbrooke, Quebec, Canada

Purpose
Most references agree that the uncinate fasciculus, inferior occipitofrontal fasciculus and Meyer’s loop of the optic radiation pass through the stem of the temporal lobe or temporal stem. However, the anatomical definition of the temporal stem has shown some inconsistency in the literature. Some authors include also the anterior commissure, ansa peduncularis and extreme capsule in the definition (1). A previous study has presented a progressive dissection guided by three-dimensional MR renderings and cross-sectional images (2). High angular resolution diffusion imaging (HARDI) is an MR imaging (MRI) technique that permits in vivo white matter tract visualization and overcomes some of the drawbacks of diffusion tensor imaging (DTI) such as crossing, diverging or highly curved fibers (3). This technique permits better visualization of tracts in brain regions with many convergent fiber tracts such as in the temporal stem. To our knowledge, HARDI has never been used to study the anatomy of the temporal stem. Here, we
propose to use this technique to demonstrate the relationship of the temporal stem with its main tracts.

Materials and Methods
A literature review will be performed in order to accurately discuss the anatomy and function of the temporal stem. MR images: Images were acquired with a Siemens 1.5 T MRI scanner. High-resolution axial T1-weighted images were acquired with gadolinium enhancement. Single shot echo planar (EPI) sequence was used (TR:11700ms; TE:98ms; b-value:1000s/mm2; Number of diffusion directions:64; in-plane resolution: 2x2mm2; slice thickness: 2mm). Diffusion image processing and tractography: Susceptibility and motion artifacts were corrected on all images (4) and Rician noise correction was used for denoising DW images. Streamline tractography was used on the field of fiber orientation distribution function (5) using MRtrix. 120000 streamlines were reconstructed. The FiberNavigator software (6) was used to define regions of interests based on anatomical sites of interest for isolating the fiber tracts.

Results
This educational exhibit will present a literature review of the anatomy and function of the tract passing through the temporal stem. The review will focus not only on the functional importance of the temporal stem, but also on the importance of this structure in spread of tumors, infection, and seizures. A brief introduction on the HARDI technique will be presented with state of the art HARDI images of the temporal stem. Finally, emphasis on surgical recognition of this structure will be made to avoid important repercussions for the patient such as hemianopia or quadrantanopia.

Conclusions
At the end of this presentation, the viewer should be familiar with the anatomy and function of the temporal stem and its importance in tumor, infection and epilepsy propagation pathway.

KEYWORDS: DTI Tractography, Fiber Tracking
standard for evaluation of spinal vascular anatomy and pathology; however the cost and relative risk has advanced the need for the development of noninvasive techniques. Spinal MRA, conventional and dual energy spinal CTA for assessment of the spinal vasculature are described and illustrated using normal and pathologic examples. Assessment of the spinal vasculature, particularly the artery of Ademkiewicz, in the setting of aortic aneurysm and spinal dural arteriovenous fistula are demonstrated.

Conclusions
Noninvasive and invasive spinal imaging are adjunctive in the evaluation of patients with suspected spinal vascular lesions. Accurate interpretation of cross-sectional spinal vascular anatomy requires an understanding of anatomy, pathology and flow characteristics optimally demonstrated by catheter angiography. Knowledge of correlative vascular anatomy can improve diagnostic yield on invasive and noninvasive imaging techniques.

KEYWORDS: Angiography, Spinal Vascular Disorders

**Evaluation of Oral Cavity Carcinomas: A Case-Based, Computer-Interactive Tutorial**

M VanTassell¹, L Gentry², W Smoker¹

¹University of Iowa Hospitals and Clinics, Iowa City, IA, ²University of Wisconsin, Madison, WI

Purpose
Educational Objectives: 1. Review normal anatomy of the oral cavity. 2. Learn the American Joint Committee on Cancer (AJCC) criteria for staging of oral cancer carcinoma (OCCA). 3. Gain an understanding of how to assess extent of lesions in the various oral cavity subsites.

Materials and Methods
Following a brief review of pertinent normal oral cavity anatomy, we present multiple cases of OCCa in each of the top five subsites on CT/MR. We employ a computer-interactive checklist approach for systematic evaluation of tumors in the various subsites and lead the reader through a step-by-step analysis of each tumor.

Results
The AJCC tumor node metastasis (TNM) criteria for oral cavity carcinoma is useful for staging and prognosis, typically dictating treatment options. Tumor node metastasis staging, however, may be incomplete in terms of describing individual tumor extent for the variety of subsites. The top five "oral cavity" carcinoma subsites, in decreasing order of frequency, are: 1) lower lip; 2) oral tongue; 3) floor of mouth; 4) gingiva/retromolar trigone; and 5) hard palate. Although the lip and oral cavity are separated in terms of T4 lesions, these subsites otherwise share common AJCC staging criteria. The patterns of spread for tumors in these various locations, however, differ considerably, making radiological evaluation of OCCa tumors a challenge for both the radiology trainee and the experienced radiologist, given the complex anatomy and various patterns of spread. Accurate assessment of tumor extent is extremely important for appropriate tumor staging as this information impacts patient prognosis and optimal treatment options. We suggest a simplified "checklist approach" for systematic analysis of OCCa. Such an approach could be used by the radiologist to help ensure thorough imaging analysis while, at the same time, directly providing pertinent information for appropriate clinical tumor staging.
Conclusions
A simplified computer-interactive checklist is presented to assist the radiologist in systematically analyzing the extent of various subsites of OCCa. This permits the reviewer to optimize his/her imaging reports by inclusion of both pertinent positive and negative findings, thus providing accurate information for appropriate clinical staging.

Go with the Flow: Employing Arteries and Veins in the Face and Neck to Predict Lesion Origin

A Dubey¹, S Lavianlivi¹, S Pulitzer¹, D Reede², L Gentry³, R Holliday⁴, W Smoker⁵
Purpose
After viewing this module the reviewer will be able to: 1. Identify major vascular structures in the face and neck. 2. Correlate vascular anatomy to surgical landmarks in the face and neck. 3. Identify typical patterns of vascular displacement associated with commonly encountered lesions of the face and neck.

Materials and Methods
Normal anatomy of the major arteries and veins in the face and neck is reviewed, emphasizing the relationship of vessels to submandibular gland, parotid duct, major nerves and muscles. Representative cases are presented to demonstrate typical patterns of vascular displacements produced by common neoplastic and nonneoplastic processes. Ancillary imaging findings that aid in interpretation are discussed.

Results
Vascular anatomy is useful in the detection of pathology involving the parotid duct, submandibular gland, and localization of the thoracic duct. Branchial cleft and thymic cysts also can be recognized by their relationship to the carotid sheath. Additionally, lesions arising from the vagus nerve, carotid body, thyroid gland, and sympathetic chain all cause typical patterns of displacement of the carotid sheath or its contents.

Conclusions
Correct identification of major vascular structures is essential prior to surgical intervention/biopsy. An image-based algorithm is provided to assist in the development of an appropriate differential diagnosis for a lesion based on patterns of vascular displacement and/or location with reference to a vessel.

KEYWORDS: Anatomy, Head And Neck, Neck Masses
Imaging Findings of Cystic Lesions of the Head and Neck

A Missoi¹, A Agarwal¹, M Maqbool¹
¹University of Missouri School of Medicine, Columbia, MO

Purpose
To describe CT and/or MR imaging (MRI) appearance of common head and neck cystic lesions to aid in correct diagnosis and facilitate appropriate management.

Materials and Methods
The authors will review retrospectively all cases of cystic lesions of the head and neck imaged at University of Missouri Hospital and Clinics between 07/01/2010 and 10/01/2013.

Results
Cysts and cystic-appearing lesions of the head and neck have a broad imaging spectrum. They can be developmental or acquired. Majority of the cystic lesions in infants and newborn are developmental such as thyroglossal duct cyst, vascular malformations, thornwaldt's cyst and cystic hygromas. In children and adults, majority of cystic lesions are inflammatory or neoplastic in nature and include lesions such as cystic metastatic nodes, ranula and abscess. Some of the cystic lesions can mimic other lesions on imaging. This poster will convey the spectrum of imaging findings related to cystic masses of the head and neck using a variety of examples and multiple modalities. Each case will include characteristic imaging findings, relevant differentials
diagnoses, discussion of the optimal imaging strategy and pathologic correlation when available. Reference will be made to the appropriate nomenclature used in the classification of each lesion.

Conclusions
Cystic masses of the head and neck constitute a wide array of developmental and acquired lesions. Patient's age, history and physical exam as well as lesion location are important in formulating a reasonable differential diagnosis.

KEYWORDS: Cystic Neck Mass, Cysts

eEdE-130
Imaging of Referred Otalgia - What You Should Look For

L Gentry¹, W Smoker², D Reede³, T Kennedy¹, M Hartman⁴
¹University of Wisconsin Hospital, Madison, WI, ²University of Iowa Hospitals and Clinics, Iowa City, IA, ³SUNY Downstate Medical Center, Brooklyn, NY, ⁴University of Wisconsin Madison, Madison, WI

Purpose
This exhibit will provide guidance for the imaging work up of patients with ear pain and no identifiable abnormality within the ear (referred otalgia). We will demonstrate the wide spectrum of abnormalities that can present with referred otalgia and discuss the anatomical basis for referred ear pain.

Materials and Methods
The sensory innervation of the ear is quite complex with contributions arising from cranial nerves 5, 7, 9, and 10 as well as spinal nerves 2 and 3. Pathologic lesions that involve branches of these nerves distant to the ear can potentially present with symptoms of ear pain. The symptoms of ear pain can lead to erroneous work-up of the cause of pain. We will systematically review the detailed anatomy of these major cranial nerves in order to provide an understanding of the problem of referred otalgia. We will provide numerous examples of head and neck pathologies that present with referred otalgia and discuss the cranial nerve branches that are the basis of referred ear pain.

Results
Patients with ear pain may be seen initially by either an otolaryngologist or a primary care physician. Otolaryngologist may order additional diagnostic studies if the ear exam is negative. The radiologist needs to be aware of referred causes of ear pain in order to rule out sinister lesions that may be remote from the ear. Contrast-enhanced CT or MR scans that include the neck, nasopharynx, aortic arch, and upper spinal canal usually will detect the most common lesions causing referred otalgia. A primary care physician may not be as familiar with referred otalgia and order examinations dedicated to the ear. It is important to communicate to these physicians that a temporal bone CT may not be sufficient for work up of the patient.

Conclusions
Referred otalgia is a common problem encountered in head and neck imaging. Numerous etiologies must be considered during the work up in order to avoid diagnostic error. This exhibit reviews the common etiologies of referred otalgia and the neuroanatomical basis of referred ear pain.
Purpose
Sellar and parasellar region is a critical area with several vital structures including pituitary, parts of the optic pathway, cavernous sinus and its contents, carotid arteries, meninges, etc. Several important pathologies occur in this location and can provide an ultimate test to the skills of anyone dealing with imaging of brain as well as head and neck. Recognition of normal variants, identification of life threatening conditions such as aneurysms, pituitary apoplexy and cavernous sinus thrombosis, etc. without delay, identification of the extent and relationship of a tumor to the several vital structures and accurate diagnosis of various pathologies are fundamental steps in the correct management of sellar and parasellar lesions. This exhibit will serve to update the knowledge of imaging features of various sellar and parasellar lesions.

Materials and Methods
The exhibit will provide a definition of sellar and parasellar regions. A detailed imaging anatomy of the sellar and parasellar regions will be discussed with color plates, computed tomography (CT) and MR imaging (MRI) to facilitate the understanding of various pathologies occurring in this area and also the extension of pathologies from nearby anatomical areas. A brief review of embryology will be provided to understand the developmental lesions affecting pituitary and
tumors such as craniopharyngioma. Various imaging techniques will be highlighted under appropriate pathologies. Relevant clinical cases will be used to discuss the imaging features of various pathologies occurring in this location. An imaging algorithm will be provided at the end of the presentation to facilitate the imaging analysis of sellar and parasellar lesions.

Results
Sellar lesions consist mainly of the pituitary gland. Pathologies affecting the pituitary gland including developmental lesions, variants, incidental lesions and tumors will be discussed. Further, extension of a tumor to the suprasellar cistern, relationship of a pituitary tumor to the optic chiasm and invasion of the cavernous sinus as well as the skull base will be discussed. Anatomical variants at the skull base and sella and their influence on surgical treatment will be emphasized. Also, influence of MR signal characters of pituitary tumors on transphenoidal resection will be discussed. Further, relevant clinical features, laboratory investigations and posttreatment changes will be discussed. Imaging pitfalls will be highlighted particularly in the detection of pituitary tumors less than 3 mm and the available technologies will be explored. Parasellar lesions will be categorized as lesions of cavernous sinus and suprasellar region. Pathologies from the cavernous sinus including vascular lesions such as carotid artery aneurysm, carotid cavernous fistula and sinus thrombosis will be discussed. Tumors from the cranial nerves traversing cavernous sinus and the lesions originating from the dural wall of cavernous sinus will be discussed. Also developmental lesions near the parasellar region will be discussed. Finally, suprasellar lesions including developmental anomalies, infection, tumors and vascular lesions will be discussed. Posttreatment imaging features will be discussed in appropriate conditions. The importance of identifying posterior pituitary bright signals will be emphasized in relationship to suprasellar tumors. Finally, skull base lesions invading sellar and parasellar regions either directly or through perineural invasion will be discussed.

Conclusions
A review of the exhibit will help to understand the sellar and parasellar anatomy, identify various pathologies occurring in this location, guide the appropriate imaging technique and recognize the posttreatment changes.

KEYWORDS: Parasellar, Pituitary Gland, Suprasellar Mass

Imaging of Tongue Lesions - "A Tasty Pictorial Review"

P Hanagandi¹, F Goncalves², S Chakraborty¹, L do Amaral³, J Chankowsky⁴, T Nguyen¹, J Chong⁴, S Patro¹, C Torres⁴
¹The Ottawa Hospital, University of Ottawa, Ottawa, Ontario, Canada, ²Brasilia Children's Hospital, Brasilia, Brasilia, Distrito Federal, Brazil, ³Medimam – Hospital Beneficencia Sao Paulo, Sao Paulo, Brazil, ⁴Montreal General Hospital, McGill University Health Centre, Montreal, Quebec, Canada

Purpose
To highlight the imaging features of various intrinsic tongue-based lesions and extrinsic pathologies causing tongue changes.
Materials and Methods
We intend to describe the computed tomography (CT) and MR imaging (MRI) features of multiple pathologies involving the tongue with clinical correlation.

Results
The tongue forms a major component of the oral cavity and a part of the oropharynx. In this pictorial we intend to emphasize on various pathologies involving the tongue. The lesions can be intrinsic and comprising of congenital, vascular malformations and neoplasms. Extrinsic pathologies involving brainstem and skull base also can manifest with secondary changes in the tongue and comprises of skull base tumors, brain stem lesions and other pathologies along the course of hypoglossal nerve. The pictorial will highlight the imaging features of lingual thyroid, lingual dermoid, lipoma, venolymphatic malformations, tongue hemangioma, ranula, skull base pathologies like hypoglossal nerve schwannoma, squamous cell carcinoma of the tongue, lymphomas of tongue base, skull base tumors and brain stem lesions.

Conclusions
Imaging and identification of intrinsic tongue pathologies plays a vital role in their surgical management. The tongue also can serve as a clue in diagnosing brainstem and skull base pathologies.

KEYWORDS: Congenital Anomalies, Masses, Tongue
Inherited and tumor syndromes of head and neck: Neuroimaging review

P Adapa¹, M White¹, M Keiper¹, M Omojola¹, Y Zhang¹

¹University of Nebraska Medical Center, Omaha, NE
Purpose
To identify the key radiologic findings, discuss the clinical features and review the surveillance guidelines of the most common phakomatoses, multiple endocrine neoplasias and other tumor syndromes with neurological manifestations.

Materials and Methods
A review of our PACS database and personal teaching files performed by the authors. Representative cases of various imaging findings of phakomatoses, MEN syndromes and other head and neck manifestations of tumor syndromes are presented with the help of computed tomography (CT) and MR imaging (MRI). Emphasis is on syndromes that need long term surveillance.

Results
Many inherited syndromes and tumor syndromes like neurofibromatosis (types 1 and 2), tuberous sclerosis, Sturge-Weber syndrome, von Hippel-Lindau disease, cardiofaciocutaneous syndrome, PHACE syndrome, multiple endocrine neoplasias, (MEN 1 and 2 syndromes), basal cell naevus syndrome, Cowden syndrome, Carney syndrome, Li-Fraumeni syndrome and Turcot's syndrome have neurological lesions and associated malignancies, both neurological and/or non-neurological. Recognizing the characteristic lesions, differentiating between syndromes with similar manifestations is essential for accurate diagnoses and appropriate patient management. Genetic abnormalities that cause many of these syndromes are well characterized allowing us to understand the genotype-phenotype correlation. We review the various clinical and imaging characteristics of some of the more common syndromes. Imaging of the head, neck and spine and nonneurological sites in these disorders plays an important role in diagnosis, determining the extent of involvement and guiding surgical interventions when necessary. As some of these syndromes are associated with increased malignant potential (cranial, spinal or non-neurological), surveillance programs have been developed for early detection.

Conclusions
We aim to provide a comprehensive review of the most common inherited and tumor syndromes with head and neck manifestations based on radiologic and clinical characteristics. We describe prognosis and provide guidance on the appropriate use of surveillance imaging in affected individuals.

Learning Neuroradiology: A Web-Based Learning Tool for Medical Students

T Kennedy¹, N Marinelli¹, M Ostmoe²
¹University of Wisconsin Hospital and Clinics, Madison, WI, ²University of Wisconsin School of Medicine and Public Health, Madison, WI

Purpose
Neuroradiology plays an integral role in the diagnosis of neurologic conditions. It is important for medical students to have an understanding of the different types of imaging studies that are used to assist in the diagnosis of diseases affecting the brain and spine as well as the indications and contraindications of imaging tests. We have converted a lecture-based neuroradiology curriculum for 3rd and 4th year medical students into a self-paced website that enables students to learn about Neuroradiology. This interactive web-based learning module provides the student an opportunity to review neuroimaging techniques, learn neuroanatomy and navigate through a series of cases that review core concepts in the neurosciences.
Materials and Methods
Using a Google platform we were able to create a site that is easily authored by course instructors. The instructional website can be accessed by students from any location and any web-based viewing device. The site has several primary sections including a homepage, a section on imaging techniques, a section on neuroanatomy and a section with cases. The URL for the site is www.learningneuroradiology.com.

Results
At the end of the learning module, students should be able to recognize the differences between CT and MR imaging (MRI) scans of the brain and spine, understand the most common indications and contraindications for brain and spine imaging and understand the indications for contrast in neuroimaging. Students also should be able to identify important anatomical structures of the brain and spine and recognize patterns of disease including intracranial hemorrhage, stroke, tumor, infection and multiple sclerosis.

Conclusions
Medical students now require alternative tools for learning beyond a traditional lecture-based curriculum. This self-paced learning module is an effective tool that teaches students Neuroradiology and can be integrated into any Radiology, Neurology or Neurosurgery elective.

Limbic Encephalitis: What is new in Paraneoplastic Syndromes, Autoimmune Diseases and Infections?

A Ramos¹, D Plata¹, E Salvador¹, J Millan¹, L Koren¹, A Lagares¹, A Hilario¹
¹Hospital 12 de Octubre, Madrid, Spain

Purpose
1) To classify limbic encephalitis according to etiology and pathophysiology. 2) To describe MRI findings of the different subtypes of limbic encephalitis. 3) To review the differential diagnosis with other causes of temporal lobe involvement (tumor, trauma...)

Materials and Methods
In this poster we review the MR imaging (MRI) findings of limbic encephalitis and illustrate other possible causes of temporal lobe involvement.

Results
Limbic encephalitis is an uncommon entity with a subacute clinical presentation characterized by impaired short-term memory, confusion, seizures and psychiatric disorders. The most common causes are infectious and autoimmune diseases. In infectious limbic encephalitis, the herpes simplex virus type I (HSV-1) is the most commonly implicated agent. In limbic encephalitis with autoimmune origin, antibodies against neural antigens are created in the central nervous system. This encephalitis can be classified in turn as paraneoplastic and nonparaneoplastic. Antibodies in paraneoplastic encephalitis are developed predominantly against intracellular antigens (anti-Hu, anti-Ma2, anti CV2/CRMP-5), but not exclusively. Tumors most commonly associated with temporal lobe involvement are those of lung, breast and testicular origin, non-Hodgkin lymphoma, teratoma, and thymoma. In the case of autoimmune encephalitis of nonparaneoplastic
source, the antibodies are mainly produced against the cell membrane antigens, including some involved in paraneoplastic encephalitis such as NMDA receptors, AMPA receptors, GABAB receptors, anti-GAD and the classic voltage-gated potassium channels (VGKC), which are currently under investigation and known as the VGKC-complex antigens (LGI1, CASPR2 and contactin-2).

Conclusions
Advances in clinical knowledge, pathophysiology and immunology of limbic encephalitis have allowed a better characterization of the disease with a higher chance of treatment. To be familiar with imaging findings is of great importance in the timely diagnosis, appropriate treatment and patient's clinical course.

KEYWORDS: Autoimmune, Limbic Encephalitis, Paraneoplastic

**Median Raphe of the Pharynx - Complete or Not**

A Mahajan	extsuperscript{1}, B Jeun	extsuperscript{2}, F Landino	extsuperscript{3}, W Pechter	extsuperscript{4}

	extsuperscript{1}Yale University School of Medicine, Woodbridge, CT, 	extsuperscript{2}Yale University School of Medicine, New Haven, CT, 	extsuperscript{3}Yale School of Medicine, New Haven, CT, 	extsuperscript{4}Yale, New Haven, CT

Purpose
Describe the median raphe of the pharynx and discuss whether its complete or not to evaluate its importance to limit spread of infection or cancer.

Materials and Methods
Clinical database was evaluated retrospectively to illustrate normal, variant and pathologic anatomy in patients with infections and cancers. Correlation with described fascial planes was done to look for variations to the normal anatomy.

Results
Median raphe is a septum attaching the pharynx to the cervical spine. The anatomy of the raphe has not been described well. This exhibit aims to define the raphe and its extent as well its clinical significance. During discussions of the fascial planes, the raphe often is overlooked. The present exhibit aims to define it as an important structure that limits the spread of pathology from one side of the neck to the other. The relevant conditions include kissing carotid arteries, retropharyngeal infections, nasopharyngeal and oropharyngeal cancers.

Conclusions
Median raphe of the pharynx is an important structure that tethers the pharynx to the spine and is deficient beyond the pharyngoesophageal junction. It limits spread of pathology from one side of the neck to the other in the upper neck.

KEYWORDS: Anatomy

**Middle Ear Masses: A pictorial Review.**
M Simons¹, D Varon¹, F Chiang¹, G Tedesqui¹, M Castillo¹, B Huang¹, B Battal¹
¹University of North Carolina at Chapel Hill, Chapel Hill, NC

Purpose
The literature describes multiple disorders that affect the middle ear; however, often the descriptions are vague and differential diagnoses are poorly formulated. The purpose of this exhibit is to review the differential diagnosis of mass lesions that affect the middle ear and present a systematic approach to these entities using their principal location and specific imaging features on CT and MR imaging (MRI).

Materials and Methods
This exhibit discusses the appearance of tumors and other lesions that affect the middle ear using CT and MRI. We researched the literature and then selected appropriate examples from our teaching files to develop an organized and rational approach to the differential diagnosis of middle ear masses.

Results
One can narrow the differential based on the specific subsite or structures involved. Common characteristic locations include: Prussak's space and adjacent to the tympanic membrane (acquired cholesteatomas); along the tegmen tympani (cephaloceles); along the cochlear promontory (paraganglioma); and along the canal for the tympanic segment of the facial nerve (schwannoma). Some masses, including choristomas, hemangiomas, congenital cholesteatomas, adenomatous tumors, sarcomas, metastases, myeloma, and infections occur anywhere in the middle ear; however most of these are rare. In addition, vascular variants like aberrant ICA and dehiscent jugular bulb can be mistaken for intratympanic masses clinically. The presence or absence of bone erosion and the type of erosion can further subdivide these lesions into those that cause no or smooth bone erosion such as small glomus tympanicum tumors, hemangiomas, schwannomas, small cholesteatomas, and choristomas. Masses which result in more aggressive bone erosion include those described above when large, as well as jugulotympanic paragangliomas, sarcomas, carcinomas, metastases, myeloma and infections. When the tegmen tympani is violated, one also must include encephaloceles and meningoceles, which tend to spare other bony structures. Cholesteatoma of the mural type is the only lesion which may result in bone erosion without a mass. Although the diagnosis of middle ear masses is primarily based on CT, MRI allows for assessment of intracranial extension, lesion enhancement, and ADC of lesions which, when decreased, may suggest cholesteatoma, abscess, or malignancy. Hyperintensity on unenhanced T1-weighted imaging is virtually pathognomonic for cholesterol granuloma, while lesion enhancement should suggest neoplasm or granulation tissue. Digital subtraction angiography (DSA) should only be used if the mass is suspected to be hypervascular based on its MRI appearance and/or if pre-operative embolization is being considered.

Conclusions
Although middle ear masses can exhibit varying and nonspecific imaging manifestations, they usually can be characterized based on location and specific radiologic characteristics. In many cases CT and MRI can establish the diagnosis or help narrow the differential, oftentimes obviating the need for exploratory middle ear surgery.

eEdE-109
Mirror, Mirror, on the Wall, Which Is the Greatest Salivary Gland of All?

S Lam¹, J Nair², P Hanagandi³, S Patro³, C Torres², J Chankowsky², R del carpio²
¹McGill University, Montreal, Quebec, Canada, ²Montreal General Hospital, McGill University Health Centre, Montreal, Quebec, Canada, ³The Ottawa Hospital, University of Ottawa, Ottawa, Ontario, Canada

Purpose
The parotid gland is the most noble of the salivary glands. In this exhibit, the embryology, anatomy, and imaging landmarks of the parotid gland will be reviewed, followed by a discussion of the key imaging findings of the different parotid masses, illustrated with cases from our institution.

Materials and Methods
A search of our PACS will be undertaken to identify the cases of parotid masses. The cases that best illustrate the typical imaging findings on computed tomography (CT) and MR imaging (MRI) of each type of parotid lesion will be retained and used as examples in this exhibit.

Results
The parotid gland has several unique features, being the only secretory gland to have both an important motor nerve running through it, and lymph nodes within its parenchyma. These properties, as well as the important landmarks of the gland, must be thoroughly understood, as certain disease processes can be recognized based on how they affect these structures, which, in turn, will alter any potential surgical management. For this reason, imaging plays a crucial role in the evaluation of parotid gland masses. The CT and MRI findings of the different parotid gland masses will be discussed and examples of each will be given.

Conclusions
Of all the salivary glands, the parotid has the most unique anatomy and relation to several important structures in the head and neck. These features must be recognized and taken into consideration when imaging parotid lesions, in order to better determine the type of lesion, and to guide surgical management.

KEYWORDS: Anatomy, Masses, Parotid Gland
T1 and T2 hyperintense lesion that completely suppresses on fat-saturated sequences, extending from the parotid space to the parapharyngeal space through the stylo-mandibular tunnel, in keeping with a lipoma.
imaging (DWI) has revolutionized our ability to detect acute to early subacute infarctions. Many ischemic insults are tiny in size but result in significant symptomatology as they affect a complex area of the brain, e.g., the brainstem. These tiny infarctions often are missed because of suboptimal imaging (e.g., too thick slice thickness) or their decreased conspicuity on the various sequences including DWI. Comprehensive knowledge of the structural and functional anatomy of the brain can predict the location of the ischemic insult based on patient's presentation and clinical findings facilitating: #1 appropriate protocolling of MRI examinations, #2 identification of those tiny infarctions that may be otherwise easily overlooked.

Materials and Methods
A series of tiny to small stroke cases will be presented in a quiz format. Each case will start with the initial stroke symptoms and clinical findings prompting the radiologist to predict the expected site of pathology. Subsequently, the MRI correlates will be displayed and the key anatomy will be discussed using diagrams and/or animations.

Results
Comprehensive review of the structural anatomy will be performed focusing on the clinical presentation of tiny/small ischemic insults to specific, often complex areas of the brain such as: basal ganglia nuclei, different tracts in the internal capsule, thalamic nuclei, brainstem cranial nerve nuclei and specific white matter tracts, cerebellum, as well as cerebral and cerebellar peduncles. The vascular supply also will be discussed briefly.

Conclusions
Radiologists play an important role in the multidisciplinary evaluation and triaging of patients with acute stroke. Tiny infarctions may be difficult to detect requiring a comprehensive knowledge of the structural and functional anatomy of the brain. After completing this exhibit, the radiologist will more confidently correlate presenting symptoms to anatomical regions of concern and will be able to tailor the study to optimize detection of more subtle infarctions.

KEYWORDS: Brainstem, Stroke, Thalamic

eEdE-101

J Fritz¹, S Li²
¹Baystate Medical Center, Tufts Univ Sch of Med, Springfield, MA, ²Baystate Medical Center, Longmeadow, MA

Purpose
Upper airway includes nasopharyngeal to larynx. Disease entities causing acute upper airway obstruction usually are serious and life-threatening, and require immediate diagnosis and intervention. Imaging often plays an important role for accurate identification of the pathology causing upper airway obstruction. The aim of this exhibit is to describe different type of diseases causing acute upper airway obstruction, imaging techniques for evaluation and discuss the treatment, common pitfalls and clinical course of those diseases.

Materials and Methods
All cases are gathered from Baystate Health System between 2008-13. The disease entities
described are divided into different categories. They are evaluated by multimodal imaging, highlighting relevant embryologic anatomy and associated anomalies. The goal is not only to review each lesion, but to highlight potential diagnostic pitfalls, optimal imaging techniques/sequences, and current best-practice guidelines in order to streamline care.

Results
The exhibit will begin with signs of acute upper airway obstruction. Different causes of obstruction are illustrated, combining the patients's clinical history and imaging findings. Common diseases causing upper airway obstruction are described, including trauma, infectious or inflammatory diseases, foreign body, .... In some cases, radiologic-pathologic correlation are provided. Benefits and pitfalls of different imaging techniques are discussed. The treatment option and clinical course of the diseases are briefly mentioned.

Conclusions
Acute airway obstruction is a serious condition which needs urgent intervention. Clinical history often provides very useful information. Radiographic imaging are extremely important tools for detecting the underlying etiology. At the end of this exhibit, the reader will be able to accurately identify signs of acute upper airway obstruction, find most suitable imaging technique for evaluation, and help make proper diagnoses, so that timely treatment can be initiated.

KEYWORDS: Emergencies, Head And Neck
Sensorineural Hearing Loss: A Review of Cross Sectional Imaging Findings

N Coffey¹, R Glikstein¹, C Torres¹, S Patro¹
¹The Ottawa Hospital, Ottawa, Ontario, Canada
Purpose
To demonstrate the spectrum of radiographic findings of the various structural causes of sensorineural hearing loss.

Materials and Methods
Several cases have been collected that illustrate the multimodal imaging manifestations of both the common and rare diseases of the inner ear, internal auditory meatus, cerebellopontine angle and the vestibulocochlear nerve, all of which often represent pathology that primarily presents with sensorineural hearing loss (SNHL). In order to be able to identify the myriad of abnormalities, many of which can have a very subtle appearance, the neuroradiologist must be familiar with the intricate details of the normal anatomy and anatomical variants of the inner ear. After reviewing these cases and the available literature, we describe the relevant imaging findings, anatomical details and pathophysiological processes that underlie these pathologies.

Results
Hearing loss represents a major public health problem. It is the third most common chronic condition in older Americans after hypertension and arthritis. Sensorineural hearing loss is a common reason for referral for cross-sectional imaging. The most common causes of SNHL include noise exposure, ototoxicity and presbycusis which are most often due to dysfunction of the hair cells of the organ of Corti and cannot be appreciated on imaging. Neuroimaging frequently is required to exclude congenital malformation, central or peripheral nervous system neoplasm, vascular malformations and trauma amongst other etiologies. This exhibit is intended to give a comprehensive review of these pathologies. Of the potential causes of SNHL which are identifiable on imaging, vestibular schwannomas are the most common. As this is a common presentation, we have explored in some detail both the typical and unusual features of vestibular schwannomas. However, many uncommon causes of sensorineural hearing loss have typical, although subtle, features on neuroimaging that neuroradiologists should be familiar with in order to not miss other potential diagnoses. Some of the cases included demonstrate cerebellopontine angle meningioma, pilocytic astrocytoma, glioma, Wegner's granulomatosis, metastases, arachnoid cyst, hemangioma and epidermoid cyst. Cases which focus on the inner ear include temporal bone fracture, large endolymphatic sac anomaly, large vestibular aqueduct syndrome, endolymphatic sac tumor, endolymphatic sac, aneurysmal bone cyst, otosclerosis, and Ramsay-Hunt syndrome. Although the management of the pathologies is varied, many of these patients progress to consideration of cochlear implants. Therefore, the neuroradiologist must have an awareness of "what the clinician needs to know" including the pertinent features that deem a candidate suitable for cochlear implants.

Conclusions
As neuroradiologists we should be familiar with the many possible causes of SNHL in order to correctly characterize pathology of the cochlear and retrocochlear auditory pathway.

KEYWORDS: Inner Ear, Sensorineural Hearing Loss, Vestibulocochlear Nerve

6:30AM - 9:00PM
Skull Base: Review of anatomy, imaging technique, and illustration of common benign and malignant tumors at the skull base.

I Meesa1, W Bou-Assaly1, A Srinivasan2, J Wesolowski1, R Shastri1, A Hurlbut3
Purpose
To provide an overview of the skull base anatomy including the bones, apertures and contents. Discuss the skull base imaging technique at our institution and illustrate imaging features of some common benign and malignant skull base tumors.

Materials and Methods
After obtaining IRB approval, our database will be searched for pathologies of interest utilizing the RadQuery software at our institution.

Results
The exhibit will discuss and illustrate the normal skull base anatomy followed by a discussion of the skull base imaging technique and illustration of some common benign and malignant skull base tumors: Benign tumors (paragangliomas (glomus jugulare), nerve sheath tumors, meningiomas, chordomas) and malignant tumors (metastases, lymphoma/leukemia, myeloma, chondrosarcoma and osteosarcoma).

Conclusions
After reading the exhibit, the radiologist will have a better understanding of the skull base anatomy, imaging technique and will become familiar with the imaging features of some common benign and malignant skull base tumors.

KEYWORDS: Skull Base Neoplasms
Systematic Approach to Hyperdense Intracranial Masses

A Chaudhry¹, M Gul², R Peyster³

¹Stony Brook University Medical Center, Westbury, NY, ²Winthrop University Hospital, Mineola, NY, ³Stony Brook University Medical Center, Stony Brook, NY

Purpose

Hyperdense intracranial lesions are a common finding on noncontrast CT with hemorrhage being the most common cause. However, a number of additional processes can present as hyperdense lesion on CT scan which can be benign or malignant. Distinguishing between the two can be challenging and is critical for patient care as miss of a malignant lesion can prove to be fatal. Although there is overlap in imaging findings, radiologists can play a critical role in identifying key imaging feature which can be helpful in distinguishing these lesions and arriving at the diagnosis promptly. We aim to present a case based pictorial essay of hyperdense intracranial masses highlighting key points that can help to narrow the differential diagnosis.
Materials and Methods
Case-based demonstration of common and uncommon causes of hyperdense intracranial lesions. Case examples include: malignant fibrous histiocytoma, hemangiopericytoma, hematoma, lymphoma, metastasis, abscess, meningioma, gliomas, desmoids, esthesioneuroblastoma, etc. Discussion of their different clinical findings, imaging feature, treatment and prognosis of the presented entities will be discussed. A flowchart of salient features for quick reference will help summarize these key points.

Results
This exhibit focuses on the imaging findings of hyperdense intracranial masses with radiology-pathology correlation that can assist in narrowing the differential diagnosis. A stepwise approach will be used for each entity to narrow the differential diagnosis by identifying if the disease as solitary or multifocal; symmetric or asymmetric; intracranial location; presence osseous changes and involves the soft tissues. Key findings on magnetic resonance imaging (MRI) sequences (DWI, SWI, DTI, etc.) can further help delineate origin of the lesion.

Conclusions
Hyperdense intracranial lesions are a common finding on noncontrast CT and their presence should be explained as these may be from a benign or malignant process. The differential diagnosis can be narrowed utilizing age, clinical features, and imaging characteristics of the hyperdense lesion (e.g., MRI findings, enhancement pattern, necrosis, cystic degeneration, etc.). By the conclusion of the presentation, the viewer should be able to aid in the work up, guide any potential biopsy and recommend appropriate imaging follow up.

That's a Nothing: Common Brain MR Artifacts and Pitfalls Encountered by Radiologists in Training

M Whitehead¹, A Choudhri²

¹Children’s National Medical Center, Arlington, VA, ²University of Texas Health Science Center/LeBonheur Children’s Hospital, Memphis, TN
Purpose
To the untrained eye, artifacts, normal variants, and physiologic developmental changes encountered on brain MR can be mistaken for disease. The purpose of this exhibit is to depict some of the more common of these pathologic mimickers.

Materials and Methods
Selected images from brain MR exams depicting various artifacts, variants, and normal phenomena are reviewed and exhibited. Didactic explanations will be provided with correlative CT images when appropriate.

Results
Many types of signal alterations on brain MR examinations are nonpathologic. While elementary to the seasoned radiologist, they may be a source of distress to the radiologist in training. It is imperative that these disease imitators be recognized as such. In this exhibit, signal changes reflecting the following entities will be presented: cerebrospinal fluid (CSF) flow voids, vascular pulsation artifact, perivascular spaces, parenchymal and meningeal mineralization, immature myelin/terminal myelination zones, arachnoid granulations, asymmetric petrous apex pneumatization, diffusion-weighted imaging (DWI) skull base artifacts, and corticospinal tract/optic radiation hyperintensity.

Conclusions
Signal alterations reflecting nonpathologic processes such as artifacts and variant anatomy are commonly encountered on brain MR. It is important for radiologists in training to recognize the common appearance of these various signal changes to avoid misdiagnoses.

KEYWORDS: Artifacts, Normal Variant
The Embryologic Cervical Aortic Arch

C Torok¹, R Ringel¹, P Gailloud¹, L Gregg¹
¹The Johns Hopkins Hospital, Baltimore, MD

Purpose
Since its original description in 1914, the cervical aortic arch has been variably defined throughout the literature. The most common usage of the term is as a general descriptor of an abnormally high position of the aortic arch extending into the lower neck, potentially presenting clinically as a pulsatile mass. However, this definition encompasses a wide variety of underlying aortic arch configurations, ranging from pseudocoarctation and circumflex aortic arches to what we define as the embryologically true cervical aortic arch. The purpose of this study was to review the cervical aortic arches described in the literature, identify the number of cases representing true cervical aortic arches, and reclassify the remaining arch types.
Materials and Methods
A PubMed search of the literature was conducted using the search term "cervical aortic arch", limiting the text search field to Title/Abstract and English. This yielded 54 search results. Nine of the articles were excluded due to inadequate description or imaging, such that the final number of articles for review was 45. Three articles presented two separate cases, with a final sample size of 48 cases. The images depicting the individual cases were reviewed by one diagnostic neuroradiologist, one interventional neuroradiologist, and one anatomist/medical illustrator. Based on aortic arch embryology and the spectrum of aortic arches presented in the reviewed cases, the following classification scheme was identified: Type 1: True embryologic cervical aortic arch (with separate origins of the internal and external carotid arteries from the arch), Type 2: Right aortic arch with aberrant left subclavian artery, Type 3: Left circumflex aortic arch, and Type 4: Right circumflex aortic arch. Each case then was classified collectively by the group with one or a combination of these aortic arch types. A Type 0 arch represented aortic arches that had normal branching patterns.

Results
Of the 48 cases reviewed, 19/48 (39.6%) of cases were Type 0 (reflecting coarctation or pseudocoarctation), 7/48 (14.6%) of cases were Type 1 (Figure 1A), 4/48 (8.3%) of cases were Type 2, 4/48 (8.3%) of cases were Type 3, and 12/48 (25%) of cases were Type 4 aortic arches (Figure 1B). One additional case exhibited features of both a Type 1 and Type 3 aortic arch. Another single case exhibited features of both a Type 1 and Type 4 aortic arch.

Conclusions
Our findings demonstrate the various types of aortic arches that have become included under the umbrella term "cervical aortic arch," which is applied widely to any type of aortic arch that extends into the neck. However, we believe that a more precise and developmentally correct description of aortic arches is warranted, including recognition of "true" cervical aortic arches where the third arch persists in an embryologically high position in the neck with separate origins of the internal and external carotid arteries. Other types of aortic arches are best described based on their underlying ascending, branching and descending configuration, as well as the degree of cervical extension. True cervical aortic arches are always positioned cephalad because of their embryologic third arch origin. Other types of arches with regression of the third arch that demonstrate extension into the neck likely reflect a varying spectrum of migrational anomaly secondarily in the developing embryo. Normal arches (39.6%) and right circumflex arches (25%) were misidentified most commonly as cervical arches.

KEYWORDS: Anatomy, Aortic Coarctation
The Lost Art of Interpreting Skull Abnormalities: Appearance on CT and MRI Imaging

M Westpfal¹, C Brown¹, B Wilson², S Shah², M Carleton¹, J Smith¹, S Chaudhary¹
¹Geisinger Health System, Danville, PA, ²Geisinger Health System, N/A

Purpose
At one time, skull plain films played an important part in diagnosing intracranial abnormalities and systemic disease. As CT scanning and MR imaging (MRI) have become more prevalent in cranial imaging, skull plain film images have become relatively rare. Frequently, radiologists are
more familiar with the findings of the intracranial contents than the skull. The purpose of this exhibit is to examine the lesions that can occur in the cranium and demonstrate their appearance on CT and MRI. An approach to the differential diagnosis of these lesions will help the radiologist comfortably evaluate these lesions.

Materials and Methods
The electronic exhibit will review pertinent anatomy and review various skull abnormalities in that context. Computed tomography (CT) and MRI images of various cranial lesions with discussion will delineate these findings and aid the radiologist in diagnosing these lesions.

Results
The cases presented will include congenital/developmental changes, metabolic and hematologic changes, and benign and malignant lesions and other various abnormalities, such as Paget's. Their characteristics will be contrasted with other similar lesions to help develop a differential of these lesions. Their involvement in the inner or outer tables or the diploic space, and their densities also will help to narrow the differential of a particular lesion.

Conclusions
Many radiologists are not comfortable with the diagnosis of skull abnormalities. This exhibit is designed to examine the spectrum of changes in the cranium and to aid the radiologist in developing a differential diagnosis of any finding in the skull.

KEYWORDS: Differential Diagnosis, Skull

eEdE-114

The Piccadilly Circus of the Head and Neck: Cross Sectional Imaging and Angiography of the Pterygopalatine Fossa

Ma M1, Alexander MD1, Metting SW1, Caruso P2, Yousuf N3, Patel MR1
1Santa Clara Valley Medical Center, San Jose, CA, 2Massachusetts General Hospital, Boston, MA, 3Bloomington Radiology, SC, Normal, IL

Purpose
The pterygopalatine fossa (PPF) is the convergence of numerous structures of the oral and nasal cavities, nasopharynx, orbits, masticator space, cavernous sinus, and the middle cranial fossa. The PPF may permit spread of tumor and infection to and from the skull base and head and neck. Knowledge of its anatomy and involvement in various disease processes is imperative for neuroradiologists. This educational exhibit reviews the anatomy of the PPF and its connections, as well as various pathologies involving this region.

Materials and Methods
Anatomy of the PPF, including its connections and boundaries, are reviewed using multiple imaging modalities. Numerous pathologic processes involving the PPF are presented. Further demonstration is made of routes of spread of disease through the PPF with attention to specific implications for surgical and radiation therapy planning.

Results
The boundaries of the PPF, as well as its contents and communications, are readily evaluated by computed tomography (CT) and MR imaging (MRI). Illustrative examples provided include perineural and local spread of malignancy, osseous tumors, lymphoma, juvenile nasopharyngeal
angiofibroma, meningeal pathologies, and infection. To tailor evaluation for these processes, utility of specific MRI sequences is discussed. Angiography also is considered as appropriate, specifically with respect to the role of endovascular therapies.

Conclusions
Knowledge of the complex anatomy of the PPF is essential for neuroradiologists. Important anatomical relationships with the orbit, nasal and oral cavities, nasopharynx, masticator space, and middle cranial fossa can be evaluated with cross-sectional imaging and angiography. Such relationships are crucial for identifying easily missed processes and spread of disease. Knowledge of these structures and processes allows neuroradiologists to better inform therapeutic management.

KEYWORDS: Anatomy, Angiography, MR Imaging

6:30AM - 9:00PM

The truth will set you free: what you need to know about the autonomic ganglia in the head and neck

W Bou-Assaly¹, I Meesa¹, A Srinivasan²
¹University of Michigan, Ann Arbor, MI, ²University of Michigan Health System, Ann Arbor, MI

Purpose
The autonomic nervous system is formed by two functional divisions, sympathetic (thoracolumbar) and parasympathetic (cranio-cervical and sacral). The purpose of this exhibit is to review the cranio-cervical autonomic system, detailing the anatomy and locations of its corresponding ganglia and nerve supply, using cross-sectional imaging examples, as well as discussing their function and presenting examples of their most frequent pathology.

Materials and Methods
A complete literature review of the autonomic nervous system anatomy and function will be reviewed and discussed in the exhibit. After obtaining IRB approval, our database will be searched for pathologies of interest at our institution.

Results
The autonomic nervous system is concerned with processes normally beyond voluntary control and consciousness. The effects of its two divisions, sympathetic and parasympathetic on the organs, are antagonistic. The stimulation of the sympathetic division results in outburst of activity (fight and flight), while stimulation of the parasympathetic division results in effects concerned with conservative and restorative processes. In this exposition we will review the cranio-cervical autonomic nervous system, detailing the anatomy and locations of its corresponding ganglia and nerve supply (otic, pterygopalatine, ciliary, submandibular, etc.), using cross-sectional imaging examples, as well as discussing their function and presenting examples of their most frequent pathology, such as perineural spread of tumor and carotid dissection causing Horner's syndrome.

Conclusions
After reading the exhibit, the reader will have a better understanding of the anatomy, distribution, function and imaging findings of the cranio-cervical autonomic system, with examples of its most frequent pathology.
SCG - Superior cervical ganglion, MCG - Middle cervical ganglion
CTG - cervicothoracic or stellate ganglion
ICA - Common Carotid artery, IJV - Internal jugular vein, SY.Ch - Sympathetic chain

Triangles in Neuroradiology

M Alexander¹, M Ma¹, S Metting¹, R Pandit¹, M Patel¹
¹Santa Clara Valley Medical Center, San Jose, CA

6:30AM - 9:00PM
Purpose
Geometric shapes can be very helpful in identifying both anatomy and pathology. A review of
the notable triangles within the field of neurology and neuroradiology will be presented, as well
as a brief biography of the historical figures responsible. The importance of these structures and
relevant anatomy in relation to pathology will be presented.

Materials and Methods
Several triangles in neuroradiology are discussed with illustrative images. Some triangles refer to
triangles constructed by actual contents, such as the myoclonic triangle or the superior sagittal
sinus. Other useful triangles are inferred by the relationship of adjacent structures, such as the
retrotracheal triangle, sylvian triangle, and Wackenheim's triangle of silence.

Results
The myoclonic triangle, also known eponymously as the triangle of Gillian and Molleret, is a
feedback circuit involving the deep cerebellar nuclei and brainstem. The rubro-olivary tract,
inferior olivary nucleus, Purkinje cells, and dentate nucleus are involved in this circuit, which
modulates motor function in the spinal cord. The dense triangle and empty triangle signs can be
used to identify venous sinus thrombosis on unenhanced and contrast-enhanced CTs,
respectively. The sylvian triangle is an inferred structure visible on lateral projections during
cerebral angiography. Bounded by middle cerebral artery branches, this landmark can indicate
presence and location of supratentorial masses. Wackenheim's triangle of silence is an additional
angiographic marker of intracranial mass effect inferred by the venous drainage of the posterior
fossa. Surgical triangles relied upon for operations involving the cavernous sinus or adjacent
structures can be discerned in neuroradiology. In head and neck imaging, the retrotracheal
triangle, also known as the Raider triangle, can be used to identify subtle plain film evidence of
vascular, esophageal, mediastinal, and neck soft tissue pathologies.

Conclusions
The use of triangles, both perceived and inferred, can aid in understanding and identification of
subtle pathologies in neuroradiology, as well as aiding understanding of fundamental
neuroanatomy.

eEdE-126

Unusual patterns of arachnoid granulations: A pictorial review:

M Bagheri1, C Torres2, J Chankowsky2, J Nair3, R Del Carpio-O'Donovan3
1Montreal General Hospital, McGill University Health Centre, Montreal, QC, 2Montreal
General Hospital, McGill University Health Centre, Montreal, Quebec, 3Montreal General
Hospital, McGill University Health Centre, Montreal, QC

Purpose
The purpose of this educational exhibit is to review unusual patterns of arachnoid granulations.

Materials and Methods
We shall present a variety of unusual cases of Arachnoid Granulations mimicking pathologic
conditions on computed tomography (CT) and magnetic resonance imaging (MRI).
Results
Arachnoid granulations are commonly seen on CT scan and brain MRI. In a minority of cases, these arachnoid granulations may present unusual imaging patterns. Imaging findings may include large erosions in the inner table or even complete defects in the calvarium, suggesting a pathological lytic process in the skull. They may also penetrate into the dural sinuses mimicking the pattern of dural sinus thrombosis.

Conclusions
A radiologist should be familiar with unusual patterns of arachnoid granulations in order for them to be differentiated from pathologic entities.

KEYWORDS: Arachnoid Granulation, Dural Sinus, Skull

What Stems from the Brainstem?

S Lam¹, P Hanagandi², F Goncalves³, L do Amaral⁴, C Torres⁵, J Chankowsky⁵, R del carpio⁵
¹McGill University, Montreal, Quebec, Canada, ²The Ottawa Hospital, University of Ottawa, Ottawa, Ontario, Canada, ³Brazilia Children's Hospital, Distrito Federal, Brazil, ⁴Hospital da Beneficência Portuguesa and Hospital São José-São Paulo, São Paulo, Brazil, ⁵Montreal General Hospital, McGill University Health Centre, Montreal, Quebec, Canada

Purpose
Pathologies affecting the brainstem are diverse and occasionally can be challenging to differentiate on imaging because of their nonspecific appearance. The purpose of this exhibit is to categorize brainstem lesions, and to describe their epidemiology, presentation, key imaging findings, and differential diagnoses.

Materials and Methods
Brainstem lesions can be classified as focal or diffuse, with further subdivisions based on etiology. A search of our PACS will be undertaken to identify patients with brainstem lesions. The cases that best illustrate the typical imaging findings of lesions in each category will be retained and used as examples in this exhibit.

Results
Brainstem lesions can be classified as focal or diffuse. Focal lesions generally are well defined and confined to a single brainstem segment, whereas diffuse lesions are larger, with ill-defined borders, occupying more than half of a brainstem segment, or extending across more than one segment. Focal and diffuse brainstem lesions can be further subdivided into tumor, ischemic, infectious, demyelinating, degenerative, metabolic, traumatic, and vascular. Some of these entities can present both as focal and as diffuse lesions. Examples of each category will be illustrated with cases from our institutions, and their characteristics and imaging findings will be highlighted.

Conclusions
Because brainstem pathologies can be so diverse, it is useful to divide them into categories to facilitate conceptualization. Placing brainstem lesions into categories, presenting different examples in each category, and reviewing their characteristics will enable better differentiation and identification of such lesions on imaging.
What’s Eating You?: Destructive Lesions of the Skull Base

J Reid¹, D Chen¹, E Ledermann¹, S Pulitzer¹, D Reede¹
¹SUNY Downstate University Medical Center, Brooklyn, NY

Purpose
• A systematic approach for imaging and diagnosing invasive osseous skull base lesions. • How to evaluate the neural foramina and correctly identify involvement of nerves and vessel. • Key concepts regarding CT and MR evaluation destructive skull base lesions. • Common and uncommon patterns of disease presentation of invasive skull base lesions.
Materials and Methods
Cases selected from the teaching file of three major medical centers will be presented in a quiz format to demonstrate destructive skull base lesions. Pertinent anatomy is presented using illustrations, animations and corresponding cross-sectional images.

Results
After a comprehensive review of the key anatomical points cases are shown to demonstrate patterns of disease presentation. Key anatomical structures that need to be evaluated in specific areas are emphasized. Pathology presented: Cholesterol granuloma, Chordoma, Giant cell tumor, Metastasis, Invasive pituitary adenoma, Interosseous meningioma, Mastoiditis with osseous break through, Paraganglioma, Wegner's granulomatosis, Schwannoma, Malignant otitis externa and Fibrous dysplasia.

Conclusions
Many different types of pathologic processes involve the skull base ranging from primary neoplasms, secondary invasion from head and neck neoplasms, intracranial neoplasms and infectious or inflammatory processes. What is unique to the skull base is that diseases can spread from the head and neck to the brain/intracranial compartment and vice versa. An in-depth understanding of the anatomy and anatomical structures within the neural foramina can help localize the disease process and lead to the proper diagnosis and treatment. An understanding of the common pathways of disease spread through neural foramina and into the soft tissues of the head and neck is required to localize the primary site of disease as well as detect and predict spread to adjacent areas. This multi-media educational exhibit will present a concise and rational approach to evaluating and diagnosing lesions involving the skull base and neural foramina.

KEYWORDS: Neural Foramen

When Zebras Look Like Horses: Atypical Teratoid-Rhabdoid Tumor (AT-RT) and its Mimics

M George 1, S Li 2
1Baystate Medical Center, Tufts University School of Medicine, Springfield, MA, 2Baystate Medical Center, Tufts University School of Medicine, Longmeadow, MA

Purpose
Atypical Teratoid-Rhabdoid Tumor (AT-RT) is a malignancy of early childhood with a rapid and devastating course. Because AT-RT was described only relatively recently (1), and has imaging and histological characteristics that overlap with less aggressive neoplasms, AT-RT presents a diagnostic challenge. Further, Hilden et al (2) have demonstrated improved survival time with new intensive therapies, making early and accurate diagnosis critical. The aim of this educational exhibit is to describe AT-RT both generally and in contradistinction to its potential mimics in the posterior fossa and supratentorially, so that early diagnosis can lead immediate intervention and increased survival.

Materials and Methods
All cases have been gathered at Baystate Hospital between 2005-2013, with histological correlates provided. An extensive literature search will be performed to describe AT-RT,
medulloblastoma (MB) and supratentorial primitive neuroectodermal tumor (S-PNET) in terms of the classical six questions of journalism: who, what, when, where, how (it presents), and why we care (treatment).

Results

Who (pathology). The sine qua non of AT-RT is a population of rhabdoid tumor cells that demonstrates brisk mitotic activity. In over 70% of lesions, sheets of primitive neuroectodermal cells are present which may obscure the rhabdoid component, leading to a misdiagnosis of S-PNET or MB (3). Immunohistochemical markers now reliably differentiate the entities. Grossly, there is a variable degree of hemorrhage, necrosis, and calcification. When (epidemiology). AT-RT typically presents earlier than MB, with a mean age of approximately 2 years, but is roughly coeval with S-PNET. While the overall incidence has increased artifically due to refinement in immunohistochemical analysis, AT-RT remains rare, composing only 7% of CNS tumors in children less than two years of age (4). No gender or racial predominance has been reported.

What (it looks like). There is overlap in the imaging characteristic of AT-RT and its mimics. The lesions tend to be hyperdense on CT, mixed on both T2- and T1-weighted images, and demonstrate heterogeneous but strong enhancement. Characteristics which may help differentiate AT-RT are a cystic component and foci of T1-shortening (4). All lesions may demonstrate restricted diffusion. Where. AT-RT may arise in the posterior fossa (50%), supratentorially (40%) or in both compartments. Localization in the cerebellopontine angle is suggestive of AT-RT. How (presentation). Presentation is nonspecific and may stem either from increased intracranial pressure or local distortion of brain parenchyma. Why we care (natural history and treatment). Whereas PNET-MB may be treated with subtotal resection and traditional chemotherapy, these measures have been ineffective with AT-RT. Recently, both total resection and myeloablative chemotherapy with autologous stem cell rescue have been shown to improve survivability (5).

Conclusions

AT-RT is an aggressive malignancy of the central nervous system in very young children. Because new therapies are being developed, familiarity with this rare entity is critical. Further, the radiologist may yet play a critical role in differentiating AT-RT from its more commonplace mimics, guiding the interdisciplinary team to confirmatory immunohistochemistry and a better outcome for the child.

KEYWORDS: ATRT, Pediatric Neoplasms
“Going for the jugular”: A computer-interactive, case-based review of jugular foramen “lesions.”

C Reilly¹, A Singh¹, W Smoker², C Bazan¹

¹The University of Texas Health Science Center San Antonio, San Antonio, TX, ²University of Iowa Hospitals and Clinics, Iowa City, IA
Purpose
1) Recognize the computed tomography (CT) and MR imaging (MRI) characteristics of jugular foramen lesions, including common and uncommon benign and aggressive pathology. 2) Understand the anatomy of the jugular foramen and the surrounding posterior skull base.

Materials and Methods
To facilitate review and discussion of jugular foramen lesions and anatomy, we present CT and MR imaging from representative cases in a computer-interactive quiz format. Unknown cases are followed by the diagnosis with discussion of each individual entity and key imaging characteristics. These cases also are used to demonstrate relevant anatomy.

Results
We present a selection of cases collected from our institutions of patients with jugular foramen lesions, both benign and malignant. Included are jugular paragangliomas, vagal paragangliomas that extend superiorly, schwannoma, meningioma, cholesterol granuloma, metastatic disease, jugular megabulb, high riding jugular bulb, jugular dehiscence, chordoma, Paget disease, and fibrous dysplasia. We emphasize key imaging characteristics of these entities and the complex anatomy of the jugular foramen and posterior skull base using annotated images followed by answers in an interactive quiz format. Figure shows a large enhancing paraganglioma in the right jugular foramen.

Conclusions
This educational exhibit demonstrates the varied common and uncommon, benign and malignant lesions arising from within or around the jugular foramen. Included is a discussion of their multimodality imaging characteristics and a discussion of the essential regional anatomy. We provide an interactive learning experience after which the reviewer will feel more confident when encountering a lesion in the jugular foramen.

KEYWORDS: Jugular Foramen, Metastases, Paraganglioma
Purpose
The utility of oblique sagittal computed tomography (CT) images in the depiction of the long axes of the malleus and incus, the long axis of the cochlea, the superior semicircular canal and the facial nerve canal is well documented (1). The purpose of this exhibit is to demonstrate the utility of nonoblique sagittal CT imaging in the evaluation of pathologic processes involving the temporal bone.

Materials and Methods
Two board-certified neuroradiologists retrospectively reviewed consecutive patients who had undergone high resolution CT of the temporal bone across five academic-affiliated institutions over a nine-month period. Scans were obtained on Aquilion (Toshiba), Sensation 16 (Siemens Healthcare), and Sensation 64 (Siemens Healthcare) scanners. The studies were performed at 0.5 – 1 mm section thickness and 0.3 – 1 mm spacing at 120 kV and 125–400 mAs. Sagittal reconstructions were created at the CT console with 1 mm thickness at 1 mm intervals and with zero angulation in the mediolateral plane. In cases of patient head rotation, sagittal images were reconstructed parallel to the long axis of the bony EAC. Temporal bone pathologies were categorized according to the anatomical subsites of external ear, mastoid/temporal cranial junction/petrous apex, middle ear, inner ear and vestibular aqueduct, and osseous foramina for the facial and vestibulocochlear nerves.

Results
We present infectious, inflammatory, traumatic, neoplastic, and vascular pathologies of the temporal bone with particular attention to the external auditory canal. Representative cases, also drawn from institutional teaching files, include malignant otitis externa, labyrinthitis ossificans, tegmen tympani dehiscence, paraganglioma, jugular diverticulum, and dilated vestibular aqueduct. Sagittal images are useful in evaluating oblique fractures or evaluating fractures which run parallel to the axial or coronal plane. Sagittal images also provide an excellent en-face evaluation of Prussak’s space and tympanic ring where attic cholesteatoma erosions can produce a dilated Prussak’s space six times as large in height and twice as large in width compared to normal individuals (2). Finally, sagittal images better evaluate the inferior wall of the tympanic facial nerve canal compared to axial and coronal images and may alert surgeons to facial nerve dehiscence (3).

Conclusions
The addition of nonoblique sagittal reformatted images to conventional axial and coronal views...
of the temporal bone improves the assessment of temporal bone pathology and optimizes pre-operative planning, especially in processes involving the bony external auditory canal.

KEYWORDS: Temporal Bone

Figure 1: CT Temporal bone without contrast in a 80-year-old female with left hearing loss. (A) Axial image of the left temporal bone demonstrates fusiform erosion and remodeling of the left EAC compatible with remote primary canal cholesteatoma. (B) Sagittal image at the same level best demonstrates the extent of bony thinning at the junction of the anterior and inferior walls of the EAC.

A Bit of a Twist on Head and Neck Imaging: When PET/CT has made a significant impact on changing the course of action relative to the patient care decision making process.

D Behr-Ventura¹, A Aiken¹, B Barron¹, K Baugnon¹, D Brandon¹, A Corey¹, P Hudgins¹, A Kendi¹
¹Emory University School of Medicine, Atlanta, GA

Purpose
The neuroradiologist with Head and Neck expertise should be familiar with the added benefits of PET/CT. We intend to illustrate the added value of PET/CT in Head and Neck imaging through presentation of cases where PET/CT had significant impact on patient care.

Materials and Methods
A retrospective review of PET/CT Head and Neck cases was performed from 2010-2013. Cases with interesting unexpected findings were identified and chart reviews were performed.

Results
The following cases will be presented in our exhibit: -Nasal carcinoma with septal involvement only seen on PET, not appreciated at CT, but positive on pathology. - Head and Neck cancer with unexpected distant metastasis during staging (liver, lung, pancreas, bone). - Unexpected nodal disease. - Post-therapy laryngeal carcinoma recurrence. - Detection of unknown primaries in cases presenting with cervical nodal disease. - Synchronous primary tumors. - Recurrences. - Metastasis during surveillance.

Conclusions
Even with dedicated Head and Neck radiologists, experienced oncologic surgeons, and high quality cross-sectional CT and MR imaging, PET/CT adds value to patient care. The addition of the metabolic information from PET is an important tool for caring for the patient with head and neck cancer. In this educational exhibit, we have shown how PET/CT can change stage, prevent unnecessary treatment, and reveal lesions that might not have been adequately treated.

KEYWORDS: Head And Neck, PET/CT

AJCC Classification of Head and Neck Cancer: A Radiologist’s Perspective

K Al-Ramadhani¹, J Chankowsky², J Nair², C Torres², H Remy²
¹McGill University Health Centre, Montreal, Quebec, Canada, ²Montreal General Hospital, McGill University Health Centre, Montreal, Quebec, Canada

Purpose
Through this interactive model, the audience is made aware of the American Joint Committee on Cancer (AJCC) staging of various types of head and neck cancer using an algorithmic approach. We shall use a case-based approach focused on computed tomography (CT) and MR imaging (MRI) of different head and neck cancers involving the nasopharynx, oropharynx, oral cavity and larynx (amongst others). We shall emphasize normal anatomy as well as nodal staging to improve the participant's interpretation of these conditions.
Materials and Methods
A PACS search will be undertaken to identify selected cases. The representative images will be combined with multiple choice questions focusing on tumor location, tumor size and extent, invasion of surrounding structures, presence of nodal metastases and the presence of distal metastases, as to arrive at the correct TNM staging. Emphasis will be placed on the prognosis and management plan of each case.

Results
AJCC staging system is the most widely used staging system for cancers affecting the head and neck. Staging is considered an important means of communication between the referring physician and the interpreting radiologist. It helps with patient management and prognosis. The radiologist should be familiar with the staging system of head and neck cancer.

Conclusions
Accurate staging of head and neck cancer is an important element in the formulation of a management plan as well as determining the prognosis of various tumors. The radiologist's input is essential in staging and therefore knowledge of TNM staging is critical.

KEYWORDS: Cancer, Head And Neck, Staging
Findings:
Large right sided transglottic tumor, centered in the true vocal cord, and extending laterally into the paraglottic space.
It is extending to the supra- and infra-glottic regions and is invading the cricoid and thyroid cartilages.
No evidence of metastatic lymphadenopathy.

Stage T4AN0M0

Approach to Sinonasal Pathology

J Gorodenker¹, A Singh¹, R Taheri²
¹George Washington University Hospital, Washington, D.C., DC, ²George Washington University Hospital, Washington, DC
Purpose
The purpose of this electronic educational exhibit is to teach an organized approach to sinonasal imaging, using multiple didactic and interactive cases to illustrate key and practical concepts. This approach aids in the clinical triage of radiologic pathology, and stresses clinically important findings while avoiding common pitfalls. Particular attention is given to whether a process appears aggressive or indolent, and whether further imaging with MRI is warranted.

Materials and Methods
The exhibit is divided into CT, MRI, Nasal and Special Cases sections. The CT section emphasizes the importance of osseous erosion as a sign of aggressive disease. The participant will also characterize lesions by density. The major obstructive inflammatory patterns of sinus disease are reviewed, and the relevant anatomy illustrated. The MRI section emphasizes the superior sensitivity of MRI in fully evaluating the extent of aggressive disease, including soft tissue and bone marrow infiltration, and in distinguishing cystic components of masses from trapped secretions or mucosal hypertrophy. The Nasal section contains interactive cases that illustrate the relevant clinical anatomy and pathology.

Results
The participant will identify erosion as related to neoplastic and infectious processes and contrast their appearance with cases of bone remodeling and expansion, sinus atelectasis and pressure demineralization, which reflect more indolent processes. The participant will learn to distinguish the above from other osseous pathology, including fibrous dysplasia and Paget's. The participant will distinguish mucosal or polypoid lesions from masses, and recognize the hyperattenuating CT appearance of mycetoma, inspissated mucus, and blood products. The participant will differentiate mass-like enhancement from mucosal enhancement on MRI, and will learn to distinguish the restricted diffusion associated with a hypercellular mass from that of a viscous collection. The participant will also recognize MR signal loss in the sinuses related to fungal disease. The nasal section focuses on nasal septal pathology, and stresses the concept that any solid mass in the nasal region is potentially aggressive. The Special Cases section reviews the classic locations associated with the more common "anatomically distinctive" sinonasal tumors such as juvenile angiofibroma, and their typical appearance and distinguishing features, as well as clinically relevant pathophysiology. The exhibit concludes with a collection of multiple choice questions to test the participant's newly acquired knowledge.

Conclusions
An organized diagnostic approach to the sinonasal region is presented using multiple interactive cases to review and emphasize clinically relevant findings, help avoid common pitfalls, and aid in identifying distinguishing features of aggressive and indolent pathology.

6:30AM - 9:00PM

Arterial Anomalies of the Middle Ear: A Pictorial Review with Clinical-Embryologic and Imaging Correlation

A Sullivan¹, G Moonis², A Quesnel³, H Curtin³
¹BIDMC, Jamesville, NY, ²Beth Israel Deaconess Medical Center, Boston, MA, ³Massachusetts Eye and Ear Infirmary, Boston, MA
Purpose
Arterial anomalies of the temporal bone are rare, but critical variations of anatomy which are important to detect on imaging studies. Failure to detect these abnormalities pre-operatively can lead to significant complications during middle ear surgery. A thorough understanding of the anatomy of the different types of persistent stapedial artery (PSA) in addition to the classical aberrant internal carotid artery is important for detecting these abnormalities.

Materials and Methods
The embryologic development of the aberrant internal carotid artery and persistent stapedial artery will be reviewed with a focus on anatomy. CT images from cases of aberrant internal carotid artery (ICA) and the various types of persistent stapedial artery will be displayed along with histopathologic and clinical correlates. The types of anomalies displayed will include PSA arising from the caroticotympanic artery, PSA arising from the inferior tympanic artery with an aberrant ICA, PSA arising from the inferior tympanic artery without an aberrant ICA, and PSA arising from a fenestrated internal carotid artery. In this variant, the internal carotid artery is present but small and there is a large vessel representing the inferior tympanic artery. These vessels join again to form a normally sized transverse petrous carotid artery.

Results
Anomalous arteries of the middle ear may be detected incidentally, or may present with symptoms or a retrotympanic red mass. Regardless, recognition of these vascular structures is vital to pre-operative patient care since misdiagnosis can lead to disastrous clinical consequences. While the CT appearance of aberrant internal carotid artery is characteristic, various types of PSA exist each with their own unique CT findings. Classically, PSA has been described as occurring with or without an aberrant ICA. A more detailed assessment of the embryology and anatomy of the four different types of PSA will enhance our understanding of these anomalies.

Conclusions
This review of the arterial anomalies of the middle ear will improve awareness of, and therefore detection of, these rare anomalies.

Can’t Take My Eyes Off the Post-op Eye: Comprehensive Imaging Assessment of the Post-operative Orbit in Adults and Children.

F Nasseri¹, S Nabavizadeh¹, L Loevner¹, A Vossough¹, S Mohan¹
¹University of Pennsylvania, Philadelphia, PA

Purpose
• To present a simplified, yet comprehensive and systematic review of the imaging spectrum of the post-operative orbit in adults and children. • To familiarize the radiologist with a broad range of oculoplastic and orbital surgeries and different types of orbital implants and prostheses. • To highlight the imaging features of potential surgical complications.
Materials and Methods
1) Orbital surgeries: a) Orbital wall reconstruction, orbital augmentation and decompression. b) Orbital enucleation, evisceration and exenteration with globe prostheses. 2) Lacrimal apparatus surgery such as dacryocystorhinostomy and nasolacrimal duct stents. 3) Strabismus surgery. 4) Glaucoma surgery. 5) Retinopexy and scleral buckles. 6) Lens surgery and implants. 7) Eyelid surgery such as blepharoplasty and eyelid weights.

Results
Imaging plays a pivotal role in the postoperative management of patients with orbital disease, facilitating early diagnosis of postoperative complications as well as long term follow-up assessment. The development of novel surgical approaches and techniques in oculoplastic and orbital surgery, as well as advances in the development of biocompatible materials offer a wide range of alternatives to traditional methods and implants for orbital surgeries.

Conclusions
Imaging assessment of the postoperative orbit remains challenging even for an experienced neuroradiologist. Oculoplastic and orbital surgeries are common and familiarity of radiologists with imaging findings of the wide ranging spectrum of postoperative changes are crucial as a part of multidisciplinary team.

Cervical Lymph Node Metastasis, a Systematic Review of CT, US, MRI and FDG-PET with pathological correlation.

G Gavern¹, O Teytelboym²
¹Mercy Catholic Medical Center, North Wales, PA, ²Mercy Catholic Medical Center, Darby, PA

Purpose
Accurate identification of cervical lymph node metastasis is critical for head and neck staging, and has a significant impact on prognosis and treatment. Lymph node size, morphologic features, and metabolism evaluation can be used to distinguish physiologic and malignant lymph nodes. A systematic approach for evaluation of the lymph nodes is imperative for accurate diagnosis and management. This exhibit will provide an image-based review of the literature for the evaluation of cervical lymph nodes with pathologic correlation.

Materials and Methods
Review the most recent literature of cervical lymph node metastasis with guidelines for evaluation with computed tomography (CT), ultrasound (US), MR imaging (MRI) and FDG-positron emission tomography (PET). Review typical patterns of lymph node spread. Predict the unknown primary location of malignancy based on the anatomical location of cervical nodal metastasis. Illustrate imaging features associated with malignancy of cervical lymph nodes. Focusing on the specific features such as hyperenhancement, round shape, hypo-echoic appearance, central cystic component and extra-nodal extension. Review size criteria and SUV-max threshold for determining malignancy of cervical lymph nodes. Evaluate various methods used including short axis and long axis measurement with the specificity and sensitivity of each. Explain the role of imaging in pre-op planning for lymph node dissection. Rationale for use of
RECIST 1.1 criteria for evaluating response to therapy of malignancy with regard to cervical lymph nodes.

Results
Will illustrate imaging features that determine the clinical decision making and treatment of cervical lymph node metastasis, based on CT, ultrasound, MRI, and/or PET-CT imaging findings. We will give the evidence based radiology recommendations for evaluation of cervical lymph node metastasis. Additionally, we will demonstrate the pathologic findings that correspond to specific imaging features.

Conclusions
This exhibit reviews what radiologist needs to know about cervical lymph nodes for the evaluation of malignancy, based on the latest guidelines and literature. Understanding the diagnosis, prognostic factors and management of cervical lymph node metastasis and the pathologic correlation has important implications for facilitating patient care.

KEYWORDS: Head And Neck, Lymph Node Metastasis, Lymph Nodes
(A) Necrotic 2 cm left level IIA lymph node in patient with history of lung cancer, originally thought to represent metastasis from lung adenocarcinoma.

(B) Pathology of the lymph node demonstrated squamous cell carcinoma, associated with a 3 mm non-visualized tonsillar carcinoma. Necrotic cervical lymph node strongly associated with head and neck primary carcinoma, as in Figure A.
Purpose
1- To review basic background about connective tissue disorders of head and neck. 2- To review typical and atypical imaging findings of connective tissue disorders at different regions of head and neck.

Materials and Methods
1- Updated classification, clinical and laboratory findings of connective tissue disorders. 2- Imaging appearance of Sjögren's syndrome of head and neck. 3- Imaging findings of rheumatoid arthritis at head and neck. 4- Imaging of relapsing polychondritis of head and neck. 5- Imaging findings of antiphospholipid antibody syndrome of head and neck. 6- Imaging findings of systemic lupus erythematosus at head and neck. 7- Imaging appearance of progressive systemic sclerosis of head and neck. 8- Imaging appearance of mixed connective tissue disease of head and neck. 9- Imaging of Polymyositis/Dermatomyositis in head and neck. 10- Imaging of adult stills disease in head and neck. 11- Imaging findings helps to differentiate connective tissue disorders from other malignancy and inflammatory lesions of head and neck. 12- Role of advanced MR imaging such as diffusion MR imaging in assessment of connective tissue disorders.

Results
Imaging shows bilateral salivary and lacrimal gland enlargement in patients of Sjogren's disease. Also, imaging shows changes in temporomandibular joints and subglottic stenosis in patients with rheumatoid arthritis. External ear calcification and subglottic stenosis are reported in patients with relapsing polychondritis. Vascular thrombosis is seen in patients with antiphospholipid antibody syndrome. Opportunistic infection is seen in patients with systemic lupus erythematosus. Areas of osteolysis in the mandible and maseter muscle changes in patients with progressive systemic sclerosis. Calcification is seen in patients with trigmenial neuropathy with mixed connective tissue disorder and cervical lymphadenopathy is seen in patients with adult stills disease.

Conclusions
We concluded that imaging in conjunction with clinical assessment are important for diagnosis of different head and neck lesions in patients with connective tissue disorders. Also, imaging can be used to differentiate connective tissue disorders of head and neck from simulating lesions.

KEYWORDS: Head And Neck

J Brucker\(^1\), T Kennedy\(^2\)
\(^1\)University of Wisconsin, Madison, WI, \(^2\)University Of Wisconsin Hospital, Madison, WI

Purpose
The aim of this educational exhibit is three-fold: 1) Familiarize the reader with the normal vascular anatomy of the nasal cavity, with attention to the areas of shared vascular supply and potential anastomotic connections. 2) Provide a framework for deciding which vascular territories are involved in epistaxis, which may facilitate diagnosis and management. 3)
Introduce a broad range of diagnoses that can be associated with morbid epistaxis, with emphasis on their classic radiologic findings across various imaging modalities.

Materials and Methods
Patients presenting with morbid epistaxis were identified over the past five years, and cases were categorized based on the type of etiology: benign neoplasm, malignant neoplasm, congenital vascular malformation, acquired vascular malformation, infectious, and inflammatory/granulomatous disease. Key images illustrating each individual disease process were selected across various imaging modalities (CT, CTA, MRI, MRA, and conventional angiography), and subsequently compared to each other with a focus on clinically relevant anatomy. Case images also were compared to "normal" angiography and CT examples, in order to emphasize the overlapping vascular territories and critical anatomical landmarks. All cases are accompanied by a brief discussion that highlights the most important clinical and radiologic features for each disease. The material is presented in a Powerpoint slideshow format, as a pictorial overview of this topic.

Results
Epistaxis is a commonly encountered albeit nonspecific clinical presentation, which can on occasion indicate the presence of a serious underlying pathology. In particular, high volume and recurrent epistaxis are more likely to be caused by any number of worrisome medical conditions, including: benign and malignant neoplasms, accidental and iatrogenic trauma, granulomatous disease, vascular malformations (both acquired and hereditary), and various infections. These conditions can be associated with high morbidity or mortality, so effective and appropriate treatment relies upon timely diagnosis. In our exhibit, we demonstrate at least 11 individual cases of morbid epistaxis, each with distinct pathologic etiologies. By emphasizing and understanding the underlying vascular anatomy, we can facilitate prospective identification of each individual lesion's arterial supply, improve pretreatment planning, and possibly expedite embolization or clipping of the critical vessel.

Conclusions
The eruption of blood from the nasal cavity is usually a self-limited condition bearing little to no significant clinical consequence. Most cases are associated with irritation or injury to a rich vascular plexus within the anterior nasal septum, and easily treated with tamponade. However, epistaxis originating from the posterior vascular territories or secondary to the presence of an underlying lesion, and it is therefore wise to maintain a broad differential in such patients. The vascular supply to these lesions often is multifold, and awareness of collateral pathways can help plan treatment and anticipate outcomes. Familiarity with the imaging and clinical features for a wide range of nasal cavity lesions is therefore a useful skill set for any radiologist.

KEYWORDS: Anatomy, Hemorrhage, Nasal

eEdE-157

Evaluation of Sinonasal Glomangiopericytoma (Hemangiopericytoma): A Distinct Entity.

A Jay1, K Montone2, L Loevner3, K Learned4
1Medstar Georgetown University Hospital, Washington, DC, 2placeholder, blank, blank,
3University of Pennsylvania Medical Center, Philadelphia, PA, 4Hospital of the University of Pennsylvania, Philadelphia, PA
Purpose
Hemangiopericytomas are rare soft tissue vascular tumors arising from capillaries and pericytes that most commonly occur in the pelvis, retroperitoneum and lower extremities. Under 20% occur in the head and neck region and have been reported in the orbit, sinonasal cavity, oral cavity, jaw, salivary glands, and the extramucosal spaces. This work evaluates the clinical presentation and imaging findings that are important in directing further work up and management of these rare but important tumors.

Materials and Methods
The medical records, cross-sectional images and pathology reports were reviewed in eight patients with hemangiopericytomas of the sinonasal cavity. The clinical presentation, and CT and MR imaging manifestations were reviewed retrospectively including tumor density on unenhanced CT, associated bone changes, MR signal characteristics, enhancement patterns, and the presence of neovascularity.

Results
Hemangiopericytomas are rare vascular tumors arising from pericytes. Pericytes are modified smooth muscle cells that surround the walls of capillaries and assist in the regulation of blood flow. Given their slow growth and vascular nature, patients often present with long-standing nasal congestion, sinus headaches and intermittent epistaxis. They usually present in middle aged adults and more often arise in the nasal cavity than the paranasal sinuses. On unenhanced CT imaging sinonasal hemangiopericytomas are often large iso- to hyperdense masses. While bony destruction can occur particularly with larger masses, smooth bony remodeling and expansion is the predominant osseous finding. On MRI, they are iso to hypointense on T2-weighted imaging, and have avid enhancement that may be homogenous or heterogenous. Careful evaluation for prominent flow voids signifying their vascular nature is recommended, and identification of this vascularity is important in suggesting the diagnosis and directing further preoperative work which may include preoperative embolization prior to surgical excision which is the mainstay of therapy. Although hemangiopericytomas are low-grade malignant tumors, the degree of malignancy can vary and their behavior can be unpredictable. They behave less aggressively in the head and neck than the abdomen and extremities. These tumors often are radioinsensitive, and surgical resection is the preferred treatment. While local recurrences and metastases do occur, they do so at a lower rate when arising within the head and neck.

Conclusions
While hemangiopericytomas are rare vascular tumors occurring in the head and neck, familiarity with their appearance on imaging is important as the imaging findings including the presence of flow voids may suggest the diagnosis preoperatively and direct the appropriate work up prior to biopsy and surgical resection.

**Functional head and neck imaging in the 21st century**

T Rath¹, M Ibrahim², A Srinivasan²
Purpose
1. To describe the functional imaging techniques applicable in head and neck imaging. 2. To discuss the clinical relevance, limitations and challenges of functional imaging in head and neck evaluation.

Materials and Methods
Diffusion-weighted imaging: • Technology, • Clinical applications, • Pitfalls and challenges. CT and MR Perfusion: • Technology, • Clinical applications, • Pitfalls and challenges. PET-CT: • Technology, • Clinical applications, • Pitfalls and challenges. PET-MR: • Technology, • Clinical applications, • Pitfalls and challenges. Dual Energy CT: • Technology, • Clinical applications, • Pitfalls and challenges. Diffusion imaging shows promise in differentiation of benign and malignant pathologies, identification of metastatic lymph nodes, differentiation of recurrent malignancy and posttherapeutic changes, and prediction and monitoring of response to chemoradiation. MR and CT perfusion measure physiological parameters that can help in prediction and monitoring of response, and stratify patients into complete and poor responders. Prediction of response to chemoradiation during early therapy can be crucial since this would be the first step towards developing modified treatment strategies (e.g., escalated radiation doses) in potentially unresponsive patients. PET-CT is the standard of care for assessment of the unknown primary and evaluation of tumor recurrence. Recent introduction of PET-MR has paved the way for merging the excellent contrast resolution of MR with the metabolic signature of PET to achieve better imaging assessment. The recent introduction of dual energy CT has opened the possibility of better tissue characterization on CT through material density analysis and this may help in differentiation of benign and malignant tissues.

Results
Treatment of patients with head and neck cancers remains challenging despite advances in delivery of chemoradiation, likely due to primary tumor radioresistance, tumor hypoxia and understaging of disease. Pitfalls of conventional imaging include identifying small volume tumor in morphologically normal appearing tissue and identifying recurrent tumor in the posttreatment neck, where distortion of normal anatomical boundaries confounds interpretation, resulting in both false positive and false negative interpretations. Accurate assessment of the neck after treatment is important to detect residual neoplastic disease and/or recognize early recurrence since these negatively affect patient outcomes. Functional imaging, defined as characterization of biologic processes at the cellular or molecular level, has the potential to detect malignant disease at an earlier stage than conventional imaging alone. Preliminary studies suggest that functional imaging may play an important role in prediction and monitoring response to therapy, allowing individualization of treatment strategies rather than a 'one-for-all' approach. Advanced imaging modalities including CT perfusion, MR perfusion, diffusion-weighted MRI, PET-CT, PET-MR and dual energy CT will be introduced with discussion of its specific role in the pre and posttreatment neck.

Conclusions
Adequate and accurate knowledge of the anatomical and functional status of head and neck cancer is essential to understanding the prognosis, making the right treatment options and a more accurate assessment of the posttreatment lesion. However, it should be remembered that the information derived from biologic imaging modalities cannot be interpreted in isolation, and the
anatomical and functional information need to be synthesized together for a comprehensive assessment of head and neck cancer.

Hypopharynx: “Don’t call me LARYnx”
A Knobel\textsuperscript{1}, M Patel\textsuperscript{1}, D Shatzkes\textsuperscript{1}
\textsuperscript{1}Lenox Hill Hospital, New York, NY

Purpose
To clarify the anatomy and function of the hypopharynx as a separate and distinct entity from the larynx.

Materials and Methods
We will illustrate the anatomy of the hypopharynx through graphic, radiological and gross anatomical images, as well as review those pathologic entities that occur in this region.

Results
The hypopharynx lies in intimate proximity to the larynx yet is an anatomically and functionally distinct structure. It is the inferior continuation of the pharyngeal space, located between the oropharynx and the cervical esophagus, and provides a conduit for food. The larynx, located anterior to the hypopharynx though sharing several structures, is the conduit for air. Both are enclosed within the laryngeal skeleton, and may be confused easily, particularly when the hypopharynx is collapsed. We will review detailed anatomy of the hypopharyngeal subsites, as well as pathologic entities that may affect the hypopharynx including squamous cell carcinoma, with particular emphasis on those features important in accurate localization and staging.

Conclusions
Given difficulties in radiologic depiction, the hypopharynx may be confused with its close neighbor, the larynx. Review of their distinct anatomical and functional features will aid the radiologist in accurate localization of disease processes.

KEYWORDS: Anatomy, Head And Neck

Imaging and neuroophthalmology: some clues to avoid mistakes

F Heran\textsuperscript{1}, J Savatovsky\textsuperscript{1}
\textsuperscript{1}Fondation Rothschild, Paris, France

Purpose
Imaging plays a mandatory part in multiple neuro-ophthalmological pathologies. Both clinician and radiologists may be aware of errors leading to misdiagnosed or missed lesions and should figure out ways to avoid them.

Materials and Methods
Selection of chosen cases among a four-year study of neuro-ophtalmological cases with a wrongly analyzed MR imaging (MRI), either because of poor clinical data or radiological mistakes. This presentation will propose several typical examples of both usual clinical and radiological mistakes leading to moderate or severe misdiagnosis.

Results
Most common mistakes are due to both clinical and radiological side. Clinician: Lack of clinical information provided to the radiologist, miserable handwriting, use of complicated abbreviations often not or misunderstood by the radiologist. Radiologist: Poor knowledge of ophthalmological pathology and/or visual and oculomotor pathways, leading to inadequate imaging (wrong
sequence or lack of useful sequence) or to poor reading of the images. Misreading of specific aspects of the pathology. Wrong interpretation of nonspecific lesion. Previous imaging not taken into account.

Conclusions
Clinician should always provide a detailed prescription and be critical when the patient comes back with his imaging (it fits the clinical data??). Radiologist should always consider clinical data while establishing the MRI protocol or reading the images. They should keep in mind that some lesions may be small, even if clinical examination shows major impairment. They should not hesitate to perform further examination or repeat the MRI in case of atypical or nonspecific images. They should remain critical, even if the diagnosis seems established. They should improve their knowledge of the pathology they have to study. Communication between clinician and radiologist before the MRI is the best weapon against misdiagnosis.

**Imaging of internal derangement of Temporomandibular joint**

A Abdel Razek

1Mansoura University, Mansoura, Egypt

Purpose
1- To illustrate basic background about biomechanics of temporomandibular joint (TMJ). 2- To review clinical classification of internal derangement (ID) of TMJ. 3- To review disk, bony and soft tissue changes in ID of TMJ with MR imaging (MRI). 4- To discuss role of other imaging modalities in diagnosis of ID of TMJ.

Materials and Methods
1- Normal anatomy and biomechanics of TMJ. 2- Different pulse sequences of MR imaging of TMJ. 3- Clinical staging of ID of TMJ. 4- Changes in position and shape of disk in ID of TMJ. 5- Retrodiskal abnormalities such as effusion and LPM muscles. 6- Bony changes of condyle and eminence. 7- Role of MRI in selection of patient management. 8- Role of advanced MR imaging such as 3 T, MR arthrogram and dynamic contrast MR in ID of TMJ. 9- Other lesions simulating ID of TMJ as arthritis, trauma and tumors. 10- Role of panorama, ultrasound and CBCT in ID of TMJ.

Results
MR imaging is essential for detection changes in position and shape of disk in ID of TMJ, retrodiskal abnormalities such as effusion and changes in lateral pterygoid muscles and may has a role in detection of bony changes. MR imaging helps in selection of patient management. Computed tomography (CT) scan can be used for detection of bony changes. Ultrasound may be used in children and for interventional guidance.

Conclusions
We concluded that MR imaging is important for diagnosis of changes in disk position and shape, retrodiskal soft tissue and bony changes at MR imaging in patients with ID of TMJ. Computed tomography scan has a role in detection of bony changes of mandibular condyle.
Purpose
The purpose of this study is to profile radiological imaging characteristics of various intraorbital implants and prostheses that are found incidentally on neuroimaging studies. While orbital implants and prostheses have been around for decades, radiographic appearances of them have not been thoroughly described in the literature. Gale et al were among the first ones to address this topic (1985) when they described post-operative CT imaging findings in patients who underwent orbital implant placements with a description of post-operative changes and implant complications(1). Subsequent studies have primarily focused on some specific ocular implants and their safety when MR is performed(2,3), along with the MR artifacts produced by them(4). While these studies have assisted in our understanding of this topic, a comprehensive study describing the radiographic imaging characteristics of various intraorbital implants and prostheses is necessary to provide radiologists with a basis for a reference during image interpretation.

Materials and Methods
Selection of subjects' images was performed using keyword search in radiology reports stored in PACS for "intraocular", "ocular", "intraorbital", 'orbital", "eye", and "implants" or "prostheses". This was followed by identification these implants and prostheses using operative and/or follow up clinical notes. Analysis of these implants and prostheses imaging characteristics were then performed on a PACS station. Images of intraorbital implants not found initially through PACS keyword search were obtained separately through collaboration with the Bascom Palmer Eye Institute.

Results
We analyzed radiographic images for corneal implants (Kpro/Boston keratoprosthesis, contact lenses, corneal rings), intraocular lenses, glaucoma implants (Baerveldt, Ahmed, Molteno), scleral banding implants, replaced vitreous fluid (oil), orbital prostheses, and cosmetic prostheses. The majority of these implants are seen on CT scan, while they generate a variety of artifacts on MRI due to their ferromagnetism properties. This is in keeping with prior finding by Aksoy et al in 1999, who addressed CT and MR imaging of contact and ocular lenses and reported that these objects were better seen on CT than MR(5). Orbital prostheses, glaucoma implants, and lens implants are the most commonly seen in our patient group.

Conclusions
In this study we have created an imaging profile for a variety of intraorbital implants and prostheses that are frequently encountered during image interpretation.

KEYWORDS: Implant, Intraocular Foreign Bodies, Orbits
Imaging of Non-neoplastic Complications Following Surgical Flap Reconstruction and Radiation for Head and Neck Malignancies.

G Jindal¹, W Zucconi¹
¹Yale New Haven Hospital, New Haven, CT

Purpose
The purpose of this exhibit is to illustrate the imaging appearance of the post-treatment neck following flap reconstructive surgeries and radiation treatment with an emphasis on accurately diagnosing various non-neoplastic complications which may arise.

Materials and Methods
We searched our institutional imaging database and selected several cases demonstrating the altered anatomy and various complications following head and neck surgical flap reconstructive surgeries and radiation therapy.

Results
Resection of head and neck cancers often requires reconstructive surgeries utilizing local/pedicle/free flaps for anatomical and functional restoration. Radiation treatment is an integral component of management. Accurate imaging evaluation of these patients requires a thorough understanding of "normal" postoperative appearances. It is imperative to be able to identify non-neoplastic complications including surgical flap infection/breakdown, pharyngocutaneous fistula, wound seroma, hematoma and abscess formation, vascular complications including thoracic duct injury and chylous fistulae. Radiation alone is associated with numerous complications including mucositis, mucosal necrosis, osteoradionecrosis, accelerated atherosclerosis, vascular injury and pseudoaneurysm formation which may require prompt recognition to prevent devastating outcomes.

Conclusions
Interpretation of neck imaging following surgical and radiation treatment for head and neck malignancies often presents as a daunting task for radiologists. In this exhibit, we present a series of cases from our institution highlighting cross-sectional imaging features of non-neoplastic complications following surgical flap reconstructive surgeries and radiation therapy.

KEYWORDS: Neck Lesions, Posttreatment Neck, Radiation Effects
Imaging of the Brachial Plexus

S Salhab¹, A Malhotra²
¹Yale University, New Haven, CT, ²Yale University School of Medicine, New Haven, CT

Purpose
Purpose: 1. To review the normal MR anatomy of the brachial plexus. 2. To review common pathologies of the brachial plexus. 3. To discuss advantages and disadvantages of different MR
protocols when imaging for brachial plexus. 4. To discuss latest imaging techniques of brachial plexus.

Materials and Methods

We retrospectively reviewed the MR brachial plexus studies performed at our institution over the last five years and will discuss the common pathologies involving the brachial plexus. The presentation will focus on: Normal MR anatomy of the brachial plexus, MR imaging techniques, Common causes for brachial plexus plexopathy, Thoracic outlet syndrome.

Results

Review normal MR anatomy of the brachial plexus including the different parts (roots, trunks, divisions, cords and branches), anatomical landmarks and spaces (interscalene triangle, costoclavicular and retropectoralis minor spaces). MR imaging techniques: Discussion of advantages and disadvantages of various MR protocols and latest imaging techniques. • Bilateral versus unilateral imaging, • High resolution imaging, • Contrast use, • High resolution 3T 3D T2 STIR imaging, • Diffusion tensor imaging (DTI) and Tractography. Common causes for brachial plexus plexopathy: Appearances of these entities on MR imaging and discussion of diagnostic pearls: • Nerve sheath tumors, • Metastases, • Direct extension of non-neurogenic primary tumor, • Lymphoma, • Traumatic injuries, • Radiation-induced brachial plexopathy, • Compressive lesions, • Brachial neuritis, • Immune mediated neuropathies. Thoracic outlet syndrome - neurogenic versus vascular (arterial or venous), MR techniques including MRA/MRV and use of Ablavar.

Conclusions

Major teaching points of the exhibit are: 1. Understand MR anatomy of the brachial plexus. 2. Review the imaging characteristics of common brachial plexopathies. 3. Discuss advantages and disadvantages of various imaging protocols and latest imaging techniques.

KEYWORDS: Brachial Plexopathy, Brachial Plexus

Imaging Review of Common Patterns of Perineural Spread of Tumor in the Head and Neck and Anatomical Review

J Gusenburg¹, D Rao², R Blinder³, O Sakai¹

¹Boston Medical Center, Boston University School of Medicine, Boston, MA, ²VA Boston Healthcare System, West Roxbury, MA, ³Brigham and Women’s Hospital, Harvard Medical School, Boston, MA

Purpose

1. To review the terminology, pathophysiology, and clinical significance of perineural spread of head and neck tumors. 2. To review the relevant anatomy with cross-sectional imaging correlates for perineural spread of head and neck tumors. 3. To understand the imaging findings of perineural spread of head and neck tumors.

Materials and Methods

A literature review on perineural spread of tumor was performed. A modern understanding of terminology, pathophysiology, and clinical relevance including the effect on treatment paradigms will be presented. Appropriate cross-sectional images demonstrating the relevant anatomy as
well as excellent examples of the typical imaging findings seen in perineural spread of head and neck tumors were collected at the Veterans Affairs Boston Healthcare System, removed of patient identifying information, and will be presented here for educational purposes.

Results

The terminology for perineural spread of tumor will be discussed including the concept of neurotropism. Pathophysiology including upregulation of neural cell adhesion molecules (NCAMs) and the histologic cancer subtypes inclined toward perineural spread will be reviewed. We will discuss the clinical significance, particularly with regard to symptoms induced, prognostic indication, increased morbidity and mortality, and treatment paradigms. Relevant anatomy will be reviewed, including skull base anatomy via CT correlates including the pathways leading to and from the pterygopalatine fossa, the course of the three branches of the trigeminal nerve, the course of the facial nerve, and the interconnections between the trigeminal and facial nerves. Computed tomography (CT), MRI, and PET-CT images will be reviewed demonstrating the salient imaging findings for perineural spread of head and neck tumors, particularly expansion of the relevant skull base fissures and foramina, fat pad effacement, nerve thickening and enhancement, restricted diffusion, and signal changes and enhancement of downstream muscles affected by motor nerve involvement.

Conclusions

Perineural spread of tumor commonly is seen in patients with head and neck malignancies, most commonly squamous cell carcinoma, minor salivary gland cancers, and lymphoma. Because the skull base foramina serve as a potential conduit from cutaneous and mucosal cancers to the brain, knowledge of this anatomy as well as the common findings associated with perineural spread of tumor are critical in correct staging and clinical management.

KEYWORDS: Cranial Nerve Pathology, Neoplasm, Perineural

Imaging Review of External Auditory Canal Lesions

Y Xie¹, A Singh¹, P Rodriguez¹, B Tantiwongkosi¹, W Altmeyer¹
¹University of Texas Health Science Center San Antonio, San Antonio, TX

Purpose

Review the spectrum of lesions involving the external auditory canal.

Materials and Methods

Various lesions of the external auditory canal were categorized and representative images were selected for this exhibit.

Results

External auditory canal (EAC) is curvilinear tubular structure with both cartilaginous and bony parts. There are a wide variety of lesions that can involve the EAC. In current practice, the modality of choice for external auditory canal imaging has been CT of the temporal bone. Here, we review the relevant EAC anatomy and imaging characteristics for the spectrum of abnormalities associated with EAC including: anatomical variants, congenital lesions, malignant/benign neoplasms, vascular lesions, infection and trauma. List of lesions: Anatomical Variant: Foramen tympanicum, cerumen. Congenital: Congenital cholesteatoma, isolated EAC

Conclusions
CT of temporal bone is the modality of choice for imaging of the external auditory canal lesions and provides the necessary clinically significant information.

KEYWORDS: Atresia, Cholesteatoma, Squamous Cell Carcinoma
Purpose
Temporal bone imaging can be challenging for most radiologists, and the evaluation can become even more perplexing when the patients have had previous surgical interventions. In today's world of multidisciplinary medicine it is imperative for the neuroradiologist to be able to provide clinically relevant information to the otolaryngologists after they have chosen to surgically intervene. In order to accomplish this, the neuroradiologists should have a firm grasp on the basic and complex postoperative imaging findings of the temporal bone. The purpose of this presentation is to discuss the imaging spectrum of the postoperative temporal bone and common complications, utilizing clinical images and diagrams, that neuroradiologists must know.

Materials and Methods
The otolaryngology surgical case logs at a tertiary care facility were searched retrospectively from 2009-2013 for temporal bone interventions. The PACS system then was searched for postoperative imaging of these patients, and cases were selected for presentation of both the common and uncommon procedures as well as their complications.

Results
The mainstay of surgical intervention of the temporal bone is the mastoidectomy, which can be further subdivided into canal wall up, canal wall down, modified radical, and radical. It is performed most commonly for cholesteatoma, with the invasiveness of the lesion determining the extent of the procedure performed. A stapedectomy removes an affixed stapes and replaces it with a microprosthesis. It is performed most commonly for otosclerosis. Tympanoplasty and ossiculoplasty commonly are performed in conjunction after a history of chronic middle ear infection. Ossicular reconstructions options include autografts (patient's own bone or cartilage), homografts, or allografts (synthetic prostheses). The two main forms of allografts, total and partial ossicular replacement prostheses (TORP and PORP, respectively), have been gaining in popularity due to their sterility and availability. Each of these procedures has their own specific complications, which can be diagnosed radiographically.

Conclusions
With the increasing roles of imaging in temporal bone surgery, it has become increasingly important for the radiologist to be familiar with the postoperative temporal bone. Common interventions include all forms of the mastoidectomy, ossiculoplasty, and stapedectomy, which must be identified on temporal bone CT, as well as their respective complications.

Major salivary gland tumors: the good, the bad, and the ugly.

R Patel¹, S Karam², K Harter¹, A Jay¹
¹Medstar Georgetown University Hospital, Washington, DC, ²University of Colorado Cancer Center, Aurora, CO

Purpose
Major salivary gland neoplasms provide a diagnostic challenge given their nonspecific clinical presentation. As such, imaging plays a major role in assessing possible malignant potential, extent, and staging of these tumors. Through our educational exhibit, we aim to provide an overview of common salivary gland malignancies and their imaging features. Furthermore, we will discuss staging of salivary gland tumors and the role of cross-sectional imaging.

Materials and Methods
The medical records, cross-sectional images and pathology reports were reviewed of 89 salivary gland tumors at our tertiary care academic institution. The clinical presentation, and CT and MR imaging manifestations were reviewed retrospectively to elucidate key imaging findings of the different malignant histologic pathologies.

Results
Tumors of the major salivary glands comprise a diversity of benign and malignant entities. Clinical history, including symptoms and tumor growth, infrequently correlates with histology. Therefore, cross-sectional imaging plays an important role in suggesting malignancy, and ultimately guiding treatment of these masses. Important radiologic findings that are essential for the radiologist to report include distinctness of the tumor margin, T2 signal intensity, presence of adenopathy, extraparenchymal extension, perineural spread, and distant metastases. We provide an image-rich overview of the pathology and CT and MRI features of various salivary gland
tumors. Cases presented in our exhibit include pleomorphic adenoma, Warthin's tumor, adenoid cystic carcinoma, acinic cell carcinoma, mucoepidermoid carcinoma, squamous cell carcinoma, lymphoma and metastatic lesions.

Conclusions
Salivary gland tumors have a nonspecific clinical presentation and cross-sectional imaging plays an important role in suggesting malignant potential and staging of these lesions. Familiarity of the imaging characteristics of the good, the bad, and the ugly salivary gland tumors is invaluable for preoperative planning and counseling.

More than Skin Deep: Neuroimaging of Dermatological Diseases

D Ginat, C Schatz
1University of Chicago, Chicago, IL, 2University of Southern California, Los Angeles, CA

Purpose
The goal of this exhibit is to review the appearance of skin lesions on neuroimaging studies.

Materials and Methods
The following topics will be reviewed: * Anatomy; * Neurocutaneous syndromes; -NF 1; -NF2; -Tuberous sclerosis; -PHACES syndrome; -Neurocutaneous melanosis; -Sturge-Weber; -Basal cell nevus syndrome; -Incontinentia pigmenti; * Skin; tumors; -Skin appendage lesions (inclusion cyst, pilomatrixoma, cystadenoma); -Primary malignancies; (melanoma, squamous cell carcinoma, basal cell carcinoma); -Metastases; * Trauma; -Lacerations; -Hematomas; -Foreign bodies; -Third-spacing; * Infectious and inflammatory processes; -Cellulitis; -Abscess; -Herpes-Zoster; -Scleroderma; -Parry Romberg disease; * Posttreatment; -Mohs surgery; -Reconstructive skin flaps and grafts; -Cosmetic facial fillers and implants.

Results
Radiological imaging, including CT and MRI, play an important role in evaluating patients with primary skin tumor of the head and neck region. Although visible on clinical exam, neuroimaging is used to determine the degree of local invasion and distant metastases, which affects patients management and prognosis. Neuroimaging also is essential for evaluating conditions associated with skin lesions in the neurocutaneous syndromes. Alternatively, skin lesions may be encountered incidentally on neuroimaging performed for other reasons. Recognizing these lesions and their significance is helpful.

Conclusions
There are a wide variety of skin diseases that can be encountered on routine neuroimaging. Therefore, it is important to be familiar with the corresponding radiological features and associated findings.

Multimodality Staging and Restaging of Laryngeal Carcinoma with MRI, CT and PET/CT

T Howard¹, C Hunt¹
¹Mayo Clinic, Rochester, MN

Purpose
The purpose of the exhibit is: 1) Review the basic anatomy of the larynx as it relates to laryngeal carcinoma; 2) Discuss the initial staging of laryngeal carcinoma with a focus on the contributions of multimodality imaging with PET/CT, CT and MRI; 3) Illustrate the importance of multimodality imaging, particularly PET/CT, in the surveillance for and restaging of disease recurrence; 4) Discuss the limitations that can be seen with conventional imaging and PET/CT and how to avoid potential pitfalls.

Materials and Methods
After a short review of the basic anatomy of the larynx, a case series of patients will be presented demonstrating the value of multimodality imaging for initial staging of laryngeal carcinoma. While the focus will be on conventional imaging with MRI and CT, a detailed review of PET/CT also will be included. For restaging of laryngeal carcinoma, the focus will be primarily on the added value of PET/CT for disease surveillance and restaging of recurrent disease with MRI, CT, and PET/CT (Figure 1). This series also will include cases which demonstrate the potential limitations of imaging and how both false negative and false positive studies can be obtained and potentially avoided.

Results
Multimodality imaging for the initial staging of laryngeal carcinoma can be a powerful tool for detecting subtle, clinically important disease both locally, regionally, and distant for the primary tumor. Knowledge and a thorough understanding of the basic anatomy of the larynx is critical to being able to clearly define the primary tumor in terms that are clinically useful to the referring surgeon. Given the potentially high rate of local recurrence, disease surveillance is a critical part of imaging laryngeal carcinoma as well. Being able to synthesize information from multiple modalities will significantly increase the ability of the imager to detect and define disease recurrence. Finally, as with all imaging studies, the potential pitfalls of imaging need to be understood and mimickers of disease need to be avoided.

Conclusions
Multimodality imaging with MRI, CT, and PET/CT can provide significant added value to the evaluation of laryngeal carcinoma. Careful understanding of the limitations of these modality is needed though to avoid unnecessary interventions.

KEYWORDS: Carcinoma, Larynx, Multimodality Imaging
Pathologic temporal bone calcification/ossification: A pictorial review.

W Altmeyer\textsuperscript{1}, A Singh\textsuperscript{1}, B Winegar\textsuperscript{1}, A Steven\textsuperscript{2}, P Rodriguez\textsuperscript{1}

\textsuperscript{1}University of Texas Health Science Center San Antonio, San Antonio, TX, \textsuperscript{2}University of Maryland School of Medicine, Baltimore, MD

Purpose
The purpose of the educational exhibit is to review the pathological processes characterized by abnormal calcification/ossification on temporal bone CT examination.

Materials and Methods
The education exhibit will be a pictorial review of pathology characterized by abnormal calcification/ossification on CT of the temporal bones. We will focus on key imaging findings that will allow differentiation of the different pathologic processes. Disease processes that will be covered include: • Tympanosclerosis (see attached image), • Labyrinthine ossificans, • Facial nerve hemangioma, • Endolymphatic sac tumor, • Otosclerosis, • Chronic Otomastoiditis, • Paget's disease, • Fibrous Dysplasia, • Osteopetrosis.

Results
Certain pathologic processes result in abnormal calcification/ossification on routine temporal bone CT. Analyzing the presence, location, and morphology of the abnormal calcification/ossification in these cases will help the radiologist clinch the correct diagnosis. Dystrophic ossification is identified in the middle ear with tympanosclerosis or the inner ear with labyrinthine ossificans. The presence of stipple calcifications on temporal bone CT help the radiologist diagnose both facial nerve hemangiomas and endolymphatic sac tumors. Irregular lucency of the otic capsule at the level of the fissula ante fenestram allows diagnosis of fenestral
otosclerosis/otospongiosis. More generalized pathologic ossification of the temporal bone can be seen in fibrous dysplasia, Paget's disease, and osteopetrosis.

Conclusions
Certain disease processes result in abnormal calcification on temporal bone CT. Analyzing the presence and morphology of the abnormal calcification will guide the radiologist to the correct diagnosis.

KEYWORDS: Temporal Bone

eEdE-151

Post-surgical neck – what is recurrence and what is expected postsurgical change?

S Kanekar¹, A Agarwal²
¹Penn State Milton S Hershey Medical Center, Hershey, PA, ²Milton S Hershey Medical Center, Hershey, PA

Purpose
1. To discuss with illustrations the various postoperative procedures for head and neck cancer and their imaging appearance. 2. To highlight the postchemo and radiotherapy changes on CT, MR and PET scan. 3. To illustrate the various post-treatment complications.

Materials and Methods
We retrospectively studied 214 patients from our oncology data which formed the basis for this exhibit. All patients had undergone surgical procedures for their head and neck cancer. One hundred sixty-three patients also had received RT while 51 patients had received RT and CT combination.
Results
We have categorized this exhibit into: 1) Neck dissections (ND): a) radical ND, b) modified ND, c) selective ND, d) extended ND. 2) Reconstructive surgery: appearances of various types of myocutaneous flaps, infection and recurrence. 3) Radio and chemotherapy changes. 4) Treatment related complications: vascular: thrombosis, pseudoaneurysm, vessel wall injury; osseous: infection, necrosis; chylous fistula; postsurgical neuroma; skin metastasis; and flap infection.

Conclusions
1. Knowledge of postsurgical procedures is essential for evaluation of post-treated neck follow up and surveillance. 2. Distinguishing early recurrence verses expected postsurgical changes are important to avoid unnecessary surgical biopsies

KEYWORDS: PET/CT, Radiation

Radial-VIBE with GRASP: A Novel Technique in Evaluation of the Head and Neck

L. Bangiev1, X. Wu1, K. Block1, T. Shepherd1, R. Jain1, C. Rossi Espagnet1, M. Hagiwara1, G. Fatterpekar1
1New York University Langone Medical Center, New York, NY

Purpose
Radial-VIBE with GRASP is a novel contrast-enhanced T1-weighted gradient-echo sequence providing excellent fat-suppressed motion robust sequences. In addition, its unique K-space sampling and data acquisition parameters allows for assessing structural permeability characteristics. The purpose of our study is to evaluate the role of Radial-VIBE in assessing head and neck anatomy and relevant pathology.

Materials and Methods
Utilizing illustrative images, we will demonstrate the different applications of Radial-VIBE with GRASP in evaluation of the neck, orbits, base of the skull, and pituitary gland.

Results
Discussion will include: - Overview of the new technique and its advantages in comparison with conventional sequences. - Demonstration of unique permeability patterns utilizing Radial VIBE with GRASP of normal structures of the neck as well as assessment of pathology such as metastatic lymph node and certain primary carcinomas. - Assessing its role in evaluation of skull base lesions. - Assessing its role in evaluation of normal anatomical structures of the orbit and associated pathology. - Demonstration of normal permeability characteristics of anterior, posterior pituitary gland and the infundibulum, and assessing its role in evaluating pathology including macroadenoma, microadenoma and cysts.

Conclusions
Radial-VIBE with GRASP provides unique insight into evaluation of head and neck anatomy and pathology. It is a potentially superior technique rather than the conventional fat-suppressed T1-weighted sequences.

KEYWORDS: Head And Neck, Permeability MR Imaging
Rare and Aggressive Thyroid Carcinoma: You May Not Have Seen Them, But They May Have Seen You!

J Sodergren¹, S Kralik², K Mosier²
¹Indiana University, Indianapolis, IN, ²Indiana University School of Medicine, Indianapolis, IN

Purpose
Due to their widespread prevalence (greater than 50% in autopsy series), incidental thyroid nodules commonly are identified on cross-sectional imaging. Citing low malignancy risk, relatively indolent growth rate, apparent increasing incidence, and costs involved in their work up, recent literature has compellingly argued that imaging-based risk stratification should be employed to determine which thyroid nodules require further imaging characterization or fine needle aspiration (FNA) in the current costconscious medical practice climate. Rare but aggressive forms of thyroid carcinoma, such as medullary thyroid carcinoma, anaplastic thyroid carcinoma, the tall cell variant of papillary thyroid carcinoma, and Hurthle cell thyroid carcinoma, are associated with poor prognosis, account for the majority of thyroid carcinoma-related deaths, and therefore always require further evaluation, including FNA and evaluation for distant metastases. Although rarely seen clinically, awareness of concerning thyroid carcinoma imaging characteristics is necessary to identify aggressive rare forms that require further assessment. After pathologic diagnosis, imaging-directed tumor staging is necessary to guide treatment planning and monitor treatment response. Appropriate imaging surveillance following initial treatment is essential to identify local/regional recurrence and presence of distant metastases.

Materials and Methods
Using pathology and radiology information systems at our institution, 30 total patients between January 2001 and November 2013 were identified with both rare forms of thyroid carcinoma and relevant imaging: nine with medullary thyroid carcinoma, four with poorly differentiated thyroid carcinoma, seven with Hurthle cell thyroid carcinoma, and ten with anaplastic thyroid carcinoma. Relevant literature review also was performed.

Results
Discussion includes: 1. Summary of concerning primary tumor imaging features requiring further evaluation/FNA. 2. Brief review of each tumor type, including demographics and clinical
characteristics. 3. Determination of appropriate imaging strategy and modalities to initially stage each tumor. 4. Review of consensus imaging surveillance guidelines for these tumors.

Conclusions
Rare but aggressive forms of thyroid carcinoma carry a poor prognosis compared with differentiated thyroid carcinoma. Awareness of concerning imaging characteristics is critical to appropriately risk-stratify incidental thyroid nodules based on imaging findings. In addition, discrete strategy for initial tumor staging and imaging surveillance is necessary, as each of these forms has a high risk of local recurrence and distant metastases.

*Read 'Em and Weep: Imaging of Lacrimal Pathology*

J Burns, L Cabusora, D Ginsburg, R Zampolin, A Erdfarb, K Shifteh

1 Montefiore Medical Center, Bronx, NY

**Purpose**
The lacrimal drainage system, including the lacrimal gland and duct, are host to a range of pathologies. Congenital, acquired and neoplastic conditions may affect the lacrimal system and its related components. The purpose of this presentation is to review the anatomy and pathologies of the lacrimal system, focusing on both common and rare conditions.

**Materials and Methods**
Content will be presented using a quiz format, beginning with a focused review of anatomy followed by case presentations highlighting the spectrum of pathologies affecting the lacrimal gland and drainage system.

**Results**
Specific developmental, inflammatory and neoplastic conditions are reviewed, with focus on highlighting characteristics that lead to the diagnosis. Specific entities to be reviewed include: - Congenital dacrocystocele, -Dacrocystitis, -Systemic disease, including sarcoidosis, -Sjogren's syndrome, -Pseudotumor, -Tumors, -Benign mixed tumor, -Squamous cell carcinoma, -Adenoid cystic carcinoma, -Lymphoma, -Metastasis.

**Conclusions**
Recognition of the range of lacrimal pathologies helps to generate a focused differential diagnosis when confronted with abnormalities of the lacrimal gland or duct. An understanding lacrimal system anatomy can help in predicting routes of spread and complications of lacrimal disease.

KEYWORDS: Lacrimal Apparatus

*Seeing is Believing: Laryngeal Carcinoma Imaging and Laryngoscopy Correlation*
M Cathey¹, T Kennedy², M Hartman¹, G Hartig¹, P Harari¹, S Daily¹, W Smoker³, D Reede⁴, L Gentry⁵
¹University of Wisconsin Madison, Madison, WI, ²University Of Wisconsin Hospital, Madison, WI, ³University of Iowa Hospitals and Clinics, Iowa City, IA, ⁴SUNY Downstate Medical Center, Brooklyn, NY, ⁵University of Wisconsin, Madison, WI

Purpose
Laryngoscopy long has been recognized as the gold standard for characterizing the extent of mucosal disease and vocal cord mobility in the setting of laryngeal neoplasia. Advances in imaging technology have improved diagnostic accuracy for tumor staging, particularly when interpreters are armed with knowledge both of normal and variant anatomy, as well as typical patterns of spread for a given pathologic entity. The radiologist should be familiar with findings at laryngoscopy and how those findings might guide patient management and subsequent imaging. The purpose of this exhibit is to review normal anatomy at laryngoscopy with an emphasis on case-based radiology-laryngoscopy correlation.

Materials and Methods
We will illustrate normal anatomy at laryngoscopy. Further, using the tumor node metastasis (TNM) system devised by the American Joint Committee on Cancer (1) as a guide, we will show imaging examples of laryngeal carcinoma with digital laryngoscopic correlation. Specific attention will be given to radiology-laryngoscopy correlation pertinent to a classification scheme for laryngeal endoscopic cordectomies (2, 3).

Results
Clinically evident tumor involving the surface of the vocal cords, cord fixation and early transglottic extension can be difficult for the radiologist to recognize on cross-sectional imaging. The traditional emphasis in head and neck imaging has been on finding the imaging correlate for a clinically apparent abnormality as well as identifying submucosal and deep extension of disease that is clinically silent to the laryngoscopist. As expected, lesion location, even in the setting of low-grade disease, can significantly alter treatment approach. Ongoing advances in laryngoscopic technology, such as narrow band imaging (4) and the ability to digitally record the examination hold further promise in improving diagnostic accuracy. The availability of laryngoscopic imaging can be helpful in directing the radiologist’s approach to a given case, further enhancing the spirit of cross-specialty collaboration and patient care.

Conclusions
Correlation with advanced techniques in digital laryngoscopy will enable the radiologist to more effectively approach the imaging evaluation of laryngeal neoplasms.

KEYWORDS: Larynx, Squamous Cell Carcinoma, Staging

**Sizing up the Extraocular Muscles: Small or Big?**

M Patel¹, A Knobel¹, D Shatzkes¹
¹Lenox Hill Hospital, New York, NY
Purpose
To review the various pathological conditions that cause the extraocular muscles to either increase or decrease in size.

Materials and Methods
1. Review the anatomy and innervations of the extraocular muscles. 2. Describe the general categories of relevant disease processes - inflammatory, infectious, congenital, acquired, metabolic, trauma, and neoplastic. 3. Provide cases of entities that cause diminished size of extraocular muscles including: Denervation atrophy, mitochondrial myopathy, chronic progressive external ophthalmoplegia, Duane's syndrome, and congenital hypoplasia. 4. Provide cases of entities that cause enlargement of extraocular muscles including: Thyroid associated orbitopathy, orbital pseudotumor, sarcoidosis, trauma, cellulitis, and malignancy.

Results
Pathology that causes the extraocular muscles to either increase or decrease in size can affect individual or multiple extraocular muscles. It is important to recognize the broad categories that these lesions fall into, in order to have a systematic way to approach and analyze these abnormalities. There are certain imaging features unique to some conditions that can help narrow the differential diagnosis.

Conclusions
Enlargement of extraocular muscles is a common phenomenon; however, entities that cause the extraocular muscles to decrease in size are uncommon and often can be difficult to appreciate on cross-sectional images. This exhibit will familiarize the reader with both conditions as well as emphasize the imaging characteristics that can aid in the diagnosis of these lesions.

KEYWORDS: Extraocular Muscle Dysfunction, Orbits

Temporal Zone from A to Z

R Sharma1, V Jewells1
1University of North Carolina Hospitals, Chapel Hill, NC

Purpose
To the inexperienced, temporal bone anatomy and pathology can be complex. This exhibit will serve as a review of the basic temporal bone anatomy and broad breadth of pathology one encounters on computed tomography (CT) and MR imaging (MRI).

Materials and Methods
This electronic exhibit will begin with a review of basic temporal bone anatomy on CT in the axial and coronal planes. The remainder of the exhibit is divided into the eight categories and will review multiple anatomical variations and pathologic processes.

Results
CONTENT OUTLINE: Anatomy: Basic Temporal Bone anatomy on CT and MRI. Anatomical variants: Aberrant CN7; Petrous Apex/ Effusion; Bilateral Vestigal Appendages; High riding Jugular Vein; Dehiscent Jugular Bulb; Aberrant ICA. Post-traumatic Processes: Cochlear/Vestibular Hemorrhage; Malleoincudal separation; Ossicle Dislocation; Temporal bone fractures. Congenital Processes: Microtia; 1st Branchial Cleft Cyst; Cochlear/Vestibular
Dysplasia; Congenital Cholesteatoma; Cochlear Nerve Hypoplasia/aplasia; Goldenhar and CHARGE syndromes; Absent Cochlear Nerve; Isolated Cochlea; EAC Atresia; CN VII ptosis; Common cavity; Large Endolymphatic Sac Anomaly. Inflammatory/Infectious processes: Otitis Media/Middle Ear Effusion; Cholesterol granuloma; Labyrinthitis; Otomastoiditis; Bezold's Abscess; Mastoiditis with Sinus Thrombosis/Sigmoid Plate Erosion; Bells Palsy; Otitis Externa/Malignant Otitis Externa; Petrous Apicitis/Gradengo's Syndrome. Tumor/Tumo- like Processes: Middle ear and EAC Squamous Cell Carcinoma; CN VII Cystic Schwannoma; Glomus Tympanicum; Facial Nerve/Labyrinthine Schwannoma; IAC Lipoma; CN VII and Petrous Apex Hemangioma; 7th CN Perineural Spread; Endolymphatic Sac tumor. Bony Pathology: Fibrous dysplasia; Petrous Apex Meningocele /Encephalocele; Temporal Bone Encephalocele; Sphenoid Encephalocele/Meningocele; IAC Osteoma; EAC Exostosis. Pathology related to Hearing Loss/Tinnitus: Retrofenestral Otospongiosis; Fenestral otospongiosis/Otosclerosis; Posterior Semicircular Canal Dehiscence; Acquired Cholesteatoma with Lateral Semi-circular Canal Dehiscence; Large Cholesteatoma; Otoradionecrosis; Petrous Apex Cholesteatoma; EAC cholesteatoma; Labyrinthitis Ossificans. Postoperative Processes/Prosthesis: Postoperative Temporal Bone/ Mastoidectomies; Tympanostomy; Complete Ossiculectomy with Prosthesis Placement; Postop Labyrinthitis; Stapes Prosthesis Herniation/Dislocation; Sound Bridge Prosthesis; Cochlear Gusher.

Conclusions
At the completion of this exhibit the radiologist should feel more comfortable with the breadth of pathology one may encounter on a temporal bone study.

The Devil’s in the Details: Small field of view MRI in imaging of laryngeal and hypopharyngeal cancers

S Gupta¹, J Goh¹, S Loke¹, A Karandikar¹, T Tan², W Smoker³
Purpose
To highlight the utility of small field of view (SFOV) MR imaging (MRI) in the evaluation, staging and management of laryngeal and hypopharyngeal cancers.

Materials and Methods
A retrospective review of patients with laryngeal and hypopharyngeal cancer imaged in our department with MRI between 2008 and 2013 was performed. Imaging findings pertinent to local staging were identified; these include cartilage involvement, extralaryngeal spread and paraglottic spread.

Results
Several studies have established the superiority of MRI in soft tissue contrast and evaluation of laryngeal cartilage over CT scan. With improved software and coil technology it is now possible to obtain superior anatomic depiction and disease delineation using surface coils and SFOV imaging, in comparison to traditional large field of view (LFOV) images. Enhanced imaging information further helps in the staging and management of the disease. This exhibit aims to show how SFOV MRI: 1. Provides improved anatomical depiction of soft tissues and cartilage compared to CT and LFOV MRI; 2. Better demonstrates locoregional invasion by neoplasms; 3. Affects tumor staging and management planning.

Conclusions
Small field of view MR is superior to CT and LFOV MRI in detailed evaluation of loco-regional invasion by laryngeal and hypopharyngeal neoplasms, thereby affecting the staging and management.

KEYWORDS: Head And Neck, Larynx, MR Imaging

Ultrasound Parotid imaging reporting and data system (PIRADS)

A Abdel Razek\textsuperscript{1}, g albair\textsuperscript{1}
\textsuperscript{1}Mansoura University, Mansoura, Egypt

Purpose
1-To review normal anatomy of parotid gland. 2-To review ultrasound appearance of benign lesions and malignant tumors of parotid gland. 3-To illustrate ultrasound parotid imaging reporting and data system (PIRADS) and its impact on patient management.

Materials and Methods
1-Normal anatomy of parotid gland with ultrasound. 2-Ultrasound appearance of benign parotid tumors. 3-Ultrasound appearance of malignant parotid tumors. 4-Ultrasound of sjogrene disease and other connective tissue disorders. 5-Ultrasound of developmental lesions of parotid gland. 6-Spectrum of bilateral and multiple parotid gland lesions. 7-Ultrasound parotid imaging reporting and data system (PIRADS). 8-Impact on PIRADS in patient management and treatment planning. 9-Summary of future prospect.
Results
Ultrasound commonly is used as an initial imaging modality for assessment of parotid tumors. Ultrasound parotid imaging reporting and data system (PIRADS) is a new proposal system for classifying parotid masses on the basis of sonographic findings. PIRADS aims to reduce variability in lesion interpretation by standardizing report content and structure; improving communication with clinicians; and facilitating decision making.

Conclusions
We concluded that ultrasound parotid imaging reporting and data system (PIRADS) is a new noninvasive that can be used to differentiate benign from malignant lesions. This reporting system has impact on patient management and treatment planning.

What did I miss? A Case Based Correlation of Videofluoroscopic Swallow Examinations with Cross-sectional Imaging Studies.

K Diaz¹, P Sullivan², I Schmalfuss³
¹University of Florida College of Medicine, Gainesville, FL, ²North Florida/South Georgia Veterans Administration, Gainesville, FL, ³North Florida/South Georgia Veterans Administration and University of Florida College of Medicine, Gainesville, FL

Purpose
Videofluoroscopy is a great tool for the initial evaluation of patients with dysphagia. Over the years, radiologist's role has shifted as to, in general, only provide fluoroscopic guidance rather than in depth interpretation of videofluoroscopic swallow studies. Speech pathologists are trained primarily to evaluate the functional process of swallowing but might overlook structural abnormalities. Therefore, it is important for every radiologist to be familiar with the videofluoroscopic appearance of normal anatomy and the various disease processes affecting the oral cavity and pharynx in order to provide interpretative assistance and suggest additional studies that may be needed for diagnosis.

Materials and Methods
Clips or still images of videofluoroscopic swallow studies will be presented in a case-based quiz format prompting the radiologist to: #1 identify the area of abnormality; #2 suggest a specific diagnosis. Subsequently important anatomy and pathology will be reviewed and corresponding cross-sectional images (CT, MRI and/or PET/CT) will be displayed.

Results
Knowledge of the normal appearance of the oral cavity and pharynx on videofluoroscopy is essential when evaluating a patient for dysphagia. We will review anatomical landmarks and various disease processes that can present during videofluoroscopic swallow evaluation. Emphasis will be placed on the detection of the abnormality through correlations to different cross-sectional imaging studies (CT, MRI and/or PET/CT). Cases to be discussed include: - functional disorders, - congenital/genetic abnormalities, - neurological disorders, - neoplasms of the head and neck, - post-treatment effects (radiation therapy versus surgery) and complications.
Conclusions
Although videofluoroscopic swallow studies are primarily interpreted by the speech pathologist, the radiologist also may assume a legal responsibility for detection of any pathology. Therefore it is crucial for the overseeing radiologist to be familiar with the normal and abnormal appearance of the oral cavity and pharynx on fluoroscopy. After reviewing the important concepts demonstrated in this exhibit, the radiologist will be able to more confidently detect abnormalities on videofluoroscopy or simply confirm a normal study.

KEYWORDS: Fluoroscopy, Head And Neck, Oropharynx

eEdE-140

J Mueller¹, L Gentry², D Reede³, W Smoker¹
¹University of Iowa Hospitals and Clinics, Iowa City, IA, ²University of Wisconsin Hospitals, Madison, WI, ³SUNY Downstate Medical Center, Brooklyn, NY

Purpose
The educational objectives of this exhibit include: 1. Describe the imaging appearance of the most common cystic neck masses. 2. Learn less common cystic lesions that also must be considered in the differential diagnosis. 3. Learn the typical locations of these various cystic neck lesions.

Materials and Methods
Reviewers are challenged with both common and uncommon cystic neck lesions utilizing a case-based, computer-interactive, tutorial approach. Each case includes representative images that illustrate key diagnostic findings for the disease entity. A brief discussion highlighting salient clinical and imaging features follows each case.

Results
Cystic neck masses can be a diagnostic challenge for the radiologist. It is important to consider both common and uncommon entities when faced with these lesions. One needs to consider congenital, neoplastic, and miscellaneous lesions. Congenital lesions include thyroglossal duct, branchial cleft (II-IV), cervical bronchogenic, and thymic cysts, as well as venolymphatic malformations. Neoplastic lesions include nodal metastases, dermoid and epidermoid cysts, and cystic schwannomas. Miscellaneous lesions include abscesses and saccular cysts.

Conclusions
After reviewing this interactive, case-based, educational exhibit, the reviewer will be able to identify common and uncommon cystic lesions of the neck. Cystic neck masses offer a diagnostic challenge to the radiologist. Careful inspection for characteristic distinguishing features often will lead to the correct diagnosis or significantly narrow the differential.

KEYWORDS: Cystic Neck Mass, Cysts
Where are You Going?: Geographic Approach for the Evaluation of Perineural Tumor Spread in the Head and Neck

V Kunam¹, p cherukuri¹, D Reede², J Nath², R Holliday³, W Smoker⁴
**Purpose**

After viewing this module the user will know the: 1. Normal gross and imaging anatomy of nerves commonly involved in perineural tumor spread (PNTS) with emphasis on their relation to various spaces/locations in the head and neck. 2. Imaging findings of PNTS and common pathways of spread encountered with lesions in specific locations. 3. Clinical findings and significance of PNTS.

**Materials and Methods**

Cross-sectional images and illustrations are used to demonstrate the anatomy of pertinent nerves most commonly involved by PNTS (greater auricular, CN V and CN VII), and their relationship to various spaces of the head and neck. Common connections between these nerves are reviewed, followed by a discussion of pathophysiology, clinical findings, therapeutic and prognostic implications of PNTS. Direct and indirect imaging findings of PNTS are presented. Cases are used to demonstrate common pathways of PNTS associated with tumors in specific locations. Lesion locations and common patterns of nerve involvement (including retrograde spread) include: Nasopharyngeal tumors (V2 and V3), masticator space (V3), parotid space (VII, auriculotemporal branch and greater auricular nerve), supraorbital lesions (V1), maxillary sinus and buccal space lesions (V2) and hard palate (palatine nerve to the pterygopalatine ganglion, vidian nerve and V2).

**Results**

Perineural tumor spread is extension of tumor along the neural sheath of cranial nerves that commonly occurs in a retrograde fashion towards the cranium but also can spread antegrade towards the periphery. It is important for radiologists to recognize subtle findings of PNTS because it has a significant impact on management prognosis. It is associated with an increased incidence of local recurrence and decreased survival. Direct signs of PNTS are enlargement and/or enhancement of the nerve. Loss of fat in the neural foramen and foraminal enlargement are indirect signs. Squamous cell carcinoma (SCCa) is the most common malignancy in the head and neck; therefore, most cases of PNTS are due to SCCa. Adenoid cystic carcinoma has the strongest association with PNTS; however, it is much less common. Lymphoma, rhabdomyosarcoma and melanoma also can demonstrate this pattern of disease spread.

**Conclusions**

Since forty percent of patients with PNTS are asymptomatic, therefore cross-sectional images of patients with head and neck malignancies should be carefully evaluated for this pattern of disease spread. Familiarity with the normal anatomy and imaging (CT/MR) appearance of pertinent nerves, imaging findings of PNTS and common pathways of disease spread based on tumor location, improves diagnostic accuracy. An imaging check list, based on tumor location, is provided to aid in detection of PNTS.

Aneurysms of the Vertebrobasilar Junction, Anterior and Posterior Inferior Cerebellar Arteries: Diagnostic Considerations and Endovascular Treatment Methods

B Griffith¹, M Kelly¹, H Marin¹, M Kole¹, W Sanders¹

¹Henry Ford Health System, Detroit, MI

Purpose
The purpose of this exhibit is to provide a pictorial review of aneurysms involving the vertebrobasilar (VB) junction, anterior inferior cerebellar artery (AICA) and posterior inferior cerebellar artery (PICA). For each entity, we will discuss relevant imaging findings and endovascular treatment options, including methods, technical considerations, and potential complications.
Materials and Methods
Using our case files, we will show clinical examples of various types of aneurysms involving the VB junction, AICA, and PICA. Cases will include berry aneurysms arising at vessel origins; distal aneurysms of the AICA and PICA, dissecting aneurysms of the intracranial vertebral artery, fenestration aneurysms, and fusiform basilar aneurysms. For each entity, we will discuss:
- Important diagnostic and therapeutic considerations, including anatomical (e.g., limited surgical access, adjacent cranial nerves, shared blood supply), as well as those related to the aneurysms themselves (e.g., size, geometry, location).
- Various treatment methods, including endovascular coils (with and without stent and balloon assistance), vessel reconstruction, parent vessel occlusion, and liquid embolization.

Results
Aneurysms involving the vertebrobasilar system are rare, representing only 8-12% of all intracranial aneurysms. In particular, aneurysms affecting the VB junction, AICA and PICA are especially uncommon lesions, ranging from approximately 0.5-3% of all intracranial aneurysms. When occurring, aneurysms in each of these locations can present a number of challenges to successful treatment, both from a surgical and endovascular approach. In addition to aneurysm characteristics, a number of anatomic factors can also influence the treatment decision, including limited surgical access secondary to the petrous bone, close proximity to the perforating arteries and cranial nerves of the brainstem, as well as potential loss of normal AICA and PICA supply. An additional factor to consider when evaluating these aneurysms is the high degree of vascular anatomic variation, which can lead to unusual presentations of aneurysms such as dissecting and fenestration aneurysms, as well as the presence of collateral pathways, which have implications on treatment planning and selection.

Conclusions
Aneurysms affecting the vertebrobasilar junction, AICA and PICA are uncommon lesions, fraught with a number of treatment challenges, both surgically and endovascularly. After viewing this exhibit, the individual will better understand the methods available for treating aneurysms in these locations, as well as important factors to consider before, during, and after treatment.

Review of Vascular Access Closure Devices

F Rahman¹, S Solander², H Alvarez²
¹University of North Carolina Chapel Hill, Chapel Hill, NC, ²University of North Carolina, Chapel Hill, Chapel Hill, NC

Purpose

Neuroangiography and many other angiographic procedures require access to the common femoral artery. Proper arteriotomy closure at the conclusion of the procedure is vital with a major complication of continued hemorrhage. Historically, manual pressure has been used to close arteriotomy sites. This requires approximately 30 minutes of operator and procedure room time as well as cessation of anticoagulation. Approximately four hours of postprocedure immobility is required by the patient to ensure proper arteriotomy closure. In addition, complications can be highly dependent on operator experience, patient body habitus, and anatomy. More recently, several femoral artery closure devices have become available to save physician, procedure room, and recovery time. This exhibit aims to explain the appropriateness of closure device usage, description of the existing devices, instructions for usage, and potential complications.
Materials and Methods
We will review the contraindications of arterial closure devices and describe the benefits. We then will discuss the various classes and mechanisms of the available devices and their usage.

Results
Internal active arterial closure devices cannot be used in vessels with atherosclerotic disease or other irregularity such as dissection. Therefore angiography of the access site must be performed to rule out these conditions. There are multiple mechanisms of action for arterial closure devices. Most devices employ an anchor within the artery to be able to apply pressure between the arteriotomy and skin surface. The Cardiva Catalyst (Boomearang) device is the simplest device with a temporary anchor which is removed after hemostasis is achieved. No foreign body is left behind. Most other devices leave a foreign material to aid in closure which also creates the risk of distal embolization if there is device malfunction. Angioseal (St. Jude Medical) devices use an absorbable anchor and collagen plug external to the vessel for closure. Because of the foreign body, there is a slightly increased theoretical risk of infection. Mynx (AccessClosure) devices utilize a temporary balloon anchor with polyethylene sealant to close the tissues outside the artery. Because no permanent anchor is left in place, the risk of embolization should be lower. Exoseal (Cordis) devices also utilize a similar synthetic material to close the surrounding tissues. Other devices utilize mechanical closure rather than biologic or chemical materials. Starclose (Abbott) uses a nitinol clip to close the arteriotomy, but have been associated with persistent oozing in many cases. Perclose (Abbott) devices utilize a suture closure system. Many of these devices have been shown to reduce complication rated and accelerate time to patient ambulation. However there are small but significant risks such as infection and lower extremity ischemia that do not occur with simple manual compression. These risks can be decreased when the devices are used in the appropriate manner and in the appropriate circumstances. This exhibit will help in understanding these devices and their usage.

Conclusions
Multiple arterial closure devices are available on the market. When indicated, these can be a valuable tool to save time for both physicians and patients. The devices must be used carefully as incorrect operation or application in a contraindicated situation can result in hemorrhage or limb ischemia.

"Uncommon Phakomatoses" Clinical and Imaging Spectrum-What The Radiologist Needs to Know ?

L Amaral¹, P Hanagandi², F Goncalves³
Purpose
To familiarize the radiologist about uncommon phakomatoses syndromes.

Materials and Methods
Computed tomography (CT) and MR imaging (MRI) findings with relevant clinical correlation and review of neuroradiology literature will be discussed.

Results
Phakomatoses comprises a diverse group of multisystemic lesions presenting in different age groups. The spectrum of neurofibromatosis (NF1 & NF2) and tuberous sclerosis (TS) are diagnosed easily in routine imaging practice. When encountered with uncommon phakomatoses syndromes, the clue to diagnosis depends on clinical examination which is often overlooked. This educational exhibit emphasizes the importance of examining skin lesions which hold the key to diagnosis in many of these conditions. A variety of mucocutaneous lesions with imaging correlation will be the highlight of this educational exhibit. Diseases like Incontinentia pigmenti, Neurocutaneous Melanosis, Hypomelanosis of Ito, PHACES, Meningioangiomatoses, Osler Weber Rendu and Sturge Weber syndrome will be discussed with review of neuroradiology literature. Very often a small nonspecific naevus, mucocutaneous telangiectasia, facial brith mark, unusual cutaneous lesions like "lines of Blaschko" may be vital in clinching the diagnosis.

Conclusions
It is of prime importance to examine the skin and accessible mucocutaneous regions as they hold the key to diagnosis of uncommon phakomatoses.

KEYWORDS: Neurocutaneous Melanosis, PHACES, Phakomatoses

3T Fetal MRI

M Tenenbaum\textsuperscript{1}, O Afacan\textsuperscript{1}, C Barnewolt\textsuperscript{1}, J Estroff\textsuperscript{1}, E Yang\textsuperscript{1}, P Grant\textsuperscript{2}, B Gagoski\textsuperscript{1}

\textsuperscript{1}Boston Children's Hospital, Boston, MA, \textsuperscript{2}Children's Hospital Boston, Enders 961, Boston, MA
Fetal MR imaging (MRI) is important both for the further evaluation of anomalies detected by ultrasound as well as for screening fetuses at risk for brain abnormalities due to family history. In the post-natal period, imaging at 3 T has become preferable due to improved signal to noise ratio compared to 1.5 T. Although these benefits also hold for fetal imaging, 3 T fetal imaging has not yet become routine. Factors contributing to this include safety concerns related to 3 T imaging and management of artifacts worsened at higher field strength. We present our experience with 3 T fetal MRI safety and artifacts, as well as protocol optimization.

Materials and Methods
1) Although no specific FDA safety criteria for fetal imaging exist, there are FDA guidelines for determining MRI risks. Factors addressed are main static magnetic field, specific absorption rate, gradient fields rate of change, and sound pressure level. Risk in each of these four areas is assessed through literature review. 2) Common artifacts encountered on 3 T fetal MRI include signal drop off due to receive coil placement and/or dielectric effects, but artifacts due to fetal motion often dominate. Signal dropouts can be due to inappropriate positioning of the receive coil array, an artifact which can be fixed easily by repositioning them. Artifacts also may be caused by the dielectric effects from the inhomogeneous transmit field observed in body imaging at 3 T. The level of inhomogeneity depends on abdominal size, with larger abdominal sizes at later gestational ages (GA) tending to introduce more signal dropouts compared to smaller abdominal size at earlier GA. To mitigate motion artifact, the fetal acquisitions done on our 3 T system use a total of 30 ch coil elements, allowing robust imaging using in-plane (GRAPPA) acceleration factor (AF) of R = 2, resulting in 40-50% reduction in the amount of time needed to acquire a single slice. For example, in a typical HASTE acquisition (voxel size 1 x 1 x 2 mm^3), acquisition time for one slice is ~900 ms for the nonaccelerated case, and ~500ms with acceleration. Although in-plane AF of 2 can be applied both at 1.5 or 3 T scanners where the number of coil elements used is much less than 30, reconstruction of these acquisitions will be prone to image artifacts due to the increased spatial correlation among the fewer coil elements. Going to in-plane acceleration factors of 2 lowers the signal-to-noise ratio (SNR), but by going from 1.5 T to 3 T, we improve the SNR due to increased field strength. A secondary benefit of using acceleration factor of 2 is a decrease in SAR due to the decreased number of phase-encode lines.

Results
Overall, there is no evidence that 3 T fetal imaging poses significant increased risk relative to imaging at 1.5 T if standard safety precautions are strictly followed. Examples of artifacts will be shown. In general, correcting for the signal dropouts due to dielectric effects at 3 T would require RF pulse design algorithms that make the transmit field uniform throughout the FOV. However, this is a challenging task given the currently available transmit hardware on the clinical 3 T systems which have one transmit channel. 3 T system with 4-8 transmit RF amplifiers could enable one to effectively correct for the transmit field inhomogeneities while reducing the SAR of the sequence in the same time. However, these systems with multiple transmit amplifiers are not yet available for clinical practice. Thus, what can currently be done is to make sure that there are no signal dropouts in the specific area of interest within the excited FOV. For example, if the dark band is occurring in the middle of the fetus' head, and the head is the objective of that acquisition, then a pre-scan that gives a transmit field map over the entire FOV can be done, which would enable adjustment of the flip angle of the sequence, so that there are no signal dropouts over the fetus' head. This would basically move the dark band to a different location,
which would not be a problem given that the fetus' head is the objective of the acquisition. Example of 1.5 T and 3 T images will be shown to demonstrate differences in image quality and image artifacts. Our current 3 T protocol will be provided.

Conclusions

3 T imaging offers benefits in improved image quality and the potential to improve diagnostic accuracy in the prenatal period without significant increases in risk compared to 1.5 T. Common artifacts can be reduced by adjusting exam technique and image quality optimized by protocol adjustment.

**An Algorithmic Approach to Posterior Fossa Cystic Malformations**

R Bhasin¹, G Saigal²

¹University of Miami, Weston, FL, ²Jackson Memorial Hospital/ University of Miami Miller School of Medicine, Miami, FL

**Purpose**
1. Discuss posterior fossa cystic malformations and their imaging features. 2. Provide an algorithm that can be utilized as an organized approach to differentiate amongst the malformations.

**Materials and Methods**

Review embryologic development of the posterior fossa. Discuss imaging findings of posterior fossa cystic malformations. Provide a generalized algorithm to differentiate amongst the malformations.

**Results**

Posterior fossa cystic malformations include Dandy-Walker Malformation, persistent Blake's pouch cyst, arachnoid cyst, mega cisterna magna and epidermoid cyst. Although the imaging characteristics of these malformations have been well documented, their overlapping features make it confusing when applying them to daily clinical encounters. Differentiating amongst the entities is important because of their implications in treatment. We review the normal embryologic development of the posterior fossa, describe the posterior fossa cystic malformations, and discuss a generalized algorithm that assists in differentiating amongst the malformations. The algorithm begins by assessing the morphology of the cerebellar vermis; An abnormal vermis is indicative of Dandy-Walker Continuum, which includes Dandy-Walker Varient and Dandy-Walker Malformation. To differentiate amongst these two entities, one then evaluates for the presence of hydrocephalus. This, along with an enlarged posterior fossa, displacement of the transverse sinuses, tentorium and torcula are suggestive of Dandy-Walker Malformation. Alternatively, the absence of hydrocephalus, normal posterior fossa size, partial agenesis of the vermis, and abnormal vallecula are indicative of Dandy-Walker Varient. Conversely, if the vermis is normal in morphology then dilatation of the fourth ventricle should be assessed; if present this suggests of a persistent Blake's pouch cyst. If the vermis and the 4th ventricle are normal, then a mega cisterna magna, arachnoid cyst or an epidermoid cyst should be entertained. Next, compression of the fourth ventricle or cerebellum is assessed. If this is
lacking, and there is communication with the surrounding CSF spaces as indicated by a CINE CSF flow study, then a mega cisterna magna is suggested. Compression of the cerebellum or 4th ventricle can be seen in arachnoid cysts or epidermoid cysts and diffusion restriction can help distinguish amongst these.

Conclusions
After completing this electronic educational exhibit, the reader will gain a better understanding of the various posterior fossa cystic malformations and will be able to apply an algorithm that offers a simplified approach to differentiate amongst the various entities in order to improve diagnostic accuracy.

eEdE-179

An Easy Approach to Diagnose Inborn Metabolic Disorders in Children: How to Make Things Easier
Purpose
To present an "easier" approach to diagnose or at least to suggest the most probable list of
diagnoses in children presenting with a clinical picture of progressive encephalopathy and with
an eventual diagnosis of inborn metabolic disorder.
Materials and Methods
We retrospectively reviewed the clinical charts and neuroimaging studies in 130 children with
inborn metabolic diseases studied in the last 18 years. MR imaging (MRI) was performed on a
1.5 T GE Signa Horizon and 1.5 T GE Excite. Available sequences included sagittal T1 and T1
3D SPGR, axial T1, T2, FLAIR, GRE and DWI, as well as coronal T2. Magnetic resonance
spectroscopy (MRS) was obtained in some patients, and gadolinium chelates were administered
in all. A neuroradiologist with 18 years experience (BL) evaluated all the images. The diagnosis
was confirmed by blood or urine evaluation, MR spectroscopy, skin biopsy, and/or clinical
evaluation.
Results
Based on the neuroimaging features and clinical picture, along with the results from the blood,
urine and cerebrospinal fluid (CSF), EEG and ophthalmologic studies, the vast majority of cases
could be categorized into the following groups: 1- Diseases that affect only (or mainly) boys; 2-
Diseases with typical changes in hair and/or skin; 3- Diseases with macrocephaly; 4- Diseases
presenting with neonatal epilepsy; 5- Diseases with a strong predilection for the brainstem and/or
cerebellum; 6- Diseases that produce cysts in the brain parenchyma.
Conclusions
Inborn metabolic disorders are a common cause of developmental arrest in children. Some
patients also present with seizures, macrocephaly, hypotonia, and impaired vision and hearing.
These disorders are usually classified according to the affected cell (i.e., lysosomes, etc.) or
organelle (i.e., mitochondria, etc.). However, this approach is not helpful from a radiological
perspective. Evaluation of the MRI findings, along with the clinical information as well as the
results of ancillary laboratory and EEG studies is helpful to categorize patients and to restrict the
scope of differential diagnosis. The use of the proposed schematic approach may be helpful in
the everyday radiological practice.

Baby’s buttocks tell what anomalies inside: Imaging of spinal dysraphism.

K Ando¹, R Ishikura¹, J Kurihara², Y Kawanaka¹, Y Igarashi¹, T Katsuura¹, Y Wakata¹, S Hirota¹
¹Hyogo College of Medicine, Nishinomiya, Japan, ²Saitama Children’s Medical Center,
Saitama, Saitama, Japan

Purpose
Spinal dysraphism is a heterogeneous group of anomalies. Classification for spinal dysraphism is
complex and also various. Patients with spinal dysraphism refer to imaging studies because of
abnormalities in their buttocks: Mass or pit. And if we classify spinal dysraphism along with these findings, this complex entity becomes simpler. In this educational review, we classify spinal dysraphism along with findings of patient's buttocks. Clinical manifestations, embryology and imaging findings and prognosis of each anomaly will be presented.

Materials and Methods
In this educational review, we classify spinal dysraphism along with findings of patient's buttocks. Clinical manifestations, embryology and imaging findings and prognosis of each anomaly will be presented.

Results
Content organization: 1. Mass on buttocks: A. Mass not covered with skin: Myelomeningocele, meningocele, or myeloschisis. B. Mass covered with skin: Lipomyelomeningocele, lipomyelocele, or terminal myelocystocele with or without intra spinal lipoma. 2. Pit in buttocks: A. Pit above gluteal cleft: Dermal sinus, which may associate with tethered cord and dermoid cyst. B. Pit between gluteal cleft: Sacrococcygeal skin dimple, which is usually without severe abnormalities. 3. Normal looking buttocks: Under normal looking buttocks, spina bifida, intraspinal lipoma, and caudal regression syndrome may be hidden.

Conclusions
Spinal dysraphism is a heterogeneous group of anomalies. However, patient's buttocks suggest which abnormality is under them and help understanding of spinal dysraphism.

Calvarial Pathology in Children Portrayed by 320 Detector 3D Volumetric CT

M Whitehead1, C Oh2, A Choudhri2
1Children's National Medical Center, Arlington, VA, 2University of Tennessee Health Sciences Center/LeBonheur Children's Hospital, Memphis, TN

Purpose
Various disease processes can affect the neurocranium. Specific patterns, morphology, and extent of calvarial pathology may be underappreciated on cross-sectional images alone. Three-dimensional (3D) computed tomography (CT) images can provide a more global picture of the skull. The purpose of this exhibit is to demonstrate examples of congenital, developmental, and post-traumatic disease processes depicted by 320 detector 3D CT.

Materials and Methods
Selected 3D CT cases from children (ages 0-18) exemplifying various disease processes of the skull are reviewed and exhibited. Normal 3D CT images of the skull also are displayed. All exams were performed using a volumetric acquisition with a 320 detector CT scanner (Toshiba Aquilion 320, Toshiba Inc., Tokyo, Japan), without intravenous contrast material. Five mm thickness axial, sagittal, and coronal bone and soft tissue algorithm multiplanar reconstructions were created by the CT scanner. Three-dimensional volume reconstructions of the skull were produced by CT scanner software with transverse rotation and anterior-posterior tumble images created at 18 degree intervals.
Results
Various disease processes affect the developing skull. Three-dimensional CT images provide an excellent global view of the calvarium, enhancing pattern recognition that may not be evident on segmental images viewed in cross-section or in reformatted planes. Case examples of congenital/developmental defects, craniosynostosis, luckenschadel skull, dermoid associated with metopic wormian bones, fibrous dysplasia, osteogenesis imperfecta, achondroplasia, Goldenhar syndrome, bruxism enthesopathy, and traumatic pathology (both blunt and penetrating traumatic injuries) are presented.

Conclusions
Three-dimensional CT images of the calvarium are a useful adjunct to cross-sectional images in the evaluation of osseous disease processes. The patterns and extent of congenital skull anomalies, bone lesions, and fractures are all readily evaluated on 3D CT.

KEYWORDS: Calvarial, CT, Skull

Central Nervous System Manifestations and Treatment-related Complications of Hematologic Malignancies in Children

P Cornejo¹, P Naidu¹, J Egelhoff¹, J Curran¹, J Miller¹, R Towbin¹
¹Phoenix Childrens Hospital, Phoenix, AZ

Purpose
Hematologic malignancies result in a wide array of central nervous system (CNS) abnormalities
in children. These varied pathologies may relate to the patient's primary disease or its treatment. The purpose of our study is to review the clinical and imaging features of disease and treatment-related neurological complications of hematologic-based malignancies in children.

Materials and Methods

We retrospectively analyzed the neuroimaging findings of 14 patients with hematologic derived malignancies: acute myelogenous leukemia (AML), acute lymphoblastic leukemia (ALL), lymphoma, Langerhans cell histiocytosis (LCH) and hemophagocytic lymphohistiocytosis (HLH). All patients had CNS tumor, cranial/intracranial involvement, or treatment-related complications that were characterized on contrast-enhanced brain and, where applicable, spine MR imaging (MRI).

Results

Among the 14 patients, eight had primary tumor-related findings. Two patients with AML had parenchymal and/or meningeal leukemia compatible with myeloid sarcoma. A patient with recurrent ALL had a posterior third ventricular/pineal region mass, a rare presentation for this subtype of leukemia. The patient also had abnormally thick enhancement of the pituitary stalk, with the constellation of findings overall suggestive of a germinoma. Another patient with ALL had abnormal enhancement of thickened dura in addition to more typical marrow abnormality. One patient with lymphoma had a parenchymal mass as well as an extra-axial mass, and had been treated for demyelination on the basis of prior imaging in which his malignancy mimicked white matter lesions. Two patients with LCH had isolated skull masses, with another lacking the normal T1 hyperintensity corresponding to the posterior pituitary gland. Another LCH patient with initial mastoid involvement recurred in the left frontal region, with disease extending into thickened dura. Imaging in the patient with neurodegenerative LCH showed areas of supra- and infratentorial brain T2/FLAIR white matter hyperintensity, including within the middle cerebellar peduncles and cerebellar white matter. Seven patients had treatment-related complications. Four ALL patients had leukoencephalopathy related to methotrexate. One HLH patient and one ALL patient had cerebrovascular abnormalities resulting in white matter signal abnormalities, and another postradiation changes.

Conclusions

Treatment advances in hematopoietic-based malignancies have improved survival, increasing the incidence of CNS disease as well as associated complications. MR characterization of these abnormalities also continues to improve, with increasing availability of higher strength magnets and implementation of advanced techniques such as perfusion imaging. Familiarization with the extensive range of imaging characteristics in this setting is essential for the radiologist. While the imaging findings occasionally may be rare or mimic other conditions, accurate assessment at the onset of new symptoms and in the evaluation of treatment response have the potential to impact further management options (such as medication regimen or bone marrow transplant) and thereby alter the clinical course.

Embryology for Neuroradiologists: a Visual Primer

J Starkey¹, T Moritani², J Kim², Y Sato³
Purpose
To illustrate the embryology of brain, head and neck, and spine imaging integrated by basic concepts through a pictorial essay.

Materials and Methods
We demonstrate complex embryology through easy-to-understand illustrations and imaging of typical brain, head and neck, and spine pathologies such as: anencephaly, encephalocele/myelomeningocele, Arnold-Chiari malformation, Dandy-Walker complex, holoprosencephaly, rhombencephalosynapsis, notochord remnant, vertebral anomaly, thymoglossal duct cyst, branchial cleft anomalies, ear anomalies, persistent hyperplastic primary vitreous, foregut malformation, and CHARGE association. We also briefly discuss associated gene expressions/mutations.

Results
The central nervous system is formed during week 3 of development as the neural plate of neuroectoderm becomes the neural tube, giving rise to the brain and spinal cord. The notochord induces the ectoderm to form the neural plate. The peripheral nervous system is derived from neural crest cells, the neural tube (nerve fibers), and mesoderm (dura matter, endo-, peri- and epineurium). The head and neck are formed by pharyngeal arches (somitomeric mesoderm, neural crest cells), pharyngeal pouches (evagination of endoderm), pharyngeal grooves (evagination of ectoderm), and pharyngeal membranes (ectoderm). These structures form the middle ear cavity (pharyngeal pouch 1), malleus and incus (pharyngeal arch 1), stapes (pharyngeal arch 2), tympanic membrane (pharyngeal membrane), external ear meatus (pharyngeal groove 1), palatine tonsil crypts (pharyngeal pouch 2), and parathyroid gland and thymus(pharyngeal pouch 3 and 4). Placodes are localized thickenings of surface ectoderm (lens placode, otic placode, olfactory placode). The endodermal lining of the foregut forms the thyroid diverticulum. Cranial nerves 5, 7, 9, and 10 supply the structures of pharyngeal arches 1, 2, 3, 4, and 6. The internal ear develops in week four from the surface ectoderm (otic placode) invagination into mesenchyme to the rhombencephalon to form the otic vesicle. The optic vesicle from the diencephalon invaginates into the optic stalk and forms the optic nerve and choroidal fissure permitting access of the hyaloid artery. Failure at any of these points gives rise to abnormalities/syndromes with which the neuroradiologist should be familiar.

Conclusions
We demonstrate complex embryology through easy-to-understand illustrations and imaging of typical brain, head and neck, and spine pathologies. An integrated knowledge of embryology is essential for understanding the anatomy and pathophysiology for image interpretation of diseases and syndromes. This educational exhibit provides a visual primer of embryology for neuroradiologists.

eEdE-180

Fetal MRI technique: What are we looking for?
Purpose
To demonstrate a step by step approach of interpreting fetal MR imaging (MRI) with respect to central nervous system (CNS) and Head and Neck pathologies based on specific pulse sequences.

Materials and Methods
Our fetal MRI protocol includes scout T1 images of the maternal pelvis in three planes, axial T1-weighted images (VIBE) along the maternal axis, three planes T2-weighted images (HASTE or TrueFISP), axial echo planar images (EPI), axial T1-weighted images and axial diffusion-weighted images (DWI) of the brain along the fetal axis. Key imaging findings in each pulse sequence will be documented, with respect to pathology detection and diagnosis. Correlation with postnatal imaging and clinical outcome will be provided, if available.

Results
We will demonstrate several cases of congenital CNS and Head and Neck pathology detected from fetal MRI. Imaging checklists and key imaging findings in each MRI pulse sequence will be highlighted as a tool for interpretation. Scout and T1 image checklists include fetal orientation, placental position, fetal situs, congenital pathology of the thyroid, and subacute CNS blood products. T2 image checklists include CNS anatomy with respect to ventricular size, symmetry, supratentorial and posterior fossa malformations, and sulcation pattern. EPI image checklist includes blood products and vessel thrombosis. The DWI checklist includes acute infarct and potential tumor grading. The various congenital pathologies we will demonstrate using this method include neural tube closure defects (encephalocele, and myelomeningocele with and without Chiari malformation), disorders of diverticulation (holoprosencephaly, corpus callosal anomalies, and absent septum pellucidum), neuronal migration and sulcation abnormalities (polymicrogyria and schizencephaly), Dandy-Walker malformation, hydrocephalus (aqueductal stenosis), infarction and/or hemorrhage (hydranencephaly), facial malformation (cleft lip and cleft palate), benign brain lesions (arachnoid cysts), congenital tumors (epignathus, head and neck teratoma, choroid plexus tumor, sacrococcygeal teratoma), and vascular lesions (hemangioma, venolymphatic malformation, sinus thrombosis, and vein of Galen malformation). Figure A demonstrates a 24-week fetus with a posterior scalp mass. Axial T1 VIBE shows a mass with internal linear hyperintensity (white arrow) consistent with vascularity. A sagittal T2 HASTE shows the circumscribed mass with prominent flow voids (white arrow) and associated cardiomegaly with ascites (black arrows), indicating high output heart failure from a fetal hemangioma.

Conclusions
Fetal MRI is a valuable imaging modality in diagnostic dilemmas when ultrasound examination is inconclusive. This information will help parents make decisions during the pregnancy, and possible advanced treatment during the pre and postnatal period. Understanding the importance of imaging sequences and having a diagnostic checklist in each sequence can improve accuracy in interpretation, assisting clinicians in optimizing patient counseling, management of pregnancy and delivery, and postnatal treatment planning.

Imaging of pediatric CNS inflammatory demyelinating disorders

A Abdel Razek

Mansoura University, Mansoura, Egypt

Purpose
1-To review basic background about pediatric central nervous system (CNS) inflammatory demyelinating disorders (CIDD). 2-To illustrate classification of pediatric CIDD. 3-To discuss typical and atypical imaging appearance of pediatric CIDD. 4-Role of advanced imaging in diagnosis of pediatric CIDD.

Materials and Methods
1-Consensus definitions proposed for pediatric multiple sclerosis and related disorders. 2-Update classification of pediatric CIDD. 3-Prevalence and incidence, world distribution, current diagnosis criteria, treatment strategies. 4-Imaging appearance of pediatric multiple sclerosis. 5-
Imaging of acute disseminated encephalomyelitis and its variants as recurrent and multiphasic. 6- Imaging of pediatric neuromyelitis optica. 7- Imaging of pediatric clinically isolated syndrome. 8- Role of advanced MR imaging in pediatric CIDD. 9- Imaging findings used to differentiate pediatric CIDD from other simulating lesions. 10- Summary and future directions.

Results
MR imaging helps for diagnosis of pediatric multiple sclerosis and differentiating from simulating disorders. We discuss the MR imaging appearance of acute disseminated encephalomyelitis and its variants as recurrent and multiphasic. Also, imaging is important for diagnosis of pediatric neuromyelitis optica and pediatric clinically isolated syndrome. Advanced MR imaging has a role in diagnosis of pediatric CIDD. Imaging findings used to differentiate pediatric CIDD from other simulating lesions.

Conclusions
We concluded that routine and advanced MR imaging in conjunction with clinical findings are useful for diagnosis of pediatric CIDDs and differentiating them from simulating lesions.

eEdE-196

IMAGING OF PEDIATRIC INTRAVENTRICULAR TUMORS

K Tun¹, K Thamburaj²
¹Penn State Milton S Hershey Medical Center, Hershey, PA, ²Penn State University, Hershey, PA

Purpose
Intraventricular tumors occur with a higher incidence in children than in adults. Intraventricular tumors in children can be found in both supratentorial and infratentorial compartments which can pose a serious diagnostic challenge. Early and accurate identification is an essential step in the management of these tumors. This exhibit aims to provide a broad understanding of the imaging features of various intraventricular tumors occurring in the pediatric age group.

Materials and Methods
Imaging anatomy of the ventricular system with color plates, CT and MR imaging (MRI) will be discussed initially to understand the intraventricular tumors. The intraventricular tumors will be classified as supratentorial and infratentorial. Supratentorial tumors will further be discussed as lateral and third ventricular tumors. Relevant clinical cases will be used to highlight the imaging features of various intraventricular tumors. Also, developmental lesions occurring in the ventricles will be discussed. An emphasis on appropriate imaging techniques will be made, for example the utility of diffusion sequence to distinguish medulloblastoma from other tumors in the fourth ventricle. An imaging algorithm will be provided at the end of the presentation to facilitate the imaging analysis of the various pediatric intraventricular tumors. An emphasis on imaging of neuraxis also will be discussed to identify and exclude CSF spread of tumors in the appropriate situations.

Results
Important intraventricular tumors in the supratentorial compartment include choroid plexus papilloma, subependymal giant cell astrocytoma, subependymoma, central neurocytoma,
meningioma and ependymoma in the lateral ventricles. The important tumors which can be found in the third ventricle include germinoma, choroid plexus papilloma, ependymoma and craniopharyngioma. Along with the imaging features, the clinical features of intraventricular tumors will be discussed to improve the accuracy of diagnosis. A discussion on colloid cyst in the roof of the third ventricle will be made. Tumor mimics of intra third ventricular tumors like pineal tumors and basilar bifurcation aneurysm will be discussed. Developmental lesions including subependymal heterotopia, arachnoid cyst, dermoid/epidermoid and cavernoma of the lateral and third ventricles will be discussed to complete the features of supratentorial intraventricular tumors. In the fourth ventricle, medulloblastoma, ependymoma, choroid plexus papilloma and subependymoma will be discussed. Also developmental lesions dermoid/epidermoid of the fourth ventricle will be discussed. Exophytic tumors mimicking intraventricular tumors such as pilocytic astrocytoma of the cerebellum/brainstem, tuber cinereum hamartoma, etc., will be highlighted. A discussion on tumor seedling through ependymal spread will be made. Finally, imaging features of intraventricular cysticercosis will be discussed to complete a comprehensive coverage of pediatric intraventricular tumors.

Conclusions
A review of the exhibit will help one to understand the intraventricular tumors occurring in the pediatric population, identify their imaging features, guide the appropriate imaging technique and recognize the post-treatment changes.

KEYWORDS: Pediatric Brain Tumors, Ventricles

Imaging the peritumoral zone of pediatric brain tumors using DTI: the good , the bad and the ugly.

N Abdeen1, A Alaref1
1Childrens Hospital of Eastern Ontario, Ottawa, Ontario, Canada

Purpose
Delineating the boundary of brain tumors is important to guide surgical resection. This can be difficult on conventional imaging due to the infiltrative behavior of some high grade tumors. The goal of this exhibit is to review a wide range of pediatric brain tumors and illustrate various appearances of the peritumoral zone on diffusion tensor imaging (DTI), correlating also with conventional imaging. Diffusion tensor imaging has been used to improve delineation and characterization of tumor margins in adult brain neoplasms but there is relatively little work in pediatric tumors. This exhibit will compare and contrast the DTI findings in low grade or noninfiltrative neoplasms ("the good"), infiltrative aggressive neoplasms ("the bad") and discuss potential pitfalls and artifacts that interfere with proper assessment ("the ugly").

Materials and Methods
Pediatric patients with intra-axial brain tumors were identified through our institution's radiology information system. Initial pre-operative MR imaging (MRI) was reviewed. Operative reports were reviewed to determine any specific difficulties in identifying tumor margin during the procedure. Pathology reports and postoperative imaging also were reviewed to determine the completeness of resection. A case-based presentation illustrating the various patterns of white
matter involvement by tumor, correlating conventional imaging and DTI was constructed. The fractional anisotropy maps, mean diffusivity map, and color map were analyzed for each case. Diffusion tractography was used to analyze the effect of tumor on adjacent white matter tracts, if applicable. The relationship of these findings to surgical planning and completeness of resection was discussed for each case.

Results
A wide range of tumor types was illustrated. Supratentorial tumors included juvenile pilocytic astrocytoma, anaplastic astrocytoma, glioblastoma multiforme, choroid plexus carcinoma with parenchymal invasion, optic nerve glioma, oligodendroglioma, PNET. Infratentorial tumors included medulloblastoma, ependymoma, anaplastic ependymoma, juvenile pilocytic astrocytoma, tectal glioma, pontine glioma and atypical teratoid rhabdoid tumor. The high grade tumors including anaplastic astrocytoma, glioblastoma multiforme, atypical teratoid rhabdoid tumor, and invasive choroid plexus carcinoma showed peritumoral zones with decreased fractional anisotropy and infiltration of white matter tracts. The low grade tumors by contrast displaced rather than infiltrating the adjacent white matter, with no peritumoral loss of fractional anisotropy. Findings were similar to those reported for adult neoplasms.

Conclusions
Diffusion tensor imaging provides a valuable complement to conventional MRI in assessment of the peritumoral zone of pediatric brain tumors, and could help distinguish low grade from high grade neoplasms. Familiarity with these findings will help the radiologist provide better pre-operative imaging assessment of pediatric brain neoplasms.

Implications of absence of Cavum Septum Pellucidum on Forebrain Commissures: An embryology based approach

D Sundarakumar1, M Dighe1, K Maravilla1, J Nixon1, C Smith2, S Gaddikeri1
1University of Washington, Seattle, WA, 2University of Texas Health Science Center at San Antonio, San Antonio, TX

Purpose
The cavum septum pellucidum (CSP) is an important landmark to identify on fetal ultrasound examination, as its absence often heralds commissural abnormalities. Anatomically and developmentally related to the CSP, various patterns of Corpus Callosal (CC) abnormalities are evident on follow-up MR imaging (MRI). However, due to the widespread misconception of an anterior to posterior sequential development of the CC, there is a dichotomy in understanding the patterns of "typical" (normally formed anterior callosum in the absence of posterior callosum) versus "atypical" callosal agenesis (normally formed posterior callosum in the absence of the anterior callosum) in the holoprocencephaly spectrum of disorders (HPE). As a result, a quagmire of terms is used in the clinical description of these abnormalities. Understanding CSP development is therefore quintessential in demystifying mid-line developmental abnormalities and anticipating their patterns in general.
Materials and Methods
1. Using simple illustration, this exhibit reviews the embryological origin and development of the CSP, CC, as well its relationship to the anterior and hippocampal commissures. 2. Significance of age-appropriate imaging features of the CSP, and its implications on prenatal screening timing. 3. Discuss the prevalence of absent CSP in various developmental disorders, and the role of absent CSP as a potential surrogate marker for midline defects on prenatal ultrasound. 4. Characterization of the patterns of possible commissural abnormalities in absent CSP on MRI.

Results
1. Embryology: CC is one of three major commissures of the forebrain that develops from a glial sling at the lamina reunions (LR), around 12 weeks; the CSP is developmentally related to anterior callosum. The growth of the CSP closely shadows the dorsoventral expansion of the developing forebrain. The posterior callosum originates independently, further dorsal to the hippocampal commissure. 2. A wide spectrum of morphologically abnormal CC is possible in the developmental absence of the CSP. a: Callosal agenesis (complete and partial): The lack of formation of the glial sling, crucial for the crossing pioneering neurons, manifests as complete agenesis of the CC. The migrating neurons therefore are misdirected posteriorly. Diffusion tensor imaging provides exquisite detail of the architecture of the heterotopic white matter fascicles in commissural abnormalities. Partial agenesis of the CC results from regional defects of the neocortex, due to focal defects of the callosal anlage, and poor dorsal expansion of the callosum happening due to expansion of cerebral hemispheres. b. In milder forms of HPE, including midline syntelencephaly, the callosal defect corresponds to the extent of interhemispheric fusion, which more severely affects the anterior callosum as it develops from the ventral LR. The posterior callosum, which develops in the dorsal LR is relatively spared ("atypical" agenesis). c. Disorders of cerebral cortex with absent CSP and agenesis of CC occurs frequently due to neuronal migration disorders. d. Schizencephaly and Septo-optic dysplasia: Absent CSP is common feature in these disorders. Common underlying genetic factors (e.g., Lhx-2 gene) have been identified which influence the CSP development.

Conclusions
The developmental absence of CSP indicates associated commissural disorders of variable clinical consequences. Knowing the embryological development of CSP and commissures simplifies the understanding patterns of these developmental disorders. The manifestations of such disorders are most apparent on the corpus callosum which is the largest commissure of the brain.

Mimics of Inherited Metabolic Disorders in Children:

H Parmar¹
¹University Of Michigan, Ann Arbor, MI

Purpose
Interpreting radiologic exams white matter disease in children often is challenging for radiologists. One of the first questions to be asked when dealing with such an exam is if it is indeed an inherited metabolic process or some other acquired disease process producing similar appearance. Multiple disease entities can present with imaging features mimicking inherited metabolic disorders. These disorders represent a spectrum of white matter disease characterized by damage to neurons or axons with resultant breakdown of myelin resulting from pure demyelination to necrosis with subsequent demyelination.

Materials and Methods
The goal of this exhibit is to give a brief overview of clinical features of mimics of inherited metabolic disorders. We will review the imaging features and provide important radiologic and clinical clues to differentiate them from metabolic disorders. The obvious clinical implication of this is to arrive at correct and early correct diagnosis and avoid expensive and unnecessary metabolic work up.

Results
Entities which will be reviewed in this exhibit include: inflammatory and infectious processes like pediatric multiple sclerosis, acute disseminated encephalomyelitis (ADEM), posterior
reversible encephalopathy syndrome (PRES), postmeasles virus-induced subacute sclerosing panencephalitis (SSPE), cytomegalovirus (CMV) related white matter changes; acquired toxic injuries and nutritional deficiencies like Wilson's disease, vitamin B12 deficiency, Wernicke's encephalopathy, postradiation leukoencephalopathy, drug-induced (like methotrexate) leukoencephalopathy; vascular causes like cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), primary CNS vasculopathy; and other disorders including neurofibromatosis type I, postischemic leukoencephalopathy, acute necrotizing encephalopathy of childhood (ANEC). To narrow the differential diagnosis combination of the clinical and laboratory data, whenever available, with the imaging features is important. Additionally, serial imaging helps to differentiate these mimickers, which tend to be stable or improve on follow-up imaging studies, in contrast to inherited metabolic disorders which are typically progressive.

Conclusions
There are numerous diseases which present as with either white matter or gray matter abnormality, in a pattern similar to inherited metabolic disorders. This assessment can be quite challenging. Knowledge of clinical and imaging features of these disorders is important to differentiate them from more complex groups of inherited disorders. This can lead to early diagnosis and avoid more expensive and often unnecessary metabolic work up.

Moyamoya disease and syndrome in children: spectrum of neuroimaging findings

T Bosemani1, A Poretti1, G Orman2, A Tekes1, M Pearl1, T Huisman2
1The Johns Hopkins University School of Medicine, Baltimore, MD, 2The Johns Hopkins School of Medicine, Baltimore, MD

Purpose
Moyamoya (MM) vasculopathy is a vascular condition which results in progressive narrowing of the distal intracranial internal carotid arteries and its supraclinoidal branches which may lead to acute or chronic ischemic injury of the brain. Moyamoya disease (MMD) refers to the idiopathic cause of the characteristic vasculopathy, whereas, moyamoya syndrome (MMS) is associated with other clinical conditions and risk factors (e.g., sickle cell disease, Down syndrome, neurofibromatosis type 1, postradiation treatment). The vasculopathy is typically bilateral in MMD; however, it may present unilateral with contralateral findings developing over time in MMS. Also, MMS may involve the vessels of the posterior circulation. It is essential to recognize MM vasculopathy if a systemic disease or condition is diagnosed which is known to be linked to MMS.

Materials and Methods
We reviewed our pediatric MRI database searching for pediatric MM vasculopathy.

Results
After a brief discussion of "how to perform neuroimaging" in MM vasculopathy, we present a review with selected case histories to illustrate the characteristic primary and secondary neuroimaging findings of MMD and MMS. In addition, a selection of the various diseases linked
to MMS will be described including Down syndrome, Keutel syndrome, sickle cell disease, neurofibromatosis, and radiation therapy. The neuroimaging findings after revascularization (e.g., pial synangiosis and encephalogaleal synangiosis) will be reviewed. The importance of recognition and utilization of various neuroimaging modalities will be highlighted.

Conclusions
Moyamoya disease and MMS are recognized, yet rather distinct causes of pediatric stroke and cerebrovascular disease. Neuroimaging plays a pivotal role in the early recognition, diagnosis, management, and follow up to prevent pediatric stroke and neurological sequelae. In addition, neuroimaging should be applied to differentiate MMD from MMS. Familiarity with the various pathologies and diseases linked to MMS is essential.

KEYWORDS: Childhood, Moyamoya, MR Imaging

MR Imaging Appearance of the Various Congenital Anomalies of the Brain

V Datta¹, S Meyers¹
¹University of Rochester University Medical Imaging, Rochester, NY

Purpose
This exhibit will utilize primarily magnetic resonance imaging (MRI) to illustrate and help further the understanding of the various congenital anomalies of the brain. We will discuss the relevant anatomy and embryologic origin of the various malformations, to facilitate a better understanding of the different congenital abnormalities.

Materials and Methods
• Brief discussion of the relevant anatomy and embryologic origin of the various congenital anomalies of the brain and organization based on their embryologic origin as follows: neural tube closure disorders; disorders of diverticulation; neuronal migration disorders; malformations from abnormal neuronal and glial proliferation, apoptosis or necrosis; malformations in late neuronal migration and cortical organization; malformations related to abnormal pial basement membrane formation; cerebellar hypoplasia malformations; and cerebellar dysplasia malformations. • Multimodality imaging findings of the various congenital malformations of the brain. • Discussion of syndromes and associated abnormalities seen with these different congenital anomalies.

Results
Congenital anomalies of the brain are not uncommonly encountered in the daily practice of a neuroradiologist; therefore, a familiarity of the different anomalies is crucial. Congenital brain malformations, which will be discussed, include: Chiari Malformations, Holoprosencephaly, Septo-optic Dysplasia, Arhinia/Arrhinenecephaly, Lissencephaly, Pachygyria, Gray Matter Heterotopia, Schizencephaly, Hemimegalencephaly, Microcephaly, Sotos syndrome, Polymicrogyria, Focal Cortical Dysplasia, Walker-Warburg Phenotype, Muscle Eye Brain Phenotype, Fukuyama Congenital Muscular Dystrophy, Dandy Walker Malformations, Joubert syndrome, Rhombencephalosynapsis and Lhermitte-Duclos disease.

Conclusions
This project will aim to familiarize the exhibit viewer with the various congenital anomalies of
the brain, which will facilitate identification of clinically significant pathology and incidental benign variants. Further understanding of associated abnormalities and complications can aide in accurate diagnosis by the practicing radiologist.

KEYWORDS: Congenital Brain Malformations

MRI of congenital spine anomalies

H Mamata¹, M Castillo², V Jewells²
¹University of North Carolina at Chapel Hill, Chapel Hill, NC, ²University of North Carolina Hospitals, Chapel Hill, NC

Purpose
Congenital spinal anomalies present with a constellation of pathologies and symptoms. It is important to understand the morphological characteristics and embryology of congenital anomalies for correct diagnosis to guide treatment of these patients. MR imaging (MRI) is an excellent tool for visualization of congenital spinal anomalies.

Materials and Methods

Results
We have observed various congenital spinal anomalies over many years using MRI at our institution. Chiari I anomaly demonstrates a small posterior fossa and skull base anomalies. Chiari II demonstrates the above findings as well as associated corpus callosum and migrational abnormalities, high-riding cerebellum, tectal beaks, sulcal interdigitation, and open associated spinal dysraphism. Atlanto-occipital assimilation/subluxation or retroflexed odontoid is commonly associated with cervicomедullary compression, increased atlanto-dental interval as well as incomplete C2-3 segmentation. Klippel-Feil syndrome is a segmentation failure of two or more cervical and thoracic/lumbar vertebrae: C2-3 (50%), C5-6 (33%), and is associated with odontoid dysplasia, syringomyelia, diastematomyelia (20%), Chiari I (8%), neuroenteric cysts/dermoids, Sprengel deformity/omovertebral bone (15-30%), sensorineural hearing loss (30%), external auditory canal abnormalities, genitourinary abnormalities (35%), CHD (14%), and facial anomalies. In addition, dysraphism is associated with kyphoscoliosis, osseous anomalies, syrinx (30-75%), Chiari II (almost 100%). Caudal regression syndrome is secondary to maternal hyperglycemia/diabetes, infections, toxins, and ischemic insults. Signaling defects by retinoic acid and sonic hedgehog during blastogenesis prior to the 4th gestational week is a
known cause. Caudal regression is associated with defects in HLBX9 homeobox gene (Chromosome 7) as well as cardiac defects (24%), genitourinary anomalies (24%), renal hypoplasia, ano-rectal anomalies- particularly atresia, and lower extremity abnormalities. Diastematomyelia also known as split notocord syndrome is associated with dorsal enteric fistula/sinus, and dorsal enteric cysts/diverticula.

Conclusions
Morphological characteristics of congenital anomalies are best demonstrated with MRI. It is important to understand the constellation of findings as well as symptoms and treatment to improve the radiologists' communication of pertinent findings to the clinician in order to improve patient care and the child's quality of life.

KEYWORDS: Congenital Anomalies, MR Imaging Spine, Spinal Imaging
Purpose
Multimodality imaging review of pediatric orbital neoplasms.

Materials and Methods
Discuss multimodality imaging characteristics of pediatric orbital neoplasms, including ocular lesions.

Results
Pediatric orbital neoplasms are distinct from neoplasms in the adult population and consist of a wide variety of lesions from congenital to neoplastic in nature. Pediatric orbital tumors and tumor-like lesions, including ocular lesions, are discussed in this exhibit. Examples include:

- Retinoblastoma: most common intraocular pediatric tumor, arises from immature retina [exhibit explains how to differentiate this entity from mimickers like pseudoretinoblastoma (a persistence and hyperplasia of fibrovascular tissue), Coats disease (a unilateral vascular malformation of retina), and retinopathy of prematurity].
- Optic nerve glioma: juvenile pilocytic astrocytomas may involve any portion of the optic pathway and the hypothalamus, most common intraconal pediatric tumor.
- Leukemia, lymphoproliferative disease.
- Osseous origin tumors: Dermoid inclusion cyst, fibrous dysplasia, juvenile ossifying fibroma, osteosarcoma, and bone metastases (i.e., neuroblastoma).
- Infantile hemangioma: most common vascular tumor in infants. These lesions are discussed with their specific imaging characteristics that help in arriving at the accurate diagnosis. Figure shows a large heterogeneous lesion arising from the left orbit with T1 hyperintense contents consistent with teratoma.

Conclusions
Early diagnosis of pediatric orbital neoplasms is important because of their significant impact on vision even with the benign lesions. Imaging characterization of pediatric orbital neoplasms provides important information regarding prognosis and available surgical and adjuvant therapies.

KEYWORDS: Orbital Tumor, Pediatric Neoplasms
Neuroimaging in Metabolic Disorders: A Pattern Based Approach.

M Tenenbaum¹, E Yang¹, S Prabhu¹
¹Boston Children's Hospital, Boston, MA

Purpose
This presentation will review a pattern-based approach to generating a differential diagnosis for suspected metabolic disorders based on their imaging appearance.

Materials and Methods
An algorithm for the classification of metabolic diseases with examples of diseases from each category and a description of their differentiating imaging features will be provided.

Results
Metabolic disorders are diseases caused by a gene mutation that leads to synthesis of an abnormal protein which then causes disruption of normal metabolic pathways. This is a widely diverse group of disorders which may or may not have neurologic involvement in addition to
systemic involvement. As such, the imaging appearance of these diseases also is widely variable, and diagnosis can be challenging. However, the features of these diseases can be used to categorize them and to generate a differential diagnosis. A commonly used method of classifying metabolic diseases is to group them as having a predominant pattern of involvement of the white matter, gray matter, both gray and white matter, or those with cerebellar involvement. White matter diseases can be further stratified as those with early periventricular predominance, those with subcortical dysmyelination, as hypomyelinating leukodystrophies, or other nonspecific pattern. Gray matter predominate diseases can be grouped as those with cortical predominance or those with predominant involvement of the deep gray nuclei. Although many diseases show overlap between these categories, particularly in their later stages, this categorization system can be used to generate a reasonable differential diagnosis for suspected metabolic diseases. In addition, some metabolic diseases have characteristic findings on spectroscopy and diffusion-weighted imaging. In combination with the pattern of disease involvement, the spectroscopy and/or diffusion findings in these diseases can add specificity to the diagnosis. Example cases in which spectroscopy and/or diffusion findings are useful, for example Maple Syrup Urine disease, Canavan disease, galactosemia, and metachromatic leukodystrophy, among others, will be shown.

Conclusions
Although diagnosis is challenging, metabolic diseases can be classified by their pattern of disease involvement. While these diseases are rare, it is important to be able to recognize them and to provide an accurate differential due to implications both for patient management and family counseling.

Neuroimaging in Pediatric Encephalitis

L Davis¹, S Pruthi², K Bloch³
¹Vanderbilt University, Nashville, TN, ²Monroe Carell Jr. Children's Hospital at Vanderbilt University, Nashville, TN, ³Vanderbilt University Medical Center, Nashville, TN

Purpose
The purpose of this educational exhibit is to describe the common imaging findings, clinical and laboratory findings and associated complications of commonly encountered forms of pediatric encephalitides, as well as some infrequently encountered ones.

Materials and Methods
Cases of clinically diagnosed encephalitis in patients aged 0-18 years are presented with emphasis on neuroimaging features and clinical data including laboratory findings. This exhibit also will discuss the challenge of determining the specific etiology in some patients with a clinical diagnosis of encephalitis.

Results
Pediatric encephalitis encompasses a wide range of causative agents and clinical syndromes. Though the cause of encephalitis remains unknown in a large number of cases, some specific causes of encephalitis have classic clinical and imaging features. This exhibit is an organized
review of pediatric encephalitis with the various diseases grouped under broad categories as described below. 1. Primary infectious (predominantly viral, bacterial, fungal, parasitic): e.g., encephalitis caused by enterovirus, influenza virus, varicella virus or herpes virus etc. 2. Postinfectious or Parainfectious (immune mediated): e.g., ADEM. 3. Paraneoplastic (malignancy related): eg. Limbic encephalitis.

Conclusions
Pediatric encephalitis is an important topic given the associated morbidity and mortality. It often is thought of as unfamiliar territory by neuroradiologists. This review will focus on key points in diagnosis with emphasis on neuroimaging, including the critical role of imaging in distinguishing encephalitis from other clinically similar entities. This exhibit will help further expand and enhance knowledge about pediatric encephalitides.

KEYWORDS: Encephalitis, Encephalopathy, Infections

eEdE-183

Neuroimaging pattern-recognition approach of subthalamic nucleus involvement in children

T Bosemani, E Boltshauser, A Hoon, P Pearl, D Craiu, M Johnston, T Huisman, A Poretti
1The Johns Hopkins University School of Medicine, Baltimore, MD, 2University Children’s Hospital, Zürich, Switzerland, 3Kennedy Krieger Institute, Baltimore, MD, 4Children’s National Medical Center, Washington, DC, 5Alexandru Obregia Hospital, Bucharest, Romania

Purpose
Neuroimaging-based pattern-recognition approach has been very helpful in the diagnosis and classification of a wide range of pediatric central nervous system diseases. The subthalamic nucleus (STN) is a key structure in the basal ganglia circuit and serves as an important relay station within the corticostriothalamocortical circuit. Involvement of the STN has been described extensively in adults with movement disorders. Subthalamic nucleus in children and its selective involvement in pediatric neurological disorders, however, seldom have been reported.

Materials and Methods
We reviewed our pediatric MR imaging (MRI) database searching for subthalamic nucleus involvement.

Results
After a short introduction about anatomy, function and age-related normal neuroimaging appearance of the STN, we present a review with selected case histories to illustrate STN involvement on MRI in various pediatric neurological disorders that may selectively affect the subthalamic nucleus in children including Leigh syndrome, succinic semialdehyde dehydrogenase deficiency, kernicterus, hepatic encephalopathy, and neonatal hypoxic ischemic injury. The involvement of structures in addition to the STN will be described to formulate a pattern recognition approach in order to narrow the differential considerations.

Conclusions
Neuroimaging-based pattern-recognition approach is a versatile tool in narrowing differential considerations to focus the diagnostic investigation pathway in a wide range of pediatric neurological diseases. The consideration of the constellation of clinical history and findings as
well as neuroimaging findings with involvement of certain structures in addition to STN (e.g., basal ganglia, thalami, brain stem structures, and dentate nuclei), should allow planning the appropriate diagnostic investigations to make the correct diagnosis in children with STN involvement.

Neuroimaging spectrum in Joubert syndrome

A Poretti¹, E Boltshauser², E Valente³, A Tekes¹, N Aygun⁴, W Gahl⁵, M Gunay-Aygun⁵, T Huisman¹

¹The Johns Hopkins University School of Medicine, Baltimore, MD, ²University Children’s Hospital, Zürich, Switzerland, ³Mendel Laboratory, IRCCS Casa Sollievo della Sofferenza Institute, Roma, Italy, ⁴Johns Hopkins University, Baltimore, MD, ⁵National Human Genome Research Institute, Bethesda, MD

Purpose

Joubert syndrome (JS) is a rare ciliopathy characterized by hypotonia, ataxia, ocular motor apraxia, facial dysmorphism, and irregular neonatal breathing. Cognitive functions are impaired in almost all patients. The diagnosis of JS is based on the recognition of the molar tooth sign (MTS) on neuroimaging. The MTS results from a midbrain-hindbrain malformation characterized by thickened, elongated, and horizontally orientated superior cerebellar peduncles and an abnormally deep interpeduncular fossa. Additionally, hypoplasia and dysplasia of the cerebellar vermis is a well known, characteristic neuroimaging finding of JS. The full neuroimaging spectrum in JS, however, is beyond MTS and hypoplasia and dysplasia of the cerebellar vermis. We aim to review the wide neuroimaging spectrum in JS and discuss the role of neuroimaging in the diagnosis and classification of patients with JS.

Materials and Methods

We reviewed neuroimaging studies of JS patients included in our pediatric MRI databases and the National Institutes of Health study "Clinical and Molecular Investigations into Ciliopathies" (www.clinicaltrials.gov, trial NCT00068224)".

Results

We present a review with selected case histories to illustrate the wide neuroimaging spectrum of JS including variability of the MTS (e.g., parallel, A-like or V-like superior cerebellar peduncles, decaying MTS due to marked asymmetry of the cerebral peduncles), enlargement of the posterior fossa, dysplasia of the cerebellar hemispheres, different morphological abnormalities of the brain stem, interpeduncular heterotopia, two different types of cephaloceles (occipital and at the level of the foramen magnum) and supratentorial anomalies including hypothalamic hamartoma, migration disorders (e.g., polymicrogyria), and callosal abnormalities.

Conclusions

We show a wide spectrum of neuroimaging findings in JS. This wide spectrum of neuroimaging findings supports the heterogeneity of JS, not only from the clinical and neurogenetic but also from the neuroimaging point of view. Variable findings in affected siblings support the intrafamilial heterogeneity in JS. Although neuroimaging is mandatory for the diagnosis of JS, it
remains of limited value in classifying patients with JS into subtypes. The pattern MTS and hypothalamic hamartoma represents the only pattern that allows to diagnose oral-facial-digital syndrome type VI, one of the sixth phenotypes of JS.

Neurological complications in the Hematological disorders: What radiologist should know?

S Kanekar¹, A Agarwal²
¹Penn State Milton S Hershey Medical Center, Hershey, PA, ²Milton S Hershey Medical Center, Hershey, PA

Purpose
To review the imaging findings of various acute and chronic neurological complications in hematological disorders.

Materials and Methods
We retrospectively studied 341 patients from our PACS, who had hematological disorders with neurological manifestations. All studies were reviewed by two neuroradiologist. These findings were correlated with the clinical findings, hematological, biochemical and CSF analysis (whenever available).

Results
For better understanding of the disease process we categorized our data into following categories: 1) RBC disorders: Fe++ /Vit B12 def, polycythemia vera, thalassemia, sickle cell disease, 2) Proliferative disorders: leukemia, lymphoma, myelomatosis, 3) Hemorrhagic disorders: hemophilia, VIII def, DIC, TTP, thrombocytopenia, H uremic syndrome, 4) Coagulation disorders: anti phospholipid antibody syndrome, hereditary thrombophilia, homocystinemia, 5) Hematological malignancy.

Conclusions
1. Neurological complications in the course of hematologic disease are frequent and varied. Early diagnosis of these complications is very vital for better neurological outcome. 2. We review the neurological complications related to hematological disorders with various illustrations with diagnostic pearl to the specific diagnosis. 3. We also discuss the treatment related complications of the hematological malignancies.

Neuroradiological Evaluation of Stem Cell Transplantation

H Tore¹, D Nascene¹
¹University of Minnesota, Minneapolis, MN
Purpose
Stem cell transplantation has become the definitive treatment modality of many diseases which were previously regarded incurable (1). These disorders include malignancies (hematologic and solid tumors) and nonmalignant diseases such as metabolic disorders (e.g., Adrenoleukodystrophy, Krabbe disease or Hurler disease), immune deficiencies or hemoglobinopathies. Here we present the role of neuroimaging assessment of the diseases treated with stem cell transplantation from pretreatment to post-treatment follow up.

Materials and Methods

Results
Indications of bone marrow transplantation and the number of patients transplanted are expanding continuously. Accordingly, more patients are being evaluated by neuroimaging studies during their course of the disease. Patients should be screened for infections before administration of conditioning regimen. After receiving stem cell transplantation patients are closely monitored for possible complications such as opportunistic infections, intracranial bleeding, drug toxicity and rejection. Post-treatment assessment also includes regression of white matter involvement, and screening for recurrence of the disease (2).

Conclusions
Understanding the diagnosis, pretreatment evaluation, post-treatment follow-up findings, and possible complications is crucial for neuroradiologists for clinical management of patients treated with stem cell transplantation.

Ossifying aka Cementifying aka "Confuse-ifying" Fibroma: Imaging Review of Ossifying Fibroma and Other Fibro-osseous Lesions

L Davis¹, S Pruthi²
¹Vanderbilt University, Nashville, TN, ²Monroe Carell Jr. Children's Hospital at Vanderbilt University, Nashville, TN

Purpose
To review the imaging characteristics of ossifying fibromas and other fibro-osseous lesions of the jaws in children.

Materials and Methods
We review pertinent anatomy and radiologic findings and show several illustrative case examples of ossifying fibroma from our institution. In addition, we present examples of benign and malignant jaw lesions in the differential diagnosis for ossifying fibroma and highlight methods to attempt to distinguish among these lesions radiologically.
Results
Ossifying fibroma is a rare benign fibro-osseous lesion occurring in children and adolescents that has a penchant for a more aggressive course than the classic ossifying fibroma seen in adults. For this reason, it has been called juvenile aggressive ossifying fibroma. There are two types - trabecular and psammomatoid - which are indistinguishable radiologically but vary slightly in their demographics and typical location. Because of the variable appearance and overlap of histopathological findings among the fibro-osseous lesions, the nomenclature of this group of lesions can be quite confusing. In this exhibit, we present a case of a gigantic trabecular juvenile ossifying fibroma (JOF) seen on plain radiographs and computed tomography (CT). We present additional cases of JOF emphasizing their appearance on MR imaging (MRI). Other jaw lesions in the differential diagnosis of JOF also are reviewed; imaging features of these lesions are compared and contrasted with JOF.

Conclusions
We present three cases of ossifying fibroma including one gigantic trabecular juvenile ossifying fibroma from our institution and highlight the plain radiographic, CT and MRI appearance of these lesions. We review distinguishing features of other jaw lesions in the differential diagnosis.

Oxygenation-based Brain MR Imaging: Advanced Concept and Clinical Application

Y Ge

New York University Langone Medical Center, New York City, NY

Purpose
Aerobic metabolism is vital to the central nervous system for maintaining the basic function and meeting normal energy demand of the neuronal and axonal activities. Oxygen metabolism is directly related to neuronal activity and cerebral blood flow (CBF). Quantitative evaluation of brain oxygen metabolism and hemodynamic responses has the potential to enhance numerous studies of neurodegenerative diseases regarding the brain pathophysiology and function. Since oxygen itself can be an intrinsic contrast agent, this study will review oxygenation-based MR imaging (MRI) concept and the advances in these techniques as well as the exciting insights into the pathophysiology revealed by these techniques.

Materials and Methods
Several novel imaging techniques that are based on blood oxygenation will be reviewed. These include: (1) blood oxygen level dependent (BOLD) MRI, (2) calibrated-BOLD MRI using vasoactive stimulus, (3) resting-state functional MRI (RS-fMRI), (4) susceptibility-weighted imaging (SWI), (5) T2-relaxation-under-spin-tagging (TRUST), and (6) quantitative susceptibility mapping (QSM). The fundamental imaging contrast concept of these techniques will be discussed. In addition, the brief clinical applications based on these techniques will be introduced.

Results
The fundamentals of neurovascular-coupling and -uncoupling will be reviewed. The following techniques for estimation of oxygen metabolism will be discussed. (1) BOLD signal is based on
the mismatch that the fractional CBF change is ~2-4 times larger than fractional change of oxygen utilization during neuronal activation. Event-related BOLD fMRI signal image processing, interpretation, and clinical application will be discussed. (2) calibrated-BOLD involves vasoactive stimulus (i.e., breathing CO2) to quantify BOLD and CBF responses and measure fractional change in cerebral metabolic rate of oxygen (CMRO2), while baseline absolute CMRO2 cannot be generated from this approach. The calibrated BOLD image processing modeling based on multimodal equations will be discussed. (3) RS-fMRI is a method to evaluate regional interactions at rest based on spontaneous fluctuations in BOLD signal. RS-fMRI is useful to explore functional network and organization disruption in many neurological and psychiatric diseases. The change of respiratory pattern or CO2 challenge on RS-fMRI network patterns will be discussed. (4) Susceptibility-weighted imaging (SWI) is a 3D gradient echo sequence using phase to enhance the visibility of venous vasculature that is dependent on blood deoxygenation level. Its clinical implication in several neurodegenerative diseases will be discussed. (5) T2-relaxation-under-spin-tagging is a relatively new technique to calculate absolute baseline CMRO2 without using vasoactive stimulus. It combines venous spin labeling and T2 relaxation rate techniques to estimate venous oxygenation in isolated superior sagittal sinus. The application of TRUST in Alzheimer disease and multiple sclerosis will be reviewed. (6) Recently, QSM, a technique using local field inhomogeneity information on phase to compute susceptibility map, provides a new quantitative contrast of blood oxygenation, the pros and cons of this technique will be discussed.

Conclusions
The oxygenation-related MRI techniques all have great potential to explore the critical physiological properties of brain such as oxygen metabolism, neuronal activity, and hemodynamic responses.

KEYWORDS: BOLD fMRI, Brain Metabolites, Oxygen

Parturitional injury of the head and neck

Parturitional injury represents injury sustained during labor and delivery. The skull, brain and head and neck regions may be affected by parturitional injuries. Parturitional injuries are classified into two major categories on the basis of their etiology, namely birth injury and birth trauma. Birth-related trauma and injury may have potential significant neurological sequela. Hence, it is of paramount importance to recognize parturitional injury and accurately differentiate them into various compartments.

Purpose
Parturitional injury of the head and neck

Materials and Methods
We reviewed our pediatric CT, US and MR imaging (MRI) databases searching for parturitional injuries of the calvarium, brain, spine, head and neck regions.
Results
We present a review with selected patients to illustrate the neuroimaging findings of parturitional injuries involving various compartments; namely, scalp and soft tissues (e.g., caput succedaneum, subgaleal hematoma, and cephalohematoma), calvarium (e.g., fractures and sutural diastasis), extra-axial compartment (e.g., epidural hematoma, subdural hematoma and subarachnoid hemorrhage), and intraparenchymal hemorrhage. The mimickers of parturitional injury which may appear as a "bump" (leptomeningeal cyst, sinus pericranii, and focal brain herniation through burr hole) will be reviewed. Finally, skeletal and spine injuries as well as congenital predisposing factors for skeletal trauma and injury (e.g., osteogenesis imperfecta) will be discussed briefly. The strength of various neuroimaging modalities in the identification and classification of these injuries will be highlighted.

Conclusions
Parturitional injuries represent a wide range of conditions in the calvarium extending from the skin surface of the scalp to the brain parenchyma involving multiple compartments and structures. Familiarity with the anatomy is a sine qua non for accurate identification and localization. The clinical presentation of a neonate may vary from being in shock due to loss of a large amount of blood volume in the subgaleal space to being encephalopathic secondary to underlying brain parenchymal injury. Therefore, a thorough and detailed neuroimaging evaluation is required to establish the cause, guide treatment, and prevent complications. Each neuroimaging modality, namely, US, CT and MRI have their respective strengths in contributing to the evaluation. In addition, mimics of parturitional injury and predisposition to birth related trauma and injury should be identified.

KEYWORDS: Neonatal, Traumatic Brain Injury

Pediatric Multiple Sclerosis and Other Immune Mediated Demyelinating Disorders of Childhood

D Raghavan\textsuperscript{1}, M Gorman\textsuperscript{2}, M Silvera\textsuperscript{3}
\textsuperscript{1}Brigham and Women's Hospital, Boston, MA, \textsuperscript{2}Boston Childrens Hospital, Boston, MA, \textsuperscript{3}Boston Children's Hospital, Boston, MA

Purpose
In this exhibit we will present the clinical criteria and imaging characteristics of pediatric multiple sclerosis and other immune mediated CNS demyelinating disorders of childhood. Findings will be presented in a case based format.

Materials and Methods
The Boston Children's Hospital departmental radiology database was queried to identify patients between 0 and 18 years of age, who were treated for demyelinating disease and had undergone an MR imaging (MRI) examination of the brain and/or spine. In addition, a review of the pertinent literature was performed.

Results
The following demyelinating disorders will be reviewed in a case-based format: Pediatric multiple sclerosis and its variants, acute disseminated encephalomyelitis, neuromyelitis optica.
and the Aquaporin 4 autoimmunity spectrum, clinically isolated syndrome, and radiologically isolated syndrome. Specific attention will be given to imaging characteristics that aid the radiologist in distinguishing between these various entities and differential considerations will be discussed. In addition, the recent 2013 revisions to the 2007 International Pediatric Multiple Sclerosis Study Group classification criteria will be highlighted as they relate to clinical and imaging findings. Additional emphasis will be placed on the following topics: 1, the growing spectrum of aquaporin 4 autoimmunity disorders; 2, the debate surrounding the management of radiologically isolated syndrome; and 3, tumefactive multiple sclerosis and its differentiation from intracranial masses.

Conclusions
In this presentation, distinctive as well as overlapping clinical and imaging features of pediatric demyelinating diseases will be reviewed and the recent 2013 proposed modifications to definitions and clinical and imaging criteria for pediatric demyelinating disorders will be discussed. This review will facilitate further understanding of the various diagnostic categories of pediatric demyelinating disorders, which is essential for the interpreting radiologist to appreciate in order to improve consistency in terminology, and to promote a uniform clinical approach to these complex disease entities.

eEdE-188
Pediatric On Call Neuroimaging – A Resident’s Survival Guide

S Thust1, I Papadopoulou2, K Mankad1, W Chong1
1Great Ormond Street Children's Hospital, London, UK, 2The National Hospital for Neurology and Neurosurgery, London, UK

Purpose
To educate residents on pediatric emergency neuroimaging including how to distinguish disease from normal childhood anatomy and specific imaging artifacts.

Materials and Methods
Simulating real-life referrals for urgent imaging, a selection of cases from Great Ormond Street Children's Hospital will be used to illustrate CT and MR imaging (MRI) features of pediatric nervous system disease with a focus on “do-not-miss” diagnoses and interpretational pitfalls. Examples include dural venous sinus thrombosis, arteriovascular disease and ischemic stroke, traumatic brain injury, spontaneous intracranial hemorrhage, hydrocephalus, infection, neonatal hypoglycemic brain injury, hypoxic ischemic encephalopathy, metabolic encephalopathy, spinal trauma and cord disease. Using a step-wise question and answer format for each case, the reader will be given a brief history before choosing an appropriate imaging method and protocol. A selection of high quality CT and/or MR images will be provided leading to the diagnosis followed by a discussion relevant to the case.

Results
For residents unfamiliar with the subject, pediatric neuroimaging can be daunting, especially when there is pressure to make a diagnosis in a sick child. Planning before scanning is essential and depending on the patient's age and condition, the need for a general anesthetic should be
considered. MR imaging is usually the preferred modality for pediatric neuroimaging, but may
be difficult to perform in an unstable child or where facilities are limited. The imaging protocol
should be tailored according to the patient's age and suspected pathology. Knowledge of normal
anatomy and artifacts typical to pediatric imaging will aid the diagnosis.
Conclusions
Having worked through this educational exhibit, the reader will be able to initiate appropriately
protocolled neuroimaging and recognize the features of serious neurological conditions in
children more confidently.

Postoperative MRI in Patients with Chiari 0 and 1 Malformation
D Ginat1, D Frim1, G Katzman1
1University of Chicago, Chicago, IL

Purpose
The goal of this exhibit is to review the various surgical modalities that are used for the treatment
of Chiari 0 and 1 malformations and the corresponding features on MR imaging (MRI).
Materials and Methods
Several types of surgical interventions are available for treatment of abnormalities in patients
with Chiari 0 and 1 malformation, including posterior fossa decompression with or without upper
cervical laminectomy, cerebellar tonsil cauterhy, fourth ventricular stenting, third
ventriculostomy, syringohydromyelia decompression, and ventricular shunting. MR imaging of
the craniocervical junction including sagittal FIESTA and cine phase contrast CSF flow studies
provide useful insights in postoperative anatomy and physiology.
Results
The following topics will be reviewed: * Optimal postoperative MRI protocols. * Expected
postoperative anatomy and physiology on imaging. * Complications, including persistent
obstructive symptoms at the foramen magnum, pseudomeningoceles, craniocervical instability,
dural graft reaction, and failed ventriculostomy. * Pitfalls, including the consequences of
operating on patients with conditions that mimic Chiari I malformation, such as acquired
tonsillar ectopia. Implications for management.
Conclusions
At institutions that specialize in treating patients with Chiari 0 and 1 malformation, MRI with
phase contrast cine CSF flow studies often is performed to evaluate patients after surgery. Thus,
it is important to be familiar with the expected imaging findings related to the different types of
interventions and to recognize potential complications and pitfalls.

eEdE-197
Rasmussen's Encephalitis: Imaging, Histopathology, and How Radiologists can Impact a Devastating Disease

M George¹, C Osakwe², S Li³
¹Baystate Medical Center, Tufts University School of Medicine, Springfield, MA, ²Georgia Regents University, Augusta, GA, ³Baystate Medical Center, Longmeadow, MA

Purpose
Rasmussen's encephalitis (RE) is an uncommon but devastating neurologic disorder of childhood. The underlying etiology has not been clearly established, but potential causes include chronic viral infection, circulating GluR3 antibodies, and T-Cell mediated inflammation. Unfortunately, the clinical and pathological presentations are confusing. Because normal and afflicted parenchyma often are interspersed, false negative biopsies may occur; moreover, the classic sign of epilepsia partialis continua is only variably present. The challenges of pathological characterization, clinical diagnosis and treatment underscore the role of the radiologist. Because standard anti-convulsant therapies are of little value, and alternative therapies must be initiated rapidly, the radiologist may facilitate early detection before irreversible tissue damage occurs. Longitudinally, value is added to the interdisciplinary team by assessing treatment response, which is unpredictable in RE. The radiologist may even have a role in localizing epileptic foci with novel fMRI-EEG. This electronic educational exhibit presents the clinical, histopathological, epidemiologic and imaging findings of RE with special emphasis on the changing and positive role of the radiologist over the course of the disease.

Materials and Methods
All cases are taken from Baystate Hospital, between 2005-2013, with histopathological correlate. Imaging is presented in conjunction with EEG, physical exam and clinical data.

Results
Rasmussen's encephalitis is a chronic inflammatory disease with a mean onset of six years. In a study by Rasmussen et al, two thirds of patients with RE had a prior exposure to an infectious or inflammatory episode before the onset of symptoms. Fara et al also reported preceding viral infections. Histopathological findings include perivascular lymphocytic cell infiltration and clusters of chronic inflammatory cells in the brain parenchyma. The majority of inflammatory cells found in RE are T lymphocytes. In the prodromal stage in RE, findings are variable and nonspecific. The child has low frequency seizures and, rarely, mild hemiparesis. In the acute phase the child's seizures classically increase in frequency (Epilepsia partialis continua) and dense hemiparesis, cognitive deterioration, and sometimes aphasia may follow. The final stage is marked by permanent and progressive neuronal death. On MR, the earliest imaging findings include unilateral enlargement of the CSF spaces and increased T2 signal intensity in the cerebral cortex and subcortical white matter, with the tempoparietal lobe most commonly effected. Critically, these findings occur well before the onset of irreversible atrophy. Later in the disease process, atrophy and gliosis predominate. Significantly, the degree of T2 hyperintensity tends to correlate to the aggressiveness of the disease rather than its duration. Treatment response may be assessed both with conventional MR and MR spectroscopy, which shows increased lactate and decreased NAA, reflecting cell turnover and active disease. Encouragingly, Cuspineda et al recently utilized combined EEG-fMRI to map epileptogenic foci in a child with RE. If these foci could be localized noninvasively, ablation could avoid the obvious morbidity of hemispherectomy.
Conclusions
Rasmussen's encephalitis is a rare and devastating inflammatory disease of childhood. The etiology of RE is uncertain and its treatment, to this point, has been ineffectual. Despite this, the radiologist positively can impact the child's course with early diagnosis, accurate prognosis, assessment of treatment response, and noninvasive mapping of epileptogenic foci which may obviate the morbidity of an anatomical or functional hemispherectomy.

eEdE-193

Spectrum of Imaging Findings in MELAS

P Shanahan¹, C Buckingham¹, S Pruthi²
¹Vanderbilt University, Nashville, TN, ²Monroe Carell Jr. Children's Hospital at Vanderbilt University, Nashville, TN
Purpose
MELAS is a rare disorder of mitochondrial dysfunction caused by a mutation in the mitochondrial DNA (mtDNA). The disease manifests in myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (1). Imaging is key in the evaluation of encephalopathy and acute stroke-like symptoms. It is important for the radiologist to be aware of the spectrum of imaging findings and clinical presentation in patients.

Materials and Methods
We review the spectrum of imaging findings in a patient with biopsy proven MELAS. The imaging findings are presented over several serial CT, MRI, and MR spectroscopy evaluations. These imaging findings are correlated with the patient's clinical presentation and evolving symptoms over serial presentations.

Results
A multimodality imaging approach is necessary in the acute and chronic evaluation of MELAS. In the setting of acute stroke-like symptoms initial CT evaluation is of benefit in ruling out other causes of symptoms such as hemorrhage, and has some utility in visualization of acute edema. Classic findings include edema and swelling commonly involving posterior cortical and subcortical regions (1). Edema may be associated with restricted diffusion commonly crossing vascular territories (2). MR imaging evaluation is of further benefit in characterizing chronic and waxing and waning parenchymal changes involving the cortex and subcortical white matter which may show "shifting" edema without restricted diffusion (2). MR spectroscopy is a diagnostic supplement in demonstrating elevated cerebral lactate levels and may demonstrate characteristic lactate peaks suggestive of the diagnosis (1).

Conclusions
Recognizing the multimodality imaging findings of MELAS is critical for the radiologist in evaluation of patients in the acute setting of stroke-like symptoms and in evaluation of chronic waxing and waning findings of encephalopathy. Although imaging does not provide the conclusive diagnosis in MELAS disease, it plays a critical role and the radiologist must be familiar with imaging findings.

SUSCEPTIBILITY WEIGHTED IMAGING AND MALFORMATION OF CORTICAL DEVELOPMENT

C Lazarte\textsuperscript{1}, J Davila\textsuperscript{1}, E Miller\textsuperscript{1}
\textsuperscript{1}Children’s Hospital of Eastern Ontario, Ottawa, Ontario, Canada

Purpose
Susceptibility-weighted imaging (SWI) is a sensitive sequence in the identification of hemorrhage, calcifications and it is a powerful tool to visualize venous structures. In Tuberous Sclerosis Complex (TSC) the cortical tuber often demonstrates blooming artifact due to calcification; a finding that has been reported as more epileptogenic. The cortical tubers; a malformation of the cortical development (MCD), are not the only lesions that demonstrate blooming in the spectrum. Often the presence of developmental venous anomaly (DVA) or de novo areas of blooming artifact in SWI sequence can guide the radiologist to search for MCD.

Materials and Methods
The aim of this presentation is to review cases of MCD and determine if SWI can contribute in the identification and characterization of these malformations. The contribution of SWI in the diagnosis of hemimegalencephaly, tumors associated with disordered cortex (DNET, ganglioglioma, gangliocitoma), etc., will be demonstrated. Whenever available the findings will be compared to CT, for better assessment of the calcification and/or bleed.

Results
Literature describes that blooming artifacts in susceptibility-weighted imaging highly correlates with epileptogenic focus including vascular malformations, postinfectious granulomas and tumors. Susceptibility artifacts can be seen also in MCD like tuberous sclerosis, tumors associated to disordered cortex, hemimegalencephaly and they highly correlate with the epileptogenic focus.

Conclusions
Susceptibility-weighted imaging appears reliable for characterizing blood flow dynamics in brain malformations. When blooming artifacts are present, this can be a red flag for the radiologist to search for another underlying lesion such as MCD.

KEYWORDS: Malformation Of Cortical, Susceptibility-Weighted Imaging
Purpose
To compare ultrafast MR Imaging (MRI) technique as a replacement for noncontrast CT head (NCCTh) as an initial imaging modality in cases of suspected nonaccidental trauma.

Materials and Methods
We are prospectively offering ultrafast MRI as a follow up to initial NCCTh from the emergency department for cases of suspected nonaccidental trauma as a pilot study starting from August 2013. Our ultrafast MRI sequences include axial and coronal T2 HASTE, axial single shot diffusion-weighted imaging (DWI), axial T2* echo planar imaging (EPI) and sagittal T1 FLASH 3D. The ultrafast MRI technique takes less than one minute per sequence to complete and can be accomplished without sedation in the pediatric population. Key imaging findings with high specificity to nonaccidental trauma will be reviewed in each pulse sequence of the ultrafast MRI in comparison with a NCCTh and routine MRI brain, if available. Findings will be correlated with ultimate clinical outcome and patient disposition from available clinical histories.

Results
Ultrafast MRI techniques in patients with suspected nonaccidental trauma can provide greater or complementary information than NCCTh from greater inherent tissue contrast, allowing the distinction of differing ages of intracranial hemorrhage from hemoglobin degradation. While ultrafast MRI sequences have less resolution and contrast than conventional spin echo MRI sequences, we will show that the available sequences in our ultrafast protocol is sufficient to evaluate for gross intracranial traumatic injury sufficient to change patient management. The lack of radiation exposure compared to NCCTh, as well as possible sedation complications from a conventional MRI exam increases patient safety along with possible cost savings if ultrafast MRI replaces NCCTh and/or conventional MRI. The greatest limitation of ultrafast MRI, as well as conventional MRI, in trauma is the sensitivity to the detection of skull fractures, for which reliance on skull films within the skeletal survey may suffice. Literature review of the appearance of intracranial hemorrhages and parenchymal injury highly specific to child abuse will be performed and demonstrated in this exhibit, with documentation of these findings on ultrafast MRI compared to NCCTh. Figures: Axial CT of the head in a four-month-old female with bilateral retinal hemorrhages demonstrates bilateral chronic subdural hematomas (white arrows). Axial T2 HASTE imaging reveals multiple neomembranes (black arrows) within the subdural collections, suggesting chronic subdurs of multiple chronicity.

Conclusions
Using ultrafast MRI techniques potentially can provide greater imaging specificity than NCCTh for nonaccidental trauma. In addition to improved patient safety and potential cost savings, this could positively change the imaging management guideline for nonaccidental trauma.

KEYWORDS: MR Imaging, Nonaccidental Trauma
Uncommon Pediatric Pontine Disorders: Case Based Review of the “Unusual Suspects”

K Rentas\textsuperscript{1}, Z Bailey\textsuperscript{1}, A Reghunathan\textsuperscript{1}, L Lowe\textsuperscript{2}
\textsuperscript{1}University of Missouri-Kansas City School of Medicine, Kansas City, MO, \textsuperscript{2}Children’s Mercy Hospitals and Clinics, Kansas City, MO

Purpose
Because pediatric pontine disorders often are treated empirically without biopsy proof of their pathology, radiologists play a particularly critical role in evaluating these lesions in children. Knowledge of uncommon central nervous disorders and systemic processes that may involve the pons is essential to narrow the differential diagnosis. After viewing this educational exhibit, the learner should be able to: (1) List uncommon pathologies that affect the pediatric pons, (2) Describe key imaging features, and (3) Construct a differential diagnosis for focal and diffuse pontine disorders in children.

Materials and Methods
Using an image rich, case-based format, this educational exhibit will demonstrate the approach to pediatric pontine lesions by highlighting characteristic clinical history and key imaging features. Pathological processes included are gliomatosis cerebri, various inflammatory disorders...
(multiple sclerosis, acute disseminating encephalomyelitis, hypertensive encephalopathy and primary cerebral angiitis), traumatic brain injury, metabolic disorders (central pontine myelinolysis and maple syrup urine disease) and systemic disorders (hemolytic uremic syndrome and drug induced changes).

Results
As CT findings are often nonspecific, MR imaging is the initial study of choice in children with pontine lesions. It allows imagers to divide lesions into focal versus diffuse categories, thus narrowing the possible diagnoses. Most pontine disorders in children are generally T1 hypo- and T2 hyperintense. However, correlation with clinical history and additional imaging features, such as enhancement pattern, diffusion characteristics and other lesions seen in the central nervous system, may allow one to suggest a specific disorder or limited differential.

Conclusions
The radiologist has a critical role in the assessment of pediatric pontine disorders, which often are diagnosed based on history and imaging findings alone. This case-based exhibit will guide learners through an imaging approach to uncommon pediatric pontine disorders emphasizing key MR imaging (MRI) features and useful clinical history. Learners will actively formulate a limited, and sometimes specific, differential diagnosis and use imaging to make treatment decisions in cases shown.

Use of imaging studies in the diagnosis and management of intracranial abnormalities in patients with the most common Neurocutaneous syndromes.

N Marks1, E Stein1
1Maimonides Medical Center, Brooklyn, NY

Purpose
Neurocutaneous syndromes are a heterogeneous group of congenital disorders which primarily involve structures derived from the embryological neuroectoderm. Characteristically, patient presentation is diverse and disease expression varies; therefore, diagnostic studies play an important role at the time of diagnosis and surveillance of patients with established disease. Our objective is to review current imaging study recommendations for diagnosis and routine follow up of patients with the most common phakomatoses to ensure best study recommendation to the referring clinician by the radiologist.

Materials and Methods

Results
1. Introduction to Neurocutaneous syndromes: a. Demographics, b. Genetics, c. Clinical presentation, d. Natural history and treatment, 2. Review of imaging study recommendations in
diagnosis and routine follow up of patients with the most common Neurocutaneous disorders: a. Tuberous sclerosis, b. Neurofibromatosis Type I, c. Neurofibromatosis Type II, d. Sturge-Weber syndrome.

Conclusions
Patients with phakomatoses require lifetime, multidisciplinary surveillance of cutaneous and intracranial abnormalities. The role of imaging is crucial from initial evaluation to routine follow up. This educational exhibit will provide the radiology resident and practicing radiologist with up-to-date recommendations on imaging studies for patients diagnosed with Tuberous Sclerosis, Neurofibromatosis, Types I and II, and Sturge-Weber syndrome.

KEYWORDS: Phakomatoses
Vascular Anomalies of the Pediatric Brain and Spinal Cord: Same lesions, new names

M Collard¹, J Sessions¹, L Lowe², K Rentas¹
¹University of Missouri Kansas City School of Medicine, Kansas City, MO, ²University of Missouri Kansas City and Children’s Mercy Hospitals, Kansas City, MO

Purpose
The purpose of this exhibit is to present a simple approach to pediatric vascular anomalies of the brain and spinal cord using modern classification. The learner will work through a case-based review of vascular lesions using the modern classification system.

Materials and Methods
After reviewing the modern classification system and tables that summarize imaging features and treatment, learners will apply their skills to cases of pediatric vascular lesions. Cases shown will emphasize key imaging features, discuss initial treatment, and clarify new versus old terminology, including the rationale for use of new terms. Take home points will be presented at conclusion of the exhibit.

Results
Accurate classification of vascular anomalies has a significant impact on children receiving the correct diagnosis and treatment. Thus, pediatric imagers and others caring for children with vascular anomalies have widely adopted the 1992 International Society for the Study of Vascular Anomalies (ISSVA) classification system. It eliminates confusing, overlapping terms of the past and applies a system that consistently correlates the initial diagnosis with lesion clinical course, treatment, and outcome.

Conclusions
After viewing this exhibit, the learner will be able to apply the ISSVA system to classify vascular anomalies, list key imaging features of pediatric vascular anomalies and state initial treatment options. Learners also will be able to state the differences between old versus new terminology, and describe how the new system allows consistent correlation between diagnosis, imaging, treatment and outcome.

Watch His Mouth: Micrognathism in Rare Congenital Craniofacial Syndromes - From Embryology to CT Findings

B Sur¹, H Wang¹, A Hussain¹
¹University of Rochester Medical Center, Rochester, NY

Purpose
Various rare congenital syndromes are associated with micrognathia and other craniofacial deformities. Radiological evaluation of these syndromes plays a critical role in patient management and reconstructive surgery planning. Specifically, multiplanar imaging techniques using high resolution CT and 3D reconstruction allow excellent delineation of bony anatomy and abnormalities in patients with these syndromes. In this exhibit, we will present characteristic facial bone deformities in rare congenital syndromes with exemplary high resolution CT images including 3D reconstruction. In addition, associated ocular, nasal, and facial soft tissue findings
are highlighted to aid the assessment of the full extent of craniofacial malformation in these syndromes. Knowledge and recognition of these imaging features will allow radiologists to make correct diagnoses and suggest appropriate differential diagnostic considerations.

Materials and Methods

We will review the embryologic evolution of the maxillofacial region with illustrations. Then, exemplary facial and head CT images are presented to demonstrate characteristic facial features in various congenital disorders that are associated with micrognathia and other craniofacial malformations including Treacher Collins syndrome, Goldenhar syndrome, hemifacial microsomia, and Pierre Robin sequence.

Results

Treacher Collins syndrome: Bilateral and relatively symmetric craniofacial deformities are seen in patients with the Treacher Collins syndrome. The mandible and zygomatic complex often are hypoplastic. Hypoplasia or aplasia of the condyle and coronoid processes of the mandible may be seen. The maxilla also may be hypoplastic. Nasal malformation and auricular anomalies including microtia, aplasia of the external auditory meatus and middle ear malformations also are demonstrated radiographically. Hemifacial microsomia: Asymmetric development of the one side of the face is seen. Hypoplasia of the maxilla and mandible including hypoplasia of the condyle and coronoid process is seen in this disorder. Unilateral auricular deformity of the external ear and ocular anomalies including a coloboma of the upper eyelid may be revealed radiographically. Goldenhar syndrome: When epibulbar dermoids and asymmetric skull and vertebral anomalies are seen in addition to other findings of hemifacial microsomia, the syndrome is called Goldenhar syndrome. Pierre Robin sequence: Micrognathia, glossoptosis, and cleft palate are classically associated with this disorder. Relatively symmetric hypoplasia of the mandible is seen in this disorder. There may be associated condylar and coronoid hypoplasia. Bimaxillary retrognathia also may be seen. Glossoptosis is caused by posterior displacement or retraction of the tongue, which can contribute to upper airway obstruction.

Conclusions

Understanding the developmental anatomy, characteristic imaging findings, and pertinent clinical history not only will allow radiologists to formulate accurate diagnoses but will ensure the full extent evaluation of these complex congenital craniofacial malformation syndromes associated with micrognathism.

"So you think you can bring something new to our practice?": Developing an Advanced Neuroimaging Program in a Non-Academic Community Hospital

C Aquino
1Kaiser Permanente, San Diego, CA
Purpose
The vast majority of radiologists in the United States work in nonacademic centers, and neuroradiologists entering these practices may be surprised to realize the relative lack of advanced imaging performed in the community compared to academia. However, there are unique issues in performing advanced imaging in a nonacademic practice that one should consider prior to implementing these techniques.

Materials and Methods
I will present my early experiences in developing an advanced imaging program in a large multispecialty, HMO practice based at a nonacademic community hospital serving over 500,000 patients. I will address issues unique to nonacademic radiologists. I also will present an interactive checklist to summarize the major areas of concern.

Results
Several questions and difficulties arise when implementing an advanced imaging program at a nonacademic center including but not limited to the following: 1) What modalities do you hope to bring to the table (CT/MR perfusion, spectroscopy, DTI, SWI, fMRI, novel MRA techniques, etc.)? 2) Is it appropriate given your patient population and referrers and what value will you add? How may you and your practice benefit? 3) Do you have the capability in software, hardware, ancillary staff, and scheduling time? 4) Do you have the experience, patience, and time to convince and possibly train your technologists and radiologist colleagues to perform and/or interpret these studies, respectively? This is in contrast to academia where there may be several expert radiologists, physicists, researchers, dedicated advanced imaging technologists, and vendor support readily available. 5) How will you balance your time developing the program with the demands of clinical productivity, which often is stressed in community practices? 6) How will you garner interest among referring clinicians and do you have the appropriate evidence justifying these techniques? 7) How will you ensure quality and are there any potential PQI projects that may improve the practice?

Conclusions
Developing an advanced imaging program at a nonacademic practice presents a unique set of challenges, but may be worthwhile as it is ultimately beneficial to patient care.

Combining a Spaced Memory Training Program with a Neuroradiology Case Bank to Improve Resident and Fellow Education
Purpose
Spaced repetition is a long-standing concept in cognitive science that has gained novel applications with innovations in tablet and mobile based electronics (1, 2). The memory training program Anki (http://ankisrs.net/) is a free desktop program with a separate fee for the iPad version that harnesses this concept in an adaptable fashion. We sought to apply this program to a pre-existing educational resource, the neuroradiology education website HeadNeckBrainSpine (HNBS; http://headneckbrainspine.com/) which has to date received almost three million visits.

Materials and Methods
Using the 424 cases collected on the HeadNeckBrainSpine website, an Anki deck was constructed. Each case was categorized as falling under brain, head and neck, and spine. The cases were imported on a free desktop Anki client before being synced to an iPad version of the application.

Results
Figure 1 shows an example of an HNBS case in a typical Anki interface on an iPad 2. The initial images are shown on the first part of the iPad screen while the answer is shown on the latter part. The re-test intervals are color coded for ease of selection and correspond to the ease with which the question is answered. Challenging cases are retested more frequently while easier cases are retested at longer intervals.

Conclusions
Memory training with spaced repetition can be applied to a well characterized neuroradiology teaching file. This application may allow for more efficient review of radiological educational case-based material in the training of residents and fellows. Future work will focus on other subspecialties.

KEYWORDS: Educational, Fellowship, Resident Training
Intracranial Post-Transplant Complications: Review of Imaging Findings with Clinical and Pathologic Correlation

Purpose
The therapeutic use of hematopoietic stem cell transplant and solid organ transplant have continued to rise over the past decade to improved immunotherapy and antimicrobial treatment/prophylaxis. As a result the number of post-transplant patients seen in clinical practice have increased as well. We aim to discuss key principles of transplant medicine and to help
Radiologists develop an understanding of CNS susceptibilities and/or complications during the pre and post-transplantation time period.

Materials and Methods
1. Introduction to transplant principles used in evaluation including bone marrow and solid organ transplantation. 2. Case-based approach to review common and uncommon complications and/or CNS pathologies encountered during pre and post-transplantation phases. 3. Summarize key elements in a flow-chart to provide reader with a chart for quick future references.

Results
1. Introduction to transplant medicine including criteria used for organ transplantation, pre-engraftment clinical requirements including key CNS processes that may preclude and/or postpone patient's transplantation. 2. Case-based approach reviewing post-transplantation CNS findings that are key to patient's management and survival. Cases will include primary disease recurrence in CNS system (e.g., leptomeningeal carcinomatosis, myeloid sarcoma, etc.), infections (TB, bacterial meningitis, toxoplasmosis, abscess, aspergillosis, cryptococcosis), post-transplant lymphoproliferative disorder (PTLD), drug toxicity (PRES, periventricular leukencephalomalacia, etc.) and graft versus host disease. Key clinical features, imaging findings (radiographs, nuclear medicine, CT and/or MRI), treatment and prognosis of all the presented entities will be discussed.

Conclusions
Transplant medicine has continued to grow over the last decade worldwide due to improved clinical management of post-transplant patients (immunotherapies and prophylaxis). Imaging plays a key role in monitory of post-transplant patients. Radiologists can help further improve clinical outcomes in these patients by familiarizing themselves with the common and uncommon set of pathologies that affect these patients and alerting referring physicians appropriately. By the conclusion of this presentation, the viewer should be able to generate a more precise differential diagnosis based on the patient's risk factors including age, gender, phase of transplant (pre-/post-transplant), medications, etc.

Understanding and Mitigating Unexpected Artifacts in Head CTs: A Practical Experience

F Raslau, J Riley-Graham, J Zhang, E Escott

University of Kentucky, Lexington, KY

Purpose
A spectrum of varying artifacts may occur on head CT scans that can mimic or obscure pathology and be the source of erroneous diagnosis. In addition to the commonly encountered CT artifacts (e.g., streak artifact, beam hardening), a potpourri of rarely mentioned artifacts are surveyed, borne out of our experience in a multifaceted academic neuroradiology practice.

Materials and Methods
A series of artifacts are presented in a 3-step format of diagnosis, understanding, and mitigation.
1. Diagnosis: Head CT images are presented with questions that scrutinize image quality and identify the artifact. 2. Understanding: A physicist weighs in with concise explanations that bring...
technical insight. 3. Mitigation: A radiologist offers perspective pertaining to the artifact's clinical significance and practical steps for its prevention.

Results
We review unexpected artifacts rooted in technologist practice, scanner technology limitations, and protocol design (or implementation). One such artifact is pseudo acute infarct due to patient off-center positioning, which is explained in relation to the beam-shaping bowtie filter. Another artifact is periodic hyperattenuation subjacent to the calvaria, which is due to cone beam artifact. We also consider the effects of exceedingly high pitch (1.75), excessively fast rotation time (0.5 seconds), table interference during obliqued sequential scans, and other interference-type artifacts.

Conclusions
Artifacts can be a source of diagnostic errors on head CT scans and therefore need to be recognized and reduced. Radiologists play an active role in image quality improvement by recognizing these artifacts, diagnosing root causes, and mitigating them. This usually involves interactive collaboration with a comprehensive team of technologists, physicists, and vendor specialists. By understanding and mitigating unexpected artifacts in head CT scans, these diagnostic errors can be avoided.

6:30AM - 9:00PM

**Vision and Perception: A Teaching Module to Improve the Detection of Lesions on Head CT**

J Agrawal¹, S Lev¹

¹Nassau University Medical Center, East Meadow, NY

Purpose
The task facing the neuroradiologist; that is, the act of detection and recognition of lesions with varying shapes, contours, and shades against a background of numerous visual stimuli, is not unlike the job of an air traffic controller or professional race car driver. Our purpose is to help the viewer avoid perceptual errors and expedite lesion detection, introducing concepts integral to pattern, search, and detection theories. We have developed an interactive and case-based tutorial that emphasizes a pattern recognition approach and standard sequence of analysis that refines visuospatial recognition.

Materials and Methods
We retrospectively reviewed the neuroradiological misses in our database for the past five years at our level I trauma center. In order to ascertain the causes of these errors, we broadly categorized them as perceptual (visual) or cognitive (interpretive). A pretest containing selected head CT cases with subtle findings is given to assess the viewer's skill level. Afterward, the viewer is led through a series of instructional slides illustrating basic concepts of visual theory, progressing from simplified block representations of the brain to actual CT images. Finally, a post-test to assess the level of improvement is administered. To encourage the viewer to utilize a search pattern approach, we vary the allotted time interval for cases in the pre- and post-tests.
Results
In analyzing an image, neuroradiologists correlate incoming visual stimuli to a mental template of a normal study. We see with our central (foveal) and peripheral vision. At 60 cm, the distance between neuroradiologist and monitor, the detailed foveal vision is about the size of a dime. The remaining image is part of the peripheral field. High contrast findings (e.g., hemorrhage and air) stand out from the background and are seen easily by the peripheral vision, with no need to focus. Peripheral vision is motion sensitive, serving an adaptive purpose during our evolution, when it was necessary to scan for threats. When one scrolls rapidly, lesions flicker into view, activating peripheral vision detectors. Increasing volume and complexity of ancillary lesions can distract from more important findings (satisfaction of search). A methodical approach begins with assessing for symmetry. Focusing on the midline with foveal vision, one may simultaneously use peripheral vision to detect surrounding contrast differences, which then can be further scrutinized. A new finding may induce one to redirect the search, as when evaluating for a contrecoup lesion. Updating the search pattern as additional evidence is acquired is a form of Bayesian inference. Contrast may be accentuated by windowing, which may help in stroke detection. An interesting phenomenon is background contrast effect, where the perceived brightness of an object is affected by a neighboring area. Focal sparing of gray matter within an infarct may mimic hemorrhage. While one may readily identify contours with high contrast, situations with little contrast may be encountered. Subjective contour formation of unrelated structures, with overlapping shapes and similar densities, may contribute to the appearance of pathology. Additional reformats may help define the boundaries of a lesion. These concepts are fundamental to pattern theory, which explores how to identify and understand complex visual information.

Conclusions
Interpretation of a head CT is a complex perceptual endeavor. The expert neuroradiologist will focus his/her attention on regions where lesions are more likely to occur. Once a lesion is noted, the next phase of analysis can occur--feature detection, in which incoming stimuli are broken down into their component parts, including anatomical, morphological, and density characteristics. A comprehensive strategy must be developed as not all lesions are equally probable. We explore the relevance of several models of applied mathematics, such as pattern theory (represents and analyzes complex systems), search theory (uses available information to determine the most efficient search path), and detection theory (discerns visual stimuli from background noise). These models of applied mathematics may help elucidate how a neuroradiologist perceives an abnormality.

Monday
6:30AM - 3:00PM
Palais des congres de Montreal, 220d

Electronic Education Exhibits (eEdE) - Spine
eEdE-235
6:30AM - 9:00PM
Purpose
To review relevant cervical spine anatomy, biomechanics, injury patterns, and imaging techniques in cervical spine trauma.

Materials and Methods
We will review spinal anatomy and the classification/mechanics of spine injury, with attention to the appropriate imaging management of cervical spine injury and an approach to the identification of unstable injuries.

Results
Cervical spine trauma is a common condition, with an estimated incidence of between 2%–6% in blunt trauma victims. The identification of patients with an unstable spine is essential as this group is at high risk for neurologic impairment. Stability of the cervical spine relies on the integrity of both osseous and ligamentous structures. The Denis 3-column concept provides a basic framework for identifying unstable injuries, but probably oversimplifies the complex functional relationships that determine mechanical function. The anatomy of both the ligamentous and osseous structures contributing to each column will be reviewed. Computed tomography (CT) is well established in the diagnosis of cervical spine fractures, but its sensitivity for diagnosis of ligamentous injury remains a matter of controversy. Its reported sensitivity ranges from poor to equivalent to MR imaging (MRI). To an extent the differences in reported sensitivity depend on the gold standard, MR finding of abnormality, which favors MR, or evidence of functional instability, which suggests that CT is quite reliable. We will review these arguments, and illustrate CT findings of ligamentous injury. MR imaging may identify abnormalities whose functional significance is unclear. These include high ligamentous signal, adjacent fluid, or ligament thinning without disruption. We will relate these to biomechanical considerations and discuss their possible implications for ligamentous integrity. As a result of these issues, the clinical setting and overall pattern of injury are needed for appropriate MRI evaluation. Although MRI may have a high false positive rate with its added sensitivity, a combination of CT and MRI evaluation is standard and considered the safest approach in the setting of abnormal neurologic exam, obtunded state, or suspected abnormality on CT.

Conclusions
The evaluation of cervical spine trauma is a common and important topic in radiology practice. Understanding the anatomy and biomechanics of the cervical spine is critical in the interpretation of cervical spine imaging and the identification of unstable injuries. Although controversies exist regarding the significance and diagnosis of ligamentous injuries on MRI, the overall pattern of injury, including clinical, CT, and MRI findings can be helpful in assessing spine stability.

KEYWORDS: Cervical Spine, Ligaments
C Nguyen¹, C Plastaras¹, B Pukenas¹
¹Hospital of the University of Pennsylvania, Philadelphia, PA

Purpose
Spinal pain and radiculopathy are very common debilitating conditions which in many cases can be treated successfully using fluoroscopic or computed tomography (CT)-guided percutaneous injection of local anesthetics or long-acting steroids. We illustrate techniques for cervical, thoracic, lumbosacral, and sacroiliac image-guided percutaneous zygapophysial joint, selective spinal nerve, epidural, and sacroiliac joint injections including preprocedural evaluation and postprocedural patient follow up.

Materials and Methods
Using three-dimensional animations to illustrate relevant anatomy and intraprocedural imaging to highlight treatment approach we present a series of cases involving percutaneous injection of the cervical, thoracic, lumbosacral spine. Level by level correlation with preprocedural cross-sectional imaging identifying relevant pathology will be presented. Pre and postprocedural patient evaluation, treatment efficacy, and patient outcomes as evidenced by literature review will be discussed.

Results
Clinical and radiographic factors affecting proper patient selection as well as decision to perform zygapophysial joint, epidural, sacroiliac, or selective spinal nerve injection will be discussed. Advantages and disadvantages of CT or fluoroscopic guidance for certain anatomical sites and treatment approaches will be reviewed. Techniques including patient positioning, appropriate needle placement, and medication selection will be emphasized. Important features such as postprocedural follow up and complication avoidance will be highlighted.

Conclusions
Given the increasing demand for image-guided percutaneous spine injections, proper patient selection and technique is critical for safe performance with minimum patient discomfort. Preprocedural patient evaluation including relevant imaging, knowledge of anatomy, and appropriate follow up is crucial to ensure good patient outcomes and will be effectively reviewed using animations and intraprocedural imaging.

6:30AM - 9:00PM

Extramedullary Intraspinal Injuries without Osseous involvement: Diagnostic Challenges on MR and CT
Purpose
Intraspinal pathology that does not involve the surrounding bone and is not intrinsic to the spinal cord may create a diagnostic dilemma, both on CT, where soft tissue contrast is limited, and even on MR, where injuries such as epidural or subdural hematoma can demonstrate a multilevel abnormality without significant contrast enhancement. This exhibit will demonstrate these findings as well as other entities with similar imaging features including an atypical sequestered disk, a spinal meningeal cyst and an epidural phlegmon associated with paraspinal myofasciitis. With careful analysis, the correct diagnosis, or at least an appropriate differential diagnosis, can be established. Many, but not all, such cases will require surgical management.

Materials and Methods
Computed tomography and MR cases accumulated in the neuroradiology teaching file of a Level I trauma center over the prior three years were reviewed retrospectively, and several which demonstrated the characteristics of intraspinal fluid collection, hematoma or other extramedullary mass without osseous involvement were selected for inclusion in the exhibit after review of the pertinent literature.

Results
Pathologic entities included in the exhibit included an intraspinal subdural hematoma which was almost certainly secondary to nonaccidental trauma, i.e, "shaken baby" syndrome, an epidural hematoma due to iatrogenic steroid injection, a mass-like sequestered disk posterior to the thecal sac, an epidural phlegmon with paraspinal myofasciitis, but without associated diskitis-osteomyelitis, and a spinal-meningeal cyst for which the etiology was either congenital, or the result of remote trauma. Identification of these abnormalities was made possible by signal changes on MR, including both T1 and T2 shortening, in the extramedullary spaces. In the case of inflammatory disease, involvement of the paraspinal musculature was a supportive finding. Mass effect, often multisegmental, on the spinal cord or cauda equina is useful to help distinguish pathology from complex flow artifacts which can occur with MR of the spinal axis. The absence of contrast enhancement, except at the periphery of several of the abnormalities, is helpful in delineating epidural abnormalities, and in excluding a neoplasm but is otherwise nonspecific. CT, and in one case CT myelography, was of adjunctive benefit.

Conclusions
Traumatic spinal injuries are identified most readily on cross-sectional imaging in the presence of fracture and/or disruption of the supporting spinal ligaments. The cases presented here lack those features and therefore present an added diagnostic challenge. It is important to recognize that nonaccidental trauma in childhood often is associated with intraspinal subdural hematoma, which is quite rare in accidental childhood injury. By contrast, epidural hematoma as a result of therapeutic injection is very unusual, but warrants immediate consideration in a patient who develops increased pain and neurologic deficit following one of these commonly performed procedures. The additional unusual cases presented demonstrate that congenital, inflammatory and degenerative entities also are relevant when formulating a differential diagnosis.

Fluoroscopically Guided Lumbar Puncture. Teaching Points.

M Gaha1, A Weill1, M Bélair1, C Bard1
1Centre Hospitalier de l'Université de Montréal, Montréal, Québec, Canada

Purpose
Evidence-based protocols for fluoroscopically guided lumbar puncture (LP) do not exist. This presentation describes the different fluoroscopically guided LP techniques used by neuroradiologists.

Materials and Methods
The authors searched MEDLINE, PubMed, EMBASE, Cochrane Library and Scopus for articles published up to November 2013. Studies about fluoroscopically guided LP were considered. The following search strategy was used: (lumbar OR spine) AND puncture AND guided AND fluoroscopy.

Results
We reviewed seven parameters of the fluoroscopically guided LP: thecal sac puncture position, spinal level, direction of needle during the puncture, opening pressure measurement technique, needle type and length, observation post LP, fluoroscopy setup. We resume the most important indications, contraindications and complications of LP.

Conclusions
Neuroradiologists generally appear to perform fluoroscopically LP in a similar fashion. The main steps in this technique were described. Post Lp headache observation has been related to the needle type. A randomized double-blind study evaluating different needle types is actually going
on. Practice guidelines for standardizing the fluoroscopically guided LP technique would improve the accuracy of opening pressure measurement.

KEYWORDS: Fluoroscopy, Lumbar Puncture

6:30AM - 9:00PM

Intramedullary thoracic spinal cord epidermoid in a 20 year-old male: case report and review of the imaging features of the most common intramedullary tumors of the spinal cord in adults.

B Scott1, J Maxwell1, E Spitzer1, S Ifthikharuddin1, A Bhatt1, K Kaplan-List2

1Rochester General Hospital, Rochester, NY, 2Rochester General Hospital, Webster, NY

Purpose
In adults primary spinal cord tumors are rare, accounting for 2-4 percent of all central nervous system tumors with intramedullary spinal cord tumors accounting for 8-10 percent. Among the intramedullary spinal cord tumors, ependymomas, astrocytomas and hemangioblastomas [of which 15% to 25% are associated with von Hippel-Lindau (VHL) syndrome] represent the majority of all intramedullary tumors. Intramedullary epidermoid tumors are rare, and are more common in pediatric patients. We report a case of an intramedullary thoracic epidermoid tumor in a 20-year-old male and review of the imaging features of the most common intramedullary tumors of the spinal cord in adults.

Materials and Methods
Case report of an intramedullary epidermoid tumor in the thoracic spinal cord of a 20-year-old male presenting with right leg weakness and progressive asymmetric growth over a period of five years, with new onset of bowel and bladder incontinence, sustained clonus, hyperreflexia and positive Babinski reflex on the right. MR imaging (MRI) of the spine demonstrated expansile, partially cystic, minimally enhancing, intramedullary lesion involving the upper thoracic spinal cord. The diffusion-weighted sequences were nondiagnostic due to significant motion artifact.

Results
The mass initially was believed to be an astrocytoma or an ependymoma based on its imaging characteristics. Patient underwent gross total excision of the mass and histopathology revealed an epidermoid tumor. We compare and contrast MRI characteristics of the most common intramedullary spinal cord tumors (astrocytoma, ependymoma and hemangioblastoma) and a rare intramedullary thoracic epidermoid to illustrate the distinguishing imaging features on MRI.

Conclusions
While certain imaging features of intramedullary spinal cord tumors overlap, some specific features point toward one diagnosis rather than the other. In younger age group, differential diagnoses of an intramedullary tumor should include ependymomas, astrocytomas and hemangioblastomas (particularly in patients with VHL syndrome) as well as neurodevelopmental tumors, such as epidermoid tumors, dermoid tumors, lipomas and teratomas. Diffusion-weighted imaging (DWI) sequences can be helpful in differentiating more common lesions from rare epidermoid tumors that usually demonstrate restricted diffusion. Familiarity with the imaging
features of the intramedullary tumors of the thoracic cord can help in the diagnosis of spinal cord tumors.

KEYWORDS: Epidermoid, Intramedullary, Spinal Cord

Oooh! My back aches! Why should I consult a Radiologist for relief?

J Nair¹, J Chankowsky¹, C Torres¹, T Hegazi¹, M Radhakrishnan¹, T Powell¹
¹McGill University Health Centre, Montreal, Quebec, Canada

Purpose
Using an interactive model, to select and perform image-guided percutaneous procedures for patients presenting with backache, based on patient assessment and previous imaging findings.

Materials and Methods
Each procedure presented as a case with relevant clinical history and previous imaging findings. Based on these findings, decision made on the procedure to be performed using multiple choice
questions for interaction. Justification for each procedure selected followed by technique and possible complications are explained.

Results
Technique for image-guided procedures used in spine pain management including relevant anatomy and instrumentation discussed in detail. The procedures include epidural block, nerve root and facet blocks, lumbar synovial cyst rupture, ganglion impar block, radiofrequency ablation of nerve roots and osteoid osteoma, diskography and vertebroplasty (amongst others). The potential pitfalls, complications and measures to avoid them also are reviewed.

Conclusions
The Exhibit provides insight to the various percutaneous needle techniques for diagnosis and treatment of backache. It also emphasis the fact the radiologist is no longer an innocent spectator providing guidance for fluoroscopy but has a very significant role in pain management.

KEYWORDS: Epidural, Lumbar Spine, Nerve Root Block

Optimized Imaging of the Postoperative Spine
I Corcuera-Solano¹, A McLellan², S Daniel³, L Tanenbaum³
¹Icahn School of Medicine at Mount Sinai, New York, NY, ²Mount Sinai Medical Center, New York, NY, ³Mount Sinai Hospital, New York, NY

Purpose
There are few imaging tasks more challenging than optimizing evaluations of the instrumented spine secondary to artifacts induced by implanted metal devices on MR imaging (MRI) and CT examinations. MR imaging artifacts are due primarily to volume magnetic susceptibility mismatch between metal devices and tissue. In CT the issues are beam hardening and streak artifacts. Purpose: 1. To review the essential techniques for optimization of MR and CT imaging of the postoperative spine. 2. To explain the nature and cause of artifacts that hinder evaluations of the instrumented spine. 3. To demonstrate the value of advanced CT techniques such as dual energy in imaging the postoperative spine. 4. To demonstrate the value of novel MR sequences such as chemical shift, and multispectral imaging in imaging the postoperative spine.

Materials and Methods
1. Brief review of the principles underlying optimized imaging for postoperative spine focusing on key technical factor adjustments, the value of innovations such as dual energy CT, and new MR techniques such as metal artifact reduction and chemical shift imaging. 2. Illustration cases with stepwise implementation of optimizations will be presented. 3. Highlight the advantages and pearls of the new imaging methods. 4. Discuss the potential pitfalls and limitations of basic and advanced techniques.

Results
We reviewed the modifiable variables of the CT acquisition parameters and advanced CT techniques such as dual energy CT, including multiple types of dual or single sources (sequential and layered) images, the optimum MR sequences, including higher bandwidth, long echo train, small voxels, fast spin echo and adjusting the frequency coding directions and the advanced fast suppression techniques with chemical shift fat suppression and advanced multispectral imaging methods including hybrid techniques. These new enhancements demonstrated an improvement in the negative effects associated with metal implants, thus optimizing image quality.

Conclusions
Applying fundamental principles in postoperative spine CT and MR studies can significantly improve image quality. Newer and soon to be available enhancements further reduce the negative effects associated with metal implants, thus optimizing image quality.

KEYWORDS: Metal Artifact
Dixon imaging Neurofibroma. Clockwise from upper left: Water (fat suppressed) T2, pre contrast T1. Note the additional value of the in phase image which facilitates comparison with the non fat suppressed pre contrast scan. Fat suppression improves dynamic range and can lead to overestimation of enhancement.

**Pictorial Essay of Complications after Spinal Intervention**

P Lee¹, B Dahlin², P Shen², E Supsupin³

¹University of California Davis School of Medicine, Sacramento, CA, ²University of California Davis, Sacramento, CA, ³University of Texas Houston, Houston, TX
Purpose
This is a pictorial essay displaying the complications of spinal intervention. It includes rare complications of common spinal intervention as well as complications of procedures not commonly performed.

Materials and Methods
Spinal intervention, such as microdiskectomy and spinal hardware instrumentation to less invasive procedures such as myelograms, lumbar drains, epidural steroid injections and blood patches are common procedures performed in most hospital settings. Complications are uncommon and range from relatively benign mishaps such subdural injections to more devastating outcomes such as fistulas-pseudoaneurysms and spinal cord infarcts. Emphasis on imaging characteristics of rare and serious complications for early detection as well the clinical aspects will be the focus of this presentation.

Results
Complications from spinal intervention can range from the rare vascular injury resulting in fistula and pseudoaneurysm from microdiskectomy to direct cord injection from attempted myelography or diskography resulting in spinal cord infarct. Spinal cord infarcts also can occur from hardware instrumentation or myelography due to rapid changes in cerebrospinal fluid (CSF) pressure. Lumbar drain catheters can be sheared and retained in the thecal sac during placement or removal resulting in persistent myelopathy. Recognition of the imaging findings and awareness of potential complications by the operator during the procedure are the most important for prevention. However, appropriate recognition of complications is crucial in reducing the morbidity when it occurs.

Conclusions
Complications from spinal intervention are uncommon but can have devastating consequences if not recognized. Prompt recognition and appropriate intervention are crucial to minimize the extent of morbidity when it occurs.

KEYWORDS: Complications
Preoperative embolization of hypervascular spinal metastases: A Visual Approach from Cervical Spine to Sacrum

A Harsha¹, R Hurst², J Schuster², B Pukenas²
¹University of Pennsylvania, Philadelphia, PA, ²Hospital of the University of Pennsylvania, Philadelphia, PA

Purpose
Hypervascular spinal metastases associated with vertebral instability require surgical management and often times result in high intraoperative blood loss. Preoperative tumor embolization is proven to reduce intra-operative blood loss through tumor devascularization. A practical approach to patient selection, technical aspects and complications of preoperative vertebral metastases embolization will be discussed. Relevant anatomy, imaging findings, and treatment efficacy will be reviewed.

Materials and Methods
Using three-dimensional animations to illustrate relevant anatomy and intraprocedural imaging to highlight treatment approach we present a series of cases involving the embolization of cervical, thoracic, lumbosacral spine hypervascular metastases. Potential postprocedural complications will be reviewed. Treatment efficacy and outcomes as evidenced by literature review will be discussed.

Results
Preoperative imaging findings including digital subtraction angiography demonstrating arterial anatomy for different vertebral segments will be discussed. The principles of appropriate embolic agent selection and embolization technique will be reviewed. Features such as satisfactory postembolization appearance and complication avoidance will be emphasized.

Conclusions
Pre-operative embolization of hypervascular spinal metastases is an effective procedure that reduces perioperative blood loss and facilitates tumor resection. Knowledge of anatomy, technique and potential complications are crucial to ensuring good patient outcomes. These techniques are reviewed effectively using animations and intraprocedural imaging.

Review of Neuroimaging Spectrum of Pathology Involving the Lumbar Spine Paraspinal Muscles and Psoas Muscles
L Kirk¹, S Patel¹, A Wang¹, R Silbergleit¹, A Krishnan¹, K Barry²
¹William Beaumont Hospital, Royal Oak, MI, ²William Beaumont Hospital, Troy, MI

Purpose
The purpose is to highlight the wide range of pathology involving the lumbar spine paraspinal muscles and psoas muscles. The goal is to familiarize the radiologist with the different pathologic entities affecting these muscle groups and their unique imaging characteristics, so that when presented with a case with an abnormality the radiologists are able to provide appropriate diagnosis and improve clinical care.

Materials and Methods
A retrospective review of abnormal lumbar spine paraspinal and psoas muscle demonstrated on MR imaging (MRI) and CT of the lumbar spine performed at William Beaumont Hospital from the previous three-year period. The imaging findings were correlated with the clinical history.

Results
A wide range of pathology was found involving the paraspinal muscles of the lumbar spine and the psoas muscles. The categories of pathology that we found were: neoplasm, including primary neoplasm and metastatic disease; infectious disease, including bacterial processes and tuberculosis; posttraumatic changes, including hematomas; myositis; rhabdomyolysis; unilateral and bilateral denervation changes, including those with the etiology of spinal stenosis, facet degenerative changes, and polio. Each of the entities with characteristic imaging findings will be presented. A description of each disease entity and its clinical findings along with characteristic imaging findings will be included in our presentation along with CT and MR images. Reviewers of our exhibit will be able to learn about each pathological entity and should be able to provide an appropriate differential diagnosis, which will aid them in the future when they are presented with abnormalities of the lumbar spine paraspinal musculature and psoas muscles.

Conclusions
There is a wide spectrum of common and uncommon disease entities that affect the lumbar spine paraspinal musculature and the psoas muscles. After the radiologist reviews our exhibit they will be familiar with each category of pathology presented. With this knowledge they will be able to provide an appropriate differential diagnosis when presented with different pathologic entities of the lumbar spine paraspinal muscles and psoas muscles. This then will benefit the referring clinician and ultimately will improve patient care.

KEYWORDS: Infections, Neoplasm, Spinal Imaging

Spinal Calcifications and Ossifications: Boring, Beautiful and Bizarre. A Pictorial Review.

C Sereni¹, T Gorbachova¹, R Lee¹
¹Albert Einstein Medical Center, Philadelphia, PA

Purpose
Calcifications and ossifications, although routinely encountered in radiology practice, can present a diagnostic challenge when encountered in the spine. Our aim is to review typical and
unusual manifestations of common entities, as well as some rare conditions. After the completion of this exhibit, the radiologist should be able to identify classic imaging features of spinal calcifications and ossifications, as well as their mimickers, and learn how to avoid diagnostic pitfalls.

Materials and Methods
We present a systematic review of typical ossification and calcification patterns involving the spine, using a multimodality approach. Disease categories include arthritides, degenerative and inflammatory conditions, crystal deposition disorders, tumors with mineralized matrix, renal osteodystrophy and mimickers of calcifications. For each category, emphasis is placed on key anatomical features and imaging pearls that help make the diagnosis.

Results
An understanding of calcifying and ossifying disorders is essential for diagnosing musculoskeletal spinal lesions. Of particular importance is crystal deposition disease such as hydroxyapatite deposition disease (HADD), calcium pyrophosphate deposition disease (CPPD) and gout. Case examples include spinal cord stenosis secondary to HADD of the ligamentum flavum, acute calcific tendinitis of the longus colli muscle mimicking retropharyngeal abscess, widespread spinal involvement by gout, and the multiple appearances of spinal CPPD. Early and late findings of ankylosing spondylitis and diffuse idiopathic skeletal hyperostosis will be reviewed along with unusual injury patterns frequently encountered with these disorders. Spinal tumors with mineralized matrix and systemic diseases, including renal osteodystrophy, also are presented.

Conclusions
Spinal calcifications and ossifications commonly are encountered in clinical practice. Unusual manifestations of common entities and rare conditions are highlighted in this electronic exhibit.

Spinal Cysts: Imaging and Clinical features

B Battal¹, F Chiang¹, G Tedesqui¹, D Varon¹, M Simons¹, M Castillo¹

¹University of North Carolina at Chapel Hill, Chapel Hill, NC

Purpose
Multiple types of spinal cysts have been described, each one with different imaging characteristics and clinical implications. The aim of this exhibit is to discuss the spectrum of cystic lesions that affect various compartments of the spine including peri-spinal structures, vertebral column, extradural, intradural and intramedullary compartments, their imaging findings, and who these imaging findings correlate clinically and affect treatment.

Materials and Methods
This educational exhibit discusses the myelographic, ultrasound (US), computed tomography (CT) and MR imaging (MRI) features of cystic lesions of the spine. For it, we search our teaching files for the following keywords: cyst, cystic lesion, tumor, cystic tumor, meningocele, Tarlov, diverticula, parasites, syrinx, hydromyelia, terminal ventricle, myelomalacia, and
epidermoid. A pertinent literature review is provided emphasizing their differential diagnosis, clinical presentation, and treatments.

Results
In the evaluated US, CT and MR examinations, various cystic lesions originating from different compartments of the spine were identified, including synovial/ganglion cysts, simple bone cysts, hydatid cysts, aneurysmal bone cysts, diskal cysts, lateral spinal meningoceles, spinal perineural cysts (Tarlov cyst), spontaneous meningeal diverticula, occult intrasacral meningocele, neuroenteric cysts, arachnoid cysts, epidermoid cysts, dermoid cysts, spinal cysticercosis, ventriculus terminalis, syringohydromyelia, cystic myelomalacia, cystic hematoma and cystic tumors. Cysts of several different types may develop within the spinal canal. They can be found incidentally or they may cause myelopathy and/or radiculopathy. For the purposes of this exhibit we divided the different cystic lesions by their nature in congenital/developmental, neoplastic or inflammatory, and according to their location in the paraspinal soft tissues, vertebral column, spinal extradural compartment, intradural compartment and intramedullary.

Conclusions
A broad spectrum of cystic lesions can occur in the different compartments of the spine and paraspinal areas. Therefore, the diagnosis and differentiation between them can be made on a basis of a multimodality imaging approach including US, CT and MRI. MR imaging is an excellent noninvasive technique in the detection and evaluation of the spinal cystic lesions. Ultrasound is essential and the modality of choice in many pediatric patients, while CT is helpful specially in the vertebral column lesions. Advanced imaging techniques such as diffusion-weighted imaging can be used as a problem-solving tool in some spinal cystic lesions.

Spinal Hardware Complications

O McDonnell¹, J Chew¹, J Shewchuk¹, T Vertinsky¹

¹Vancouver General Hospital, Vancouver, Canada

Purpose
To illustrate the imaging appearances of common and uncommon, early and late complications of spinal instrumentation.

Materials and Methods
Imaging of patients with postoperative spinal instrumentation complications was reviewed. The imaging modalities used included plain radiographs, computed tomography (CT) and MR imaging (MRI). Radiography is the mainstay for imaging postoperative patients and has the advantage of being quick and inexpensive. MDCT also may be used, but is associated with an increased radiation dose. MR imaging is most useful at assessing for postoperative infection.

Results
We illustrate complications such as instrument malpositioning of pedicle screws, cages, bone grafts and plates. Late complications such as adjacent segment degenerative disease, failure of fusion, hardware fracture, loosening or displacement also were demonstrated, as well as postoperative infection.
Conclusions
It is important that the radiologist is aware of the possible complications associated with spinal instrumentation and their imaging appearances in order to allow early detection and treatment. Systematic evaluation is required. Although radiography remains the primary modality, MDCT and MRI also have a role in further evaluation.

KEYWORDS: Spinal Imaging, Spinal Instumentation

Spinal imaging findings of CSF hypovolemia syndrome

M Bajaj1, T Moritani2, O Pinzon2, Y Sato2, A Capizzano1, T Chandra3
1University of Iowa Hospitals & Clinics, Iowa City, IA, 2University of Iowa, Iowa City, IA, 3Medical College of Wisconsin, Milwaukee, WI

Purpose
This educational exhibit aims to: 1. Describe pertinent spinal imaging findings of cerebrospinal fluid (CSF) hypovolemia syndrome. 2. Illustrate the pathophysiology of CSF hypovolemia syndrome. 3. Discuss role of different modalities used to image spine in diagnosis of CSF hypovolemia. 4. Identify common differential diagnoses to be considered. 5. Suggest optimal management of CSF hypovolemia.

Materials and Methods
Spinal Imaging findings using different modalities including myelography, CT myelography, MRI, MR myelography, nuclear cisternography. In patients with diagnosis of CSF hypovolemia were evaluated. Findings were thoroughly assessed and utilized to prepare an educational exhibit describing: 1. Pathophysiology of CSF hypovolemia syndrome, 2. Common appearances on spinal imaging, 3. Differential diagnoses, 4. Pediatric versus Adult CSF hypovolemia, 5. Brain imaging findings in CSF hypovolemia in brief.

Results
• CSF hypovolemia is an important clinicoradiological entity and can be diagnosed on various modalities for imaging spine provided a high index of suspicion is present. • Coexistent findings on brain imaging can support the diagnosis.

Conclusions
A thorough knowledge of normal pathophysiology, common spinal imaging appearances on various modalities and differential diagnoses can help diagnose CSF hypovolemia with confidence and avoid misdiagnosis.

KEYWORDS: CT, MRI Spine, Spinal CSF Leak

Spinal Subdural Hematomas - Etiologies, Imaging Characteristics, Pitfalls and Techniques

C Kaufman1, H Dave1, V Kalra2, B Jeun2, A Malhotra3
Purpose
Spinal subdural hematomas are rare but can have devastating neurologic consequences and therefore are important to rapidly and accurately diagnose. We will review the etiologies of subdural hemorrhage in the spine, imaging identification, aging of hemorrhage, imaging pearls and natural course of hemorrhage.

Materials and Methods
Spine subdural hemorrhage can be idiopathic or secondary. Spine subdural hemorrhage may be secondary to trauma, lumbar puncture, spinal anesthesia, spine surgery, bleeding diathesis, anticoagulation therapy or vascular malformations. Rarely, they can be seen in association with intracranial hemorrhage and after posterior fossa decompressive surgeries. Nonaccidental trauma is an important consideration in infants with subdural hemorrhage. This poster will review the pathophysiology and different etiologies of spinal hematomas providing imaging examples of each. In addition we will cover the characteristic MR imaging findings of spinal subdural hematomas as well as imaging difficulties and techniques for diagnosis.

Results
The subdural space in the spine is a potential space between the dura and the arachnoid matter. Unlike the epidural space which contains the epidural venous plexus the spinal subdural space does not contain any major blood vessels. Spinal subdural hematomas are defined as blood products within the subdural space. This is a rare finding that can have significant clinical consequences. Patients usually present with acute neurological symptoms due to mass effect on the spinal cord or cauda equina. Smaller collections can have a more subtle presentation such as back pain or radicular pain. There are several well recognized etiologies of spinal subdural hematoma; post-traumatic, postoperative, postlumbar puncture, spontaneous due to anticoagulation, tumors, or vascular malformations, and nonaccidental trauma. MRI is the best imaging modality for: •detecting spinal subdural hematomas, •determining the extent of the hematoma, •accurately age blood products, •Assess the mass effect and compression on the nerve roots and/or spinal cord. There are several imaging pitfalls to be wary of when a patient presents with clinical history concerning for a spinal hemorrhage. Hyper acute spinal subdural hematomas (<12 hours) contain oxyhemoglobin, which is isointense on T1-weighted images, and hyperintense on T2-weighted images. This can cause difficultly distinguishing the hematoma from the surrounding structures due to the isointensity on T1-weighted images, the small space, and surrounding structures. In these cases gradient-echo imaging can be of used, as it will demonstrate a characteristic low-signal rim surrounding the hematoma. A second issue arises with subacute spinal hematomas. Subacute hematomas (3-14 days) may contain either intracellular or extracellular methemoglobin depending on the age. Methemoglobin is hyperintense on T1-weighted images, which can be difficult to distinguish from benign epidural fat. Fat suppressed T1-weighted images can be of help.

Conclusions
Spinal subdural hematomas are rare neurologic emergencies which can result from several different etiologies. MR imaging is the best imaging modality for diagnosis; however, there are several pitfalls one must be aware of to ensure accurate diagnosis.

The Broken Neck: A pictorial review of CT and MR findings in traumatic cervical spine injury

C Pluguez-Turul1, 2, W Rivera1, J Quintero-Estades1, C Quintero-Estades1, E Alvarado-Burgos1, L García1, C Cortes1

1University of Puerto Rico - Medical Sciences Campus, San Juan, PR, 2Transitional Year Program – San Juan City Hospital, San Juan, PR

Purpose
Cervical spine injuries (CSI) are both common and potentially devastating. In the USA, there are approximately 8,500 patients with CSIs who present for treatment annually. The mean age at injury is 30.7 years, but injury most frequently occurs at age 19. The three most common causes of spinal fractures are motor vehicle accident (50%), falls (25%), and sports injuries (10%). The consequences resulting from neck injuries range from simple neck pain, to quadriplegia, or even death. The spinal cord injury occurs at the time of trauma in 85% of patients and as a late complication in 15%. The initial post-injury period is critical with regard to neurologic recovery or deterioration and the delay of injury recognition or improper stabilization of the cervical spine may lead to irreversible spinal cord injury and permanent neurologic damage. This educational exhibit will review the pathophysiology, mechanism of injury (MOI), characteristic imaging findings and management strategies of cervical spine injury by examining CT and MRI findings in patients at our institution. We also will provide a review of the indications for radiological evaluation and the most common associated complications of neck trauma.

Materials and Methods
Radiological images and relevant clinical information were extracted from our PACS station and MEDITECH™ integrated healthcare system at Puerto Rico's Trauma Center. Images were retrieved for recent cervical spine imaging studies to review a wide spectrum of the major pathologies found in patients admitted for trauma.

Results
In this educational exhibit we intend to review a wide range of cervical spine pathologies encountered in neck trauma patients at our institution to include, but not limited to: simple and complex c-spine fractures, ligamentous injury, traumatic disk herniation, arterial dissection, post-traumatic vascular thrombosis and spinal cord injury. Particular attention was paid to noncontrast cervical spine CT findings, as this is usually the first study performed in this setting. Ancillary use of MRI, MRA, CTA and other specialized techniques will be presented for selected injuries where further management changing information may be obtained. Discussion of pathophysiology, MOI, management, common complications and characteristic imaging findings with pertinent radiological illustrations will provide adequate exposure to the most commonly encountered clinical scenarios after significant neck trauma.

Conclusions
Cervical spine injuries (CSI) are both common and potentially devastating. The initial postinjury period is critical with regard to neurologic recovery or deterioration. Delayed recognition of an injury or improper management and stabilization of the cervical spine may lead to irreversible spinal cord injury and permanent neurologic damage. Reviewing the pathophysiology, MOI,
common complications, indications for radiological evaluation, characteristic imaging findings and management of traumatic cervical spine injuries will help improve the outcome of patients presenting with acute craniocervical.

The Third Dimension of Cervical Spine Imaging – S.P.A.C.E.: The Final Frontier

A Myers¹, F Chokshi²

¹Emory University School of Medicine, Atlanta, GA, 2Emory University School of Medicine, Marietta, GA

Purpose
Cervical spine imaging using sagittal 3-dimensional (3D) T2-weighted (T2W) magnetic resonance imaging (MRI) sequences offers a robust technique for diagnostic evaluation with high spatial and contrast resolution, the ability for multiplanar reconstruction, and reduced cerebrospinal fluid (CSF) flow and metallic artifacts; this yields improved delineation of cervical anatomy and a range of pathology when compared to conventional T2W fast spin echo (FSE) or turbo spin echo (TSE) sequences. Scan times can also decrease by foregoing separate sagittal and axial FSE/TSE T2W sequence acquisitions.

Materials and Methods
Multiple nonsurgical and postsurgical patients with variable anatomy, pathology, and postoperative hardware were imaged using both conventional axial/sagittal T2W TSE as well as a sagittal T2W 3D volumetric, high resolution Sampling Perfection with Application optimized Contrasts using different flip angle Evolution (SPACE) sequence. Postprocessing of SPACE images included 3D myelographic reconstruction and volume/CSF segmentation.

Results
Highlights include detailed evaluation of essential cervical spine anatomy, identifying duplicated and anomalous nerve rootlets, examples of pathologic compression and tumor involvement of specific cervical nerve rootlets, and improved visualization of pathology in the setting of prior cervical surgical instrumentation, among others. Comparison is made to conventional T2W FSE images to demonstrate the advantages and improved diagnostic capabilities offered by T2W SPACE imaging, which often identifies additional clinically relevant findings.

Conclusions
High-resolution, volumetric 3D T2W imaging of the cervical spine offers a superior structural imaging method to visualize anatomical and pathologic changes in nonsurgical and postsurgical patients as well as permitting advanced imaging reconstruction, which has the potential added benefit of shorter scan times.

KEYWORDS: Anatomy, Cervical Spine, MR Imaging Spine
Utility of Diffusion Weighted Imaging for Evaluation of Benign and Malignant Spinal Tumors.

A Chaudhry¹, M Gul², Y Edelstein³

¹Stony Brook University Medical Center, Westbury, NY, ²Winthrop University Hospital, Mineola, NY, ³Stony Brook University Medical Center, Stony Brook, NY
Purpose
Radiologist frequently encounter tumor and tumor-like lesions as incidental findings on spine MRIs. These can result from a number of processes which can be benign or malignant. Deciphering between the two can be challenging and is critical for patient care as miss of a malignant lesion can prove to be fatal. This educational exhibit will be a case-based presentation of common and uncommon causes of benign and malignant processes that result in lytic and/or sclerotic lesions in the skeletal system on CT and have variable appearance on routine T1 and T2 sequences. We will focus on the utility of diffusion-weighted imaging in these cases in deciphering benign from malignant lesion.

Materials and Methods
1. Case-based presentation will include clinical features, key imaging findings, radiology-pathology correlation, treatment and prognosis of common and uncommon causes of benign and malignant spinal column neoplasms. 2. Case examples include: fibrous dysplasia, enchondroma, chondrosarcoma, sarcoma, lymphoma, metastasis (carcinoid, prostate, lung, melanoma, etc). 3. Chart of salient features for quick reference.

Results
1. Review physics of diffusion-weighted imaging (B-values: 50, 400, and 800 s/mm$^2$) with ADC mapping. 2. Review imaging findings of various spinal tumors. 3. Discuss limitations and pitfalls of diffusion-weighted imaging in the musculoskeletal system.

Conclusions
Osseous spinal tumors frequently are encountered incidentally on radiologic imaging and nonspecific imaging findings cause a diagnostic dilemma. Being familiar with discriminating imaging findings including diffusion-weighted imaging (DWI) can help characterize a tumor as benign or malignant thus assisting radiologists in guiding clinical management of the lesion.

KEYWORDS: Neoplasm
Vertebral Body: In Sickness and in Health

J Patel¹, A Ropp², J Scott³, W Smoker⁴
¹Morristown Medical Center, Morristown, NJ, ²University of Maryland Medical Center, Baltimore, MD, ³State University of New York Downstate Medical Center at Long Island College Hospital, Brooklyn, NY, ⁴University of Iowa Hospitals and Clinics, Iowa City, IA

Purpose
Many local and systemic disease processes alter the appearance and configuration of the vertebral body. The purpose of this exhibit is for the user to improve upon their knowledge of anatomy and imaging of the vertebral body. This exhibit will review various diseases that affect the vertebral body and demonstrate an image-based algorithm to aid in diagnosis.

Materials and Methods
1. Review the normal radiographic appearance of the vertebral body. 2. Learn imaging features

CT reveals mixed lytic-sclerotic lesion at multiple spinal levels.
MRI reveals T1 hypointense and T2 hyperintense lesions, which demonstrated restricted diffusion, likely representing osseous metastases. These were positive on bone scan and biopsy proven to be metastatic prostate cancer.

(Filename: TCT_eEdE-229_DWImage.jpg)
of diseases that affect the vertebral body. 3. Demonstrate an image-based algorithm to aid in diagnosis.

Results
A review of the normal appearance of the vertebral body is followed by a discussion of various diseases that alter the appearance of the vertebral body. Computed tomography (CT) and MR correlation will be provided in select cases. Cases are presented in a quiz format to emphasize major teaching points. Categories presented include: Enlarged shape/size: fibrous dysplasia, Paget's disease, Vertebra plana: lymphoma, Langerhan's cell histiocytosis, Abnormal shape and density: amyloid destructive spondyloarthropathy, diskitis/vertebral osteomyelitis, Pott's disease, sickle cell disease, avascular necrosis, Increased density: osteopetrosis, renal osteodystrophy, metastatic prostate cancer, hemangioma. Decreased density: multiple myeloma, severe osteoporosis.

Conclusions
Many local and systemic disease processes alter the appearance of the vertebral body. After completing this educational exhibit, the user will know the normal radiographic appearance of the vertebral body and based on changes in appearance and configuration, suggest a reasonable differential diagnosis.

A case diffuse cerebral micro haemorrhages in a patient who had received extra corporeal membrane oxygenation

J Cain¹, S Mathur², H Sonwalker², S Wuppalapati², C Coutinho²
¹University of Manchester, Manchester, UK, ²Lancashire Teaching Hospitals, Preston, UK

Purpose
To describe a case of cerebral microhemorrhages secondary to extracorporeal membrane oxygenation (ECMO) in a young patient and highlight that these changes can occur.

Materials and Methods
A 29-year-old male with a past medical history of two years previously developed ARDS secondary to pneumonia, during this illness he underwent extracorporeal membrane oxygenation support as part of intensive care therapy. He made a subsequent full recovery and underwent a MR imaging (MRI) examination for left-sided hearing loss with tinnitus.

Results
The MRI demonstrated multiple foci of low signal change on gradient echo sequences throughout both cerebral hemispheres. These were in a subcortical location with sparing of the basal ganglia. The appearances were in keeping with cerebral microhemorrhages. No other abnormalities were identified. The micr hemorrhages are presumed to be secondary to ECMO
therapy and the concurrent anticoagulation. The appearances are similar to amyloid angiopathy although this diagnosis is not seen routinely in this age group.

Conclusions
This case highlights a complication of ECMO which has not been identified previously within an adult population. Multiple cases of microhemorrhages and infarctions have been reported in children and infants receiving ECMO. The combination of large volume fluid transfusions with anticoagulation are a risk factor for both intracranial and visceral hemorrhage. As ECMO treatment becomes more widespread in the adult population it is important to consider the complications that may not be immediately apparent clinically.

KEYWORDS: Gradient Recall Echo, Microbleeds

A Case of Basilar Perforating Artery Aneurysm Rupture and Thrombosis: Challenges in Imaging and Treatment

J Hallstrom¹, N Farid¹
¹University of California, San Diego, San Diego, CA
Purpose
Rare basilar perforating artery aneurysms pose unique challenges in imaging and treatment. A case is presented, with review of the literature.

Materials and Methods
A 61-year-old male awoke with severe headache and neck pain, and was brought to the hospital by family. Head computed tomography (CT) revealed acute subarachnoid hemorrhage centered in the prepontine cistern, and hemorrhage within the third and fourth ventricles with mild noncommunicating hydrocephalus, suspicious for a ruptured aneurysm. Same day head CT angiography (CTA) and catheter cerebral angiogram showed no aneurysm. He became increasingly somnolent with diminished responsiveness, requiring intubation and external ventricular drain (EVD) placement. His condition improved and he was extubated the following day. His EVD was removed with placement of a lumbar-peritoneal shunt six days after presentation prior to discharge home. Follow-up head CTA 26 days after presentation revealed a 2mm aneurysm arising from the posterior distal basilar artery proximal to the basilar tip. Catheter cerebral angiogram performed three days later showed a faint arterial blush at this site, with inability to select any vessel or defect along the dorsal basilar artery wall using a SL10 catheter with 90-degree shape and Synchro-2 micro-guidewire. Forty-five days after initial presentation, the patient returned complaining of several days of occipital pressure, difficulty ambulating, and intermittent double vision and slurred speech. Exam revealed vertical nystagmus with truncal ataxia and a wide-based gait. Brain MR imaging (MRI) revealed an acute right superior pontine and right midbrain ischemic infarct, and thrombosis of the distal basilar perforating artery aneurysm, confirmed on same day brain MR angiography (MRA) and head CTA. His symptoms had nearly resolved two weeks later.

Results
Sagittal-view thick-slab image (left) from CT angiogram performed 26 days after presentation, and PA-view 3D-shaded surface rendered image (right) from catheter cerebral angiogram performed 29 days after presentation are shown. A 2mm aneurysm is seen arising from the posterior distal basilar artery proximal to the basilar tip. No early draining vein was identified to suggest a small AVM.

Conclusions
Basilar perforating artery aneurysms are rare, with five previously reported cases. All presented with acute subarachnoid hemorrhage. Four aneurysms were occult on initial CT and/or catheter angiograms, revealed on angiograms performed five days to two months after presentation. Two aneurysms had re-hemorrhaged at follow up. Four aneurysms arose from distal basilar perforators and one arose from a midbasilar perforator. Slow filling was reported in two cases, and partial thrombosis was present in three cases. Endovascular repair was attempted unsuccessfully in four cases. All cases underwent surgical repair with pterional and/or subtemporal craniotomy and aneurysm clipping, feeding artery coagulation and division, or aneurysm wrapping. Postoperative hemiparesis and dysphagia, CNIII palsy, or anisocoria occurred in three cases, with resolution over time. We have presented a sixth case, with similar presentation and imaging findings, unsuccessful attempt at endovascular treatment, and subsequent spontaneous thrombosis resulting in a small infarct. Imaging diagnosis and endovascular treatment are challenged by small size, slow-filling and thrombosis of these aneurysms. Follow-up imaging is essential to identify initially occult aneurysms. Endovascular access of the feeding artery may be precluded by an average outer diameter of 0.26mm and horizontal orientation of most basilar perforators, forming an average bifurcation angle of 93
degrees with the basilar artery. Open surgical repair has been successful, and sacrifice of the feeding perforator may be performed; however, care must be taken to avoid occlusion or injury to adjacent perforators providing collateral perfusion, and damage to cranial nerves.

KEYWORDS: Aneurysm, Basilar Artery, Perforators

A case of crossed cerebellar diaschisis in a middle aged patient.

J Cain¹, C Coutinho², S Mathur², H Sonwalker², S Wuppalapati²
¹University of Manchester, Manchester, UK, ²Lancashire Teaching Hospitals, Preston, UK

Purpose
To highlight the radiological appearances of crossed cerebellar diaschisis in a middle-aged patient with a history of previous cerebral infarction.

Materials and Methods
A 46-year-old woman who previously had suffered a left middle cerebral artery infarction underwent an acute computed tomography (CT) brain examination after a prolonged tonic-clonic seizure.

Results
The CT brain demonstrated atrophy of the left cerebral hemisphere and ex-vacuo dilation of the left lateral ventricle consistent with known previous cerebral infarction. In addition there was atrophy of the right (contralateral) cerebellar hemisphere. The imaging appearances and clinical history are in keeping with diagnosis of crossed cerebellar diaschisis.

Conclusions
Crossed cerebellar diaschisis is believed to be related to reduction of blood flow and metabolism affecting the cerebellar hemisphere contralateral to a supra-tentorial insult. Common insult may
be an infarction, hemorrhage, radiation necrosis or tumor. The cerebellar changes are thought to occur due to interruption of cortico-ponto-cerebellar connections causing reduced afferent connections and reduced metabolism within the contralateral cerebellar hemisphere.

KEYWORDS: Atrophy, Cerebellum, Infarct

A case of neurosarcoidosis with intracranial hemorrhage

H Mukai¹, H Yokota¹, T Horikoshi¹, K Motoori¹, T Uno¹
¹Chiba University Hospital, Chiba, Japan

Purpose
To describe the imaging findings of a case of neurosarcoidosis with multiple intracranial hemorrhages, which is an extremely rare complication of sarcoidosis.

Materials and Methods
A 27-year-old man with no past history presented with a year history of headache and three-month history of fever during the night. Stagger emerged from a week ago and dysarthria and restlessness developed from a day ago. Computed tomography (CT) showed multiple subcortical hemorrhages in the bilateral frontotemporal lobes. Echocardiography and angiography could not
reveal any causes of hemorrhage. Serum ACE was significantly high and CT showed diffuse miliary nodules of the lung and systemic lymph node swelling. Contrast-enhanced T1-weighted MR imaging (MRI) showed widespread nodular enhancement of pia-subarachnoid pattern. In brain biopsy noncaseating granuloma consistent with sarcoidosis was detected. Reports of sarcoidosis with intracranial hemorrhage were only 15 cases so far. Forty-six percent of cases do not have a prior diagnosis of sarcoidosis and 31% were central nervous system (CNS)-isolated disease.

Results
Computed tomography shows multiple subcortical hemorrhages with mild edema. MR imaging demonstrates diffuse leptomeningeal enhancement around the cerebrum and cerebellum. Hilar and mediastinal lymphadenopathies and miliary nodules with perilymphatic distribution are shown on chest CT. These findings are thought of as typical sarcoidosis except for multiple hemorrhages.

Conclusions
We described very rare case of neurosarcoidosis with multiple intracranial hemorrhage. Some cases of sarcoidosis with hemorrhage may have been overlooked. On cases with young-onset intracranial hemorrhage, it is necessary to consider the possibility of sarcoidosis.

KEYWORDS: Intracranial Hemorrhage, Neurosarcoidosis
Acute Amnesia due to Isolated Mamillary Body Infarct

K Amuluru¹, A Lignelli¹, C Filippi²
¹Columbia University, New York, NY, ²Columbia University Medical Center, New York, NY

Purpose
The mammillothalamic tract (MTT) is a part of the Papez circuit, and connects the mammillary body with the anterior thalamic nucleus. Recent evidence suggests that the circuit involving the mammillary bodies, the MTT and the anterior thalamus is particularly critical in the formation of new memories. There are limited case reports describing patients with acute onset amnesia after either unilateral or bilateral mammillothalamic tract infarction. To the best of our knowledge, an acute infarction isolated to the mammillary body in a patient without prior MTT injury has never been reported. We present the first case of anterograde amnesia after acute infarction isolated to the mammillary body.

Materials and Methods
A 50-year-old woman with history of hypertension, diabetes and hyperlipidemia was brought to the emergency room by her daughter for acute onset of confusion and abnormal behavior. On mental status testing, she was found to have severe anterograde amnesia with otherwise no focal neurologic deficits. An MR imaging (MRI) of the brain was performed which showed restricted diffusion abnormality involving the left mammillary body. The differential at that time included stroke, sequel of seizure, atypical Wernicke encephalopathy or an inflammatory process such as sarcoidosis. During the course of her hospitalization, a repeat brain MRI showed a growth in size of the restricted diffusion of her left mammillary body, as well as new foci of restricted diffusion in her left temporal lobe and left basal ganglia. Additional imaging examinations including MR spectroscopy (MRS) and MR angiogram, concluded the diagnosis of an initial acute mammillary body infarction due to in situ thrombosis of the P1 segment of the left posterior cerebral artery, at the origin of the perforating mammillary branch. On discharge 13 days later, the patient continued to demonstrate significant anterograde and retrograde amnesia.

Results
Axial diffusion-weighted sequence demonstrates focal restricted diffusion involving the left mammillary body. MR angiogram image demonstrates focal area of narrowing of the P1 segment of the left posterior cerebral artery, at the origin of the perforating mammillary branch.

Conclusions
The thalamus and the mammillary bodies are some of the most commonly implicated sites for memory dysfunction. Recent evidence suggests that the circuit involving the mammillary bodies, the mammillothalamic tract (MTT) and the anterior thalamus is particularly critical in the formation of new memories. To date, there have been only a few case reports that specifically document memory dysfunction following MTT infarction. We present the first case of anterograde amnesia after acute infarction isolated to the mammillary body in a patient without prior MTT injury. The mammillary body is a highly vascularized area of the hypothalamus, and is supplied mostly by perforating mammillary branches of the P1 segment of the posterior cerebral artery. In situ thrombotic or embolic events involving these perforating branches could cause infarction isolated to the mammillary body if perfusion to the MTT and thalamus is
maintained via anterior circulatory tuberotalamic arterial supply. Determining the contribution of an individual structure to memory is difficult because it is unusual to find circumscribed damage to only one anatomical region in an acute clinical setting. We present this unique case of severe amnesia due to isolated unilateral damage to the mammillary body in a patient with no history of prior MTT or thalamic damage in order to shed light on this fascinating anatomy and its contribution to the process of memory formation.

Acute Hemorrhagic Leukoencephalitis in a Postpartum Patient with H1N1 Influenza.

A Pal¹, M Post¹, E Sklar¹

¹Jackson Memorial Hospital/University of Miami, Miami, FL
Purpose
The purpose of this exhibit is to describe the imaging findings of a rare case of acute hemorrhagic leukoencephalitis in a patient with H1N1 influenza. The goal is to create awareness of the entity so that a prompt diagnosis can be made and mortality from the condition potentially can be avoided.

Materials and Methods
A 39-year-old postpartum female initially presented with productive cough to her primary care provider. The patient was exposed to H1N1 influenza in her home environment, and was prescribed Tamiflu (Oseltamivir). She unfortunately could not afford the prescribed medication, and subsequently was admitted to the ICU with a diagnosis of postpartum sepsis and ARDS. Tracheal secretions in the patient were confirmed to be positive for H1N1 influenza. Initial computed tomography (CT) of the brain was obtained secondary to the patient's poor responsiveness and was negative for acute intracranial pathology. Follow-up CT towards the end of her hospital course was performed secondary to sluggish pupillary reaction. While the CT demonstrated clear signs of global anoxia and transtentorial herniation, there were additional confluent areas of strikingly low attenuation and parenchymal hemorrhage in the periventricular and deep white matter. These findings have been described in patients with acute hemorrhagic leukoencephalitis associated with H1N1 influenza, and made this the likely diagnosis in our patient. The patient ultimately expired.

Results
Computed tomography of the brain demonstrates confluent, strikingly low attenuation and areas of parenchymal hemorrhage in the periventricular and deep white matter, which have been described in the setting of acute hemorrhagic leukoencephalitis associated with H1N1 influenza. Diffuse sulcal effacement with a "white cerebellar sign" are consistent with global anoxia. Evidence of transtentorial herniation also is noted.

Conclusions
Acute hemorrhagic leukoencephalitis is an autoimmune mediated demyelinating process, and is considered to be a rare fulminant form of acute disseminated encephalomyelitis. The entity typically follows a respiratory infection and neurological signs are nonspecific including headache, seizures, encephalopathy and coma. Imaging will demonstrate marked areas of white matter edema in addition to parenchymal hemorrhage. Pathology shows areas of vascular necrosis and perivascular hemorrhage along with neutrophilic infiltrates. Early diagnosis of this disease is critical as morbidity and mortality is high if not treated within a few days. For this reason MR imaging (MRI) with susceptibility-weighted imaging may be of particular benefit in conjunction with CT for early recognition. Treatment with combinations of corticosteroids, cyclophosphamide, and/or plasma exchange, in addition to oseltamivir for the treatment of H1N1, has been shown to improve survival.

Angiocentric Glioma: A rare cause of intractable seizures in a pediatric patient.

S Karnezis, B Yoo
1University of California Los Angeles, Los Angeles, CA, 2David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA

Purpose
We report a case of a pediatric patient with intractable seizures resulting from pathology proven angiocentric glioma, a distinct epilepsy associated WHO grade I tumor added to the WHO central nervous system tumor classification in 2007.

Materials and Methods
A previously healthy five-year-old girl first presented with difficulty enunciating words, later progressing to irregular tongue movements and twitching diagnosed as a tic at an outside hospital. She continued to have "eye rolling" and "rhythmic jaw movements" as well as multiple falling episodes eventually diagnosed as simple partial and complex partial seizures. The patient experienced approximately five to six episodes per day refractory to anti-epileptic medication. An MR imaging (MRI) performed several months after initial presentation revealed a mass centered in the right frontal lobe. Subsequent right frontal craniotomy with resection of the underlying mass resulted in resolution of seizure activity. Findings on pathology were consistent with angiocentric glioma.

Results
MR imaging demonstrated a T2 hyperintense, T1 iso- to hypo-intense, nonenhancing right frontal lobe cortically based expansile mass scalloping the inner table. Minimal surrounding edema was noted. Spectroscopy was nonspecific, showing relatively elevated choline peaks as well as a small lactate peak.

Conclusions
Angiocentric glioma is now recognized as a distinct neuroepithelial mass, relatively recently added to the WHO classification system in 2007. Greater than 95% of patients present with intractable epilepsy. While there are too few cases to reliably establish imaging characteristics, findings of a nonenhancing T2 hyperintense cortically based mass in a young patient are suggestive. Additional findings reported in the literature include extension towards the ventricles and occasionally a T1 hyperintense rim. Awareness of angiocentric glioma as a distinct clinical entity is important with respect to treatment and prognostic considerations. As it is established as a WHO grade I mass, angiocentric glioma is considered to have no malignant potential, and generally, resection results in resolution of seizure activity.

Carotidynia: A Diagnostic Challenge

M Khan¹, A Wang¹, R Jain¹, K Dalen¹
¹William Beaumont Hospital, Royal Oak, MI

Purpose
Carotidynia is an inflammatory syndrome presenting with acute onset of unilateral headache and neck pain with tenderness, swelling, and pulsations over the neck carotid artery. Clinicians may refer the patient for neuroimaging to rule out carotid artery dissection. The unfamiliar radiologist may report the carotid narrowing to be consistent with carotid artery dissection, thereby delaying the diagnosis and complications from treatment of a carotid artery dissection may occur. We report two patients who present with unilateral neck pain and headache who are suspected to have a carotid artery dissection clinically. Initial neck computed tomography (CT) with iv contrast showed focal narrowing of the affected neck carotid artery, suspicious for a carotid artery dissection but follow-up neck MR imaging (MRI) and MR angiography (MRA) showed characteristic imaging findings of carotidynia, leading to successful treatment.

Materials and Methods
Case 1 is a 33-year-old female presenting with progressive deep right neck pain which has become worse for the last 48 hours prior to presenting to the emergency room for evaluation. Case 2 is a 43-year-old female who presents with a three-day history of left neck pain. Both patients underwent CT scan and subsequent MRI where the diagnosis was confirmed. In each case, the patients demonstrated significant improvement in symptoms after administration of NSAIDs.
Results
Typically, imaging findings are localized to the distal common carotid or carotid bifurcation area. There is circumferential thickening of the carotid wall without luminal stenosis. MRI imaging is specific for making the diagnosis where enhancing soft tissue surrounding the carotid artery can be seen. MR angiography aids in the diagnosis by excluding luminal stenosis. MR imaging also serves to exclude other entities in the differential which includes giant cell arteritis, dissection, fibromuscular dysplasia, hematoma, and Takayasu arteritis.

Conclusions
Carotidynia is a self-limiting entity with classic symptoms and imaging findings. The radiologist should be alert to its existence to prevent misdiagnosis as a dissection and delay in treatment.

Central nervous system IgG4-related disease

E Fanou1, W Montanera2, L Noel de tilly2
1Sunnybrook Health Sciences, Toronto, Ontario, Canada, 2St Michael's Hospital, Toronto, Ontario, Canada

Purpose
To demonstrate some of the imaging findings of this novel entity and its proposed histopathological and imaging criteria and discuss the spectrum of differential diagnoses.

Materials and Methods
A 44-year-old female initially presented in 1998 with headaches and gradual left vision loss. Initial imaging work up of the same year showed enlarged pituitary gland and a suprasellar mass lesion. Pathology indicated lymphocytic hypophysitis. The patient had been on steroid therapy and monitored with annual imaging follow up. This year she presented with recurrent symptoms and slight progression on imaging. A repeat recent biopsy of the dura fulfilled some of the criteria for IgG4-related pachymeningitis. Serum IgG4 were elevated slightly.
Results
Series of sagittal T1-weighted pre and postcontrast and coronal T2-weighted images of the pituitary fossa over time, show thickening of the infundibular stalk and expansion of the pituitary gland. After steroid therapy there initially was regression with stable appearances over serial follow up. Most recent imaging shows minimal interval progression. There is involvement of the cavernous sinuses with gradual narrowing of the cavernous segments of the internal carotid arteries and development of a rim of very low T2-weighted signal changes enveloping the pituitary gland and the cavernous sinuses.

Conclusions
Central nervous system (CNS) IgG4-related disease is a novel entity and the spectrum of differential diagnoses (as in our case) is wide including: 1. Inflammation: Lymphocytic hypophysitis, 2. Granulomatous process: neurosarcoidosis, 3. Infectious causes, and 4. Neoplastic: lymphoma, leukemia, metastases, neurohypophysial specific glial tumors. Neuroradiologists should be aware of this rare novel entity which can present with imaging findings of hypophysitis, pachymeningitis or inflammatory pseudotumor.

KEYWORDS: IgG4 Related Disease, Pachymeningitis, Pituitary Gland

EE-20
6:30AM - 9:00PM

T Sabby¹, C Carr¹, T Kaufmann¹
¹Mayo Clinic, Rochester, MN

Purpose
To present a rare case of intracranial involvement in hemophagocytic lymphohistiocytosis (HLH) and to review the spectrum of brain MR imaging (MRI) findings in this uncommon condition.

Materials and Methods
A 56-year-old, previously healthy female developed weight loss, fatigue, fevers, and night sweats. She was evaluated by her local oncologist and no etiology was identified. She continued to decline clinically, developing profound weakness and encephalopathy. She underwent extensive outside work up without determination of an underlying cause. She then was referred to our institution for further evaluation. Laboratory studies revealed severe anemia and other cytopenias, monocytosis, and elevated ferritin and liver enzymes. Cytology from a prior paracentesis showed erythrophagocytosis, making HLH a diagnostic consideration. Pathology samples from prior liver and bone marrow biopsies were re-evaluated and hemophagocytosis was present in both tissues, leading to a diagnosis of HLH. Brain MRI demonstrated diffuse abnormalities, consistent with central nervous system involvement by a process such as HLH. The patient was started on aggressive treatment with chemotherapy and high dose steroids. She initially improved; unfortunately, she was readmitted four months later for increasing weakness and stroke symptoms. MR imaging demonstrated progression of brain abnormalities and the patient was treated for recurrent, progressive HLH. Early clinical improvement was again noted; however, she subsequently developed polymicrobial bacteremia and died six months after the initial diagnosis.
Results
The first brain MRI demonstrated diffuse leptomeningeal and mild pachymeningeal gadolinium enhancement. Follow-up MRI demonstrated innumerable new foci of T2 hyperintensity scattered within the white matter, several of which had restricted diffusion, compatible with hypercellular infiltration. The abnormal meningeal enhancement had nearly completely resolved. With worsening of the clinical status, a third MRI showed marked interval enlargement of the numerous T2 hyperintense areas within the bihemispheric white matter (Figure 1A, axial PROPELLER T2 FLAIR) and basal ganglia, many of which had associated restricted diffusion and gadolinium enhancement (Figure 1B, post-gad axial T1 CUBE). A few of these areas also demonstrated hypointensity on gradient echo sequences, suggestive of hemorrhage. These imaging features were compatible with inflammatory meningitis and diffuse cerebritis secondary to intracranial HLH and correlated with the patient's clinical course.

Conclusions
HLH is a hyperinflammatory syndrome with uncontrolled proliferation of activated, non-neoplastic lymphocytes and macrophages with overproduction of inflammatory cytokines. HLH is subdivided into primary and secondary subsets, related to genetic abnormalities or acquired viral infections or malignancies respectively. An underlying process is not always elucidated and mortality is high. In the absence of a gene mutation, the clinical diagnosis of HLH is based on the presence of five out of eight HLH criteria. Fever, splenomegaly, cytopenias, hypertriglyceridemia, hyperferritinemia, and hemophagocytosis in reticuloendothelial organs are often the diagnostic markers of HLH. While not unusual, the typical presentation of HLH is not neurologic; but, when seen, is a poor prognostic indicator. The imaging presentation of HLH can be nonspecific and overlaps with various infectious, inflammatory, demyelinating, and neoplastic etiologies; though the imaging correlates of perivascular inflammatory cell infiltration are expected. The brain MRI findings in our patient align with those previously reported in the literature, although only two adult cases have been described to our knowledge. Neuroimaging is useful for monitoring treatment response and the neuroradiologist should recognize the patterns of brain involvement.

Cerebral infarct caused by spontaneous thrombosis of a developmental venous anomaly

H Nakamura¹, F Akira², Y Hagiwara¹, H Yasuhiro¹, S Takuya¹, Y Nakajima¹, M Akamatsu¹
¹St. Marianna University of Medicine, Kawasaki, Kanagawa, Japan, ²Self Defense Forces Central Hospital, Tokyo, Japan

Purpose
To present the clinical course and magnetic resonance imaging (MRI) findings associated with a very rare case of ischemic complication of developmental venous anomaly (DVA).

Materials and Methods
A 23-year-old woman presented with homonymous lower quadrantanopsia. She complained that she saw a blinking object in left lower visual field. She had been in excellent health before the above-mentioned symptoms. Images show mass-like lesion in the medial side of the right
occipital lobe. At first, the differential diagnosis was broad. These include demyelinating lesion, brain tumor, infarct due to the vasculitis and so on. The laboratory studies including anticoagulant factor were all negative. Myelin basic protein, antibodies against collagen vascular diseases, immunoglobulin, tumor markers also were negative. In the clinical course, the degree of the symptom has been unchanged. No other symptoms were added. Physicians tried to perform steroid pulse therapy, but she showed no improvement. When we review the radiological findings, the diagnosis was considered as the infarct due to DVA. In one month, lesion was markedly decreased without treatment.

Results
Initial computed tomography (CT) shows low density area in the medial side of right occipital lobe. On the initial MRI, the lesion shows high signal on both diffusion-weighted imaging and apparent diffusion coefficient maps. Fluid-attenuated inversion recovery and T2-weighted imaging also show high signal area, which contains radial shaped linear low signal structure. The linear structure which proved to be DVA without drainage vein caused by thrombosis, referring to the susceptibility-weighted imaging and contrast enhanced study.

Conclusions
Developmental venous anomaly is the most frequently encountered vascular lesion noted on routine brain imaging. As DVAs are asymptomatic, treatment is not considered necessary and surgery is not an option because these provide venous drainage of normal brain. Hemorrhage is a well known complication of venous thrombosis and is thought to occur from the thrombosis of the draining vein of a DVA. Nonhemorrhagic infarct is very rare. The etiology of DVA-associated infarcts is thrombosis of drainage vein. The risk is considered as hypercoagulable state, using oral contraceptives and so on, but she had no risk factor. Because at first there is no drainage vein due to the thrombosis, at first we considered the lesion permeates the normal vein, but considering the shape of radical shape, DVA shoud have been considered. From now on, we should consider it when we see the radial-shaped linear structure suggesting vein within the lesion.

DRESS Syndrome with Cerebral Vasculitis. About Two Cases of a Very Rare Entity.

M Gaha¹, C Bard¹

¹Centre Hospitalier de l'Université de Montréal, Montréal, Québec, Canada
Purpose
DRESS (drug rash with eosinophilia and systemic symptoms) syndrome is a severe reaction triggered by drugs that manifests as pyrexia and eosinophilia with involvement of the skin and internal organs. We aim to show that DRESS syndrome may be associated with the presence of cerebral vasculitic involvement, which is a concept not very well known in the literature.

Materials and Methods
We describe two cases of DRESS syndrome with cerebral vasculitic involvement.

Results
The first patient is about a 46-year-old caucasian woman who was treated initially for an anaerobic cerebral abscess using 'Ceftriaxone/Flagyl' therapy. Evolution was characterized by improvement of infectious biological markers with occurrence of fever, severe headache and weakness of inferior extremities. At the same time, hot and widespread erythroderma appeared. Increased eosinophil count was found. Severe cholestatic hepatitis also was present. MR imaging (MRI) demonstrated perivascular supra and infratentorial diffuse contrast enhancement. Clinical, biological and imaging evolution was favorable after changing antibiotics and administrating high-dose steroid therapy. The second patient is about a 47-year-old caucasian woman who was treated by 'Minocycline' for an infectious diarrhea. In this case, MRI showed the same pattern of perivascular diffuse contrast enhancement. Furthermore, it demonstrated one hemorrhagic focus on the right semi-oval center and ischemic lesions involving not only borderline vascular territories but also middle and anterior cerebral arteries circulation. Evolution was favorable after high-dose steroid therapy.

Conclusions
The diagnosis of cerebral vasculitis must be considered in patients with DRESS syndrome since it can be reversed completely with high-dose steroid timely treatment.

Ectopic Intracranial Germinoma: A case report and review of literature.

S Shankar\textsuperscript{1}, A Malhotra\textsuperscript{2}, V Kalra\textsuperscript{2}
\textsuperscript{1}Yale New Haven Hospital, New Haven, CT, \textsuperscript{2}Yale University School of Medicine, New Haven, CT

Purpose
We are presenting a case of ectopic intracranial germinoma arising in the corpus callosum and will discuss the imaging features, clinical profile and reported atypical locations.

Materials and Methods
This is a case report of a 24-year-old male who developed progressive insatiable thirst, urinary frequency, impotence, muscle aches and fatigue for one year. Endocrinologic work up revealed panhypopituitarism. MR imaging (MRI) demonstrated three intracranial lesions in the pituitary infundibulum, pineal region and left corpus callosum. The initial differential diagnosis included sarcoidosis, chronic basal meningitis, and possibly germ cell tumor. Stereotactic biopsy was performed of the left corpus callosal lesion and histological examination concluded this mass to be a gerinoma.
Results
Contrast-enhanced MR imaging of the brain demonstrated three enhancing intracranial lesions. There was marked thickening and enhancement of the pituitary infundibulum. A round enhancing solid mass was present in the pineal region. Additionally, there was a cystic and solid lesion in the left corpus callosum with the solid portion showing enhancement. The patient received chemotherapy followed by radiation treatment. Follow-up imaging at three months showed complete resolution of the abnormal enhancement at all three sites with no abnormal enhancement at six month follow up.

Conclusions
Intracranial germinomas preferentially arise in the pineal and neurohypophyseal regions. Less common locations include the basal ganglia and thalami. Germinomas have rarely been reported in the corpus callosum, corona radiata, frontal lobe and temporal lobe. Intra-axial germinoma should be considered in the differential of a young male patient with the characteristic cystic and solid intra-axial mass, especially with concurrent pineal and pituitary infundibular lesions.

KEYWORDS: Germinoma

Enhancing Brain Stones in an HIV Patient: An Unusual Presentation of Toxoplasmic Encephalitis Immune Reconstitution Inflammatory Syndrome (TE-IRIS)

N Koontz¹, L Longenecker², H Dhatt², E Quigley²
¹University of Utah School of Medicine, Salt Lake City, UT, ²University of Utah, Salt Lake City, UT

Purpose
Brain stones or cerebral calculi are uncommon intracranial calculi of sundry etiologies. We present a case of rim-enhancing cerebral calculi in an immunocompromised patient, focusing on the differential diagnosis and important imaging features.

Materials and Methods
A 30-year-old HIV positive female Eritrean refugee with history of traumatic brain injury and seizures presented with three-day history of fever, difficulty walking, and neck stiffness. She started highly active antiretroviral therapy (HAART) three weeks prior, at which point her viral load was 450,000 and CD4 count was 369. Computed tomography (CT) demonstrated multiple calcified parenchymal lesions within the cortical gray matter, subcortical white matter, and left basal ganglia, two of which (parafalcine left parietal lobe and left basal ganglia) demonstrated peripheral enhancement. Marked hypoattenuation of the surrounding white matter was seen. On MRI, lesions were T1 isointense and T2 hypointense, with peripheral enhancement and susceptibility artifact on susceptibility-weighted imaging (SWI). The parafalcine left parietal lobe lesion demonstrated central reduced diffusivity, compatible with an abscess. Confluent T2/FLAIR hyperintensity within the surrounding white matter was compatible with vasogenic edema. Thallium-201 SPECT was negative for radionuclide accumulation within the lesions. In light of the clinical history, the diagnosis of TB-IRIS or TE-IRIS was favored. Lumbar puncture revealed 32 WBC, 71% lymphocytes, normal glucose, and elevated protein. She was started on empiric treatment for possible central nervous system (CNS) toxoplasmosis and subsequently demonstrated positive serum toxoplasma IgG. Symptomatic and imaging improvement were demonstrated with anti-toxoplasma therapy.

Results
Brain stones characteristically demonstrate calcific density on NECT. On MRI, they show markedly low signal intensity on T2-weighted imaging, GRE, and susceptibility-weighted imaging (SWI) without true “blooming” artifact. On T1-weighted imaging, lesions may be iso- or hypointense. Contrast enhancement is variable, depending on the underlying etiology. A compartmental model of intra-axial and extra-axial localization is useful for establishing an appropriate differential diagnosis. Extra-axial brain stones are most commonly neoplastic and may reflect dural osteomas, craniopharyngiomas, meningiomas, rare calcified/ossified tumors/metastases, calcifying pseudoneoplasms of the neuroaxis, or exuberant physiologic calcification. Intra-axial brain stones may reflect neoplastic, infectious, vascular, traumatic, metabolic, or congenital etiologies, which we detail in this presentation. Clinical history, as in this case, is a powerful discriminator for directing an appropriate differential diagnosis.
Conclusions
Cerebral calculi are an uncommon finding with numerous etiologies. Localization of the lesions as intra-axial or extra-axial is useful for establishing an appropriate differential diagnosis. An enhancing brain stone in an HIV+ patient recently started on HAART should raise concern for TE-IRIS or TB-IRIS.

KEYWORDS: Calcifications, Immune Reconstitution Inflammatory, Toxoplasmosis
Materials and Methods
A 23-year-old male patient presented to the ER with a history of heroin abuse, anxiety and attention deficit hyperactive disorder (ADHD). He last was reported to have used heroin six months ago with marijuana use two weeks ago. He was prescribed risperidone and methylphenidate by his therapist for treatment of ADHD. Approximately four days after initiation of treatment, the patient complained of headaches and nausea. He went to bed early that evening, and was found unresponsive the next morning and was brought to the ER. Complete work up was performed for the patient, including an MR imaging (MRI) of the brain. Characteristic imaging features were noted on the MRI, suspicious for heroin-inhaled toxicity. After four days of appropriate treatment initiation however, the patient was found to have developed myoclonic jerks.

Results
MR imaging of the brain revealed extensive areas of white matter signal abnormality representing diffuse encephalopathy. There was restricted diffusion in the supratentorial white matter with a posterior predominance with involvement of the right globus pallidus, splenium and bilateral cerebellar hemispheres. Symmetric T2/FLAIR hyperintensities were noted in the supratentorial white matter predominantly involving the parietal and occipital lobes, bilateral globus pallidi and splenium. Additionally T2/FLAIR hyperintensities were present in the posterior limbs of bilateral internal capsules and cerebellar hemispheres. These findings are characteristic for heroin-inhaled toxicity, also known as chasing the dragon.

Conclusions
An association between leukoencephalopathy and smoking heroin has been recognized for over 25 years, although the exact pathogenesis still is not well understood. In 'chasing the dragon', heroin is placed on a piece of aluminum foil, heated with a flame from below, and the resulting vapor (pyrolysate) is inhaled with a straw or other tube-like structure(1). The stages involved in heroin-inhaled toxicity are: 1.Cerebellar symptoms, 2.Extrapyramidal symptoms, 3.Spasms, mutism and death. These clinically recognized stages are associated with the extent of white matter involvement on MRI(2). There is symmetric spongiform degeneration of the cerebral and cerebellar white matter and corticospinal tracts. Classically on MRI, heroin-inhaled toxicity involves the posterior limbs of bilateral internal capsules and cerebellar white matter. There is symmetric involvement of the supratentorial white matter, with posterior predominance and relative sparing of the cortex and subcortical white matter. The globus pallidi may be involved. Restricted diffusion is noted in the acute phase of the disease. Diffusion-weighted images may reveal hyperintense signal without corresponding ADC drop in the subacute stages.Hypoxic ischemic encephalopathy may have similar imaging features. However there may be associated mild cortical signal, a finding not present in the patients with toxic leukoencephalopathy and periventricular white matter reduced diffusion(3). Involvement of the cerebellum and the posterior limb of the internal capsule, with sparing of the anterior limb helps distinguish it from reversible posterior leukoencephalopathy (4,5). The MRI findings are considered pathognomonic, making MRI important for diagnosis. This is especially true in busy urban emergency departments where a variety of patients may present obtunded, unable or unwilling to provide a useful history(2). In the case of chasing toxicity, prompt initiation of coenzyme Q treatments may limit the extent of disease(6).

Fat Embolism to the Brain after Traumatic Injury, a case report.

A Meshksar, R Khan, W Kubal, K Nael

University of Arizona, Tucson, AZ

Purpose

Fat embolism is an uncommon, yet important clinical entity with unique imaging findings. We describe the clinical and imaging findings of a patient with cerebral fat embolism after trauma.

Materials and Methods

The patient is a 17-year-old previously healthy male who was transferred to the emergency department after motorcycle collision. He suffered multiple long bone fractures including bilateral femoral shaft, right distal humeral and bilateral medial malleolar fractures. Upon his arrival, he had a GCS of 15 and stable vital signs. Noncontrast computed tomography (CT) scan of the head at the time of arrival did not show any abnormal findings. Approximately two hours later, while attempting to put him on traction for his femoral shaft fractures, his GCS suddenly dropped to 12. He got unresponsive to verbal stimuli and developed multiple apneic hypoxic episodes for which he was intubated. The patient then was transferred to ICU and remained intubated for seven days. Brain MR imaging (MRI) performed one day after ICU admission revealed bilateral multiple foci of restricted diffusion involving the centrum semiovale, corona radiata, and basal ganglia. Innumerable foci of susceptibility were identified in both supra and infratentorial components on susceptibility-weighted images. After relatively uncomplicated ICU course, he was returned to normal neurologic baseline with a GCS of 15 and subsequently followed by neurology team on an outpatient basis.

Results

Diffusion-weighted image (left) shows multiple foci of restricted diffusion along corona radiata and periventricular white matter. Susceptibility-weighted image (right) reveals numerous punctate foci of blooming artifact due to fat microemboli.

Conclusions

The differential considerations according to history of trauma and brain MRI findings include diffuse axonal injury or fat embolism. However given our patient's normal GCS on arrival and sudden decrease in GCS after attempting to put him on traction and return of the GCS to the baseline after a period of time, fat emboli was the final diagnosis. This case signifies the importance of understanding and interpretation of susceptibility imaging in the trauma setting. Fat droplets like blood products can be dark on susceptibility-weighted imaging and therefore fat embolism should be considered in the proper clinical setting when this finding is present.

FDG-PET Findings in Symptomatic Developmental Venous Anomaly: A Potential Pitfall for Malignancy?

D Kimbrough¹, B Mahoney¹, H Morales², K Brantley³, J Gollamudi³, T Tomsick²
¹University of Cincinnati, Cincinnati, OH, ²University Hospital/University of Cincinnati College of Medicine, Cincinnati, OH, ³University Hospital/University of Cincinnati, Cincinnati, OH

Purpose
To the best of our knowledge FDG-PET imaging findings associated with DVAs have not been reported previously. We report two cases of positron emission tomography (PET) demonstrating increased fluoro-deoxy-glucose (FDG) uptake associated with symptomatic developmental venous anomaly (DVA) on magnetic resonance imaging (MRI).
Materials and Methods
Two separate patients with histories of remote extracranial malignancy developed acute neurologic symptoms and signs suggestive of stroke. Brain MRI and PET imaging of the brain was obtained in close temporal relation. One MRI included a perfusion study. PET imaging was performed to investigate potential metastatic disease.

Results
Both MRI studies demonstrated areas of increased signal on FLAIR and DWI adjacent to a DVA. On subsequent PET, areas of increased scintigraphic activity were identified corresponding to the areas of MR signal abnormality. In case one, perfusion MRI showed increased relative cerebral blood volume (CBV) in the areas of abnormal signal. However, follow-up MR imaging demonstrated distinct volume loss and resolving FLAIR signal abnormality. It was interpreted as resolving ischemic changes rather than tumor. In case two, the DVA drained an area of arterial infarction.

Conclusions
Developmental venous anomalies are the most common intracranial vascular anomaly and are generally benign. Occasionally, symptomatic DVAs with either hemorrhagic or nonhemorrhagic infarction can be seen. A number of mechanisms for clinically symptomatic DVAs have been proposed including diminished venous outflow across the brain parenchyma drained by the DVA, draining vein stenosis, or venous tributary tortuosity. In a number of reported cases, DVAs have been associated with increased regional cerebral blood volume on MR perfusion imaging. However, to the best of our knowledge FDG-PET findings are lacking in the literature. Our findings of apparent hypermetabolism on PET imaging appear paradoxical. In acute ischemia, regions of hypometabolism are expected. However, paradoxical hypermetabolism has been reported in hypoxic-ischemic injury in young children, attributed to glutamatergic excitotoxic injury. Paradoxical hypermetabolism also have been reported in areas of cortical malformations or heterotopia. It is possible that regions of ischemic changes in association with DVAs, as seen in our cases, can have a blood pool effect with concentration of the radiotracer or the regions demonstrate a true paradoxical hypermetabolism (areas of congenitally abnormal brain tissue). This potential association of DVAs and apparent focal brain hypermetabolism represents a previously unrecognized, but potentially important imaging pitfall in the work up of patients with probable malignant disease; warranting further investigation.

Florbetapir PET Imaging in Cerebral Amyloid Angiopathy

A Betts¹, J Nepute¹, J Scheler¹, J Broderick¹
¹University Hospital/University of Cincinnati College of Medicine, Cincinnati, OH

Purpose
We describe the imaging findings of a patient with a new diagnosis of cerebral amyloid angiopathy, to include F-18 florbetapir PET imaging (Amyvid). We review the pathologic and clinical presentation of cerebral amyloid angiopathy.

Materials and Methods
A 61-year-old presented after a "spell" of vague neurologic symptoms. During this spell he had nearly hit his mailbox making a left turn into his driveway, and subsequently had a minor automobile accident in which he hit a brick pillar in his garage at low speed. Afterwards, he describes several hours of mild confusion. Neurologic examination and electroencephalogram were normal. Lumbar puncture was performed, which showed two nucleated cells and no red blood cells per microliter. CSF protein was 39 mg/dL, and CSF glucose was 48 mg/dL. IgG levels were normal without oligoclonal bands.
Results

(A) Axial gradient recalled echo (GRE) image of the brain shows multiple punctate foci of cortical susceptibility artifact in the right parietal lobe. Hyperintense white matter signal abnormality also is seen in the right parietal lobe, which corresponded to hyperintense signal on T2 and FLAIR sequences (not shown). (B) Axial F-18 Florbetapir (Amyvid) PET image through the brain shows diffuse cortical radiotrace uptake in the frontal and parietal lobes with loss of the normal gray-white matter contrast. Cerebellar reference showed normal uptake with preservation of the gray-white contrast (not shown).

Conclusions

Cerebral amyloid angiopathy (CAA) is characterized by beta-amyloid deposition within the walls of cortical and leptomeningeal cerebral vessels. This beta-amyloid is structurally similar to the amyloid within neuritic plaques of Alzheimer dementia. A less common variant of this condition is cerebral amyloid angiopathy-related inflammation (CAA-RI). These patients typically present with cognitive decline, seizures, and headaches. Unlike patients with noninflammatory CAA, patients with the CAA-RI usually have a significantly improved clinical response to immunosuppressive therapy. The typical MR imaging findings of CAA are cortical and subcortical microhemorrhages and hemosiderin deposition detected by T2* hypointense foci on gradient recalled echo (GRE) or susceptibility-weighted imaging (SWI) sequences. These commonly develop within clusters, and usually predominate in posterior regions of the cerebrum. CAA-RI additionally shows white matter edema signal changes, which also shows a posterior predilection, and may show partial or complete response to immunosuppression. Nuclear medicine PET imaging agents also may be used to demonstrate cerebral beta-amyloid. Florbetapir (Amyvid) is a Fluorine-18-based agent that recently was approved by the U.S. Food and Drug Administration for evaluation of beta-amyloid neuritic plaque density in patients with cognitive decline. Carbon-11 Pittsburg Compound B (C-11-PiB) has been used previously to demonstrate beta-amyloid deposition for both Alzheimer dementia and CAA. F-18 Florbetapir has been shown to be highly correlated with C-11 PiB imaging in patients with Alzheimer dementia. Although it does not have FDA approval in cerebral amyloid angiopathy, Florbetapir and future F-18-based amyloid agents may be helpful in confirming the diagnosis of amyloid angiopathy as well as characterizing the extent of amyloid deposition.

KEYWORDS: Cerebral Amyloid Angiopathy, PET
Hemorrhage occurring within an arachnoid cyst is a rare phenomenon that may be associated with the onset of new symptoms. However, the long term evolution of intracyst hemorrhage has not been well described. Furthermore, the hemorrhage may lead to alterations in the morphology of the cyst. We describe a case of hemorrhage within an arachnoid cyst in patient with epilepsy and the resulting structural evolution of the cyst over time.
Materials and Methods
We report the case of a 35-year-old man with a history of left temporal lobe epilepsy and a left middle cranial fossa arachnoid cyst, measuring 4.0 x 5.0 x 5.0 cm (Figure 1A), who acutely developed headaches after participation in contact sports. His initial neurological examination was unremarkable.

Results
A brain MR imaging (MRI) performed six weeks after the onset of symptoms revealed new intrinsic T1 shortening, consistent with the presence of proteinaceous material, such as hemorrhage, in the arachnoid cyst and a new 1.9cm subdural hematoma along the left cerebral hemisphere. There were differences between the T2 FLAIR signal characteristics of the cyst and the subdural collection, possibly reflecting that the hemorrhages were of different ages (Figure 1B). Furthermore, multiple new septations were observed within the arachnoid cyst. An MRI performed five months later revealed similar findings with continued asynchronous evolution of the blood products within the cyst and the subdural collection. Furthermore, the cyst had decreased in size compared to the baseline scan and now measured 3.5 x 3.9 x 4.4 cm. The size of the subdural collection had also decreased to 1.4 cm.

Conclusions
In our patient, the arachnoid cyst decreased in size following the hemorrhage. Prior reports of posthemorrhagic resolution of arachnoid cysts have been explained by formation of a communication between the cyst and extra-axial spaces leading to drainage of the cyst contents into surrounding spaces. However, in our case, there was no evidence of such a communication. Furthermore, if there were rupture of the cyst into the surrounding extra-axial spaces, one would expect a rapid decrease in the size of the cyst. Rather, serial imaging revealed gradual contraction of the arachnoid cyst, which was not noted until several months after the initial hemorrhage. One also would expect the signal characteristics of the fluid to be identical within the cyst and the adjacent extra-axial fluid collection. In our case, these diverged with time. Another possible explanation is the development of intracyst adhesions as a consequence of evolution and organization of the hematoma. As the hematoma itself contracted, the cyst walls tethered to it were pulled inward as well. This hypothesis is supported by the fact that septations were noted within the shrinking cyst. In this report, the subdural component displayed higher T2 FLAIR signal than the cyst. This may be explained by the possibility that the hemorrhages were asynchronous events. Alternatively, the differences in evolution of the hemorrhages may depend on differences in the chemical compositions of intracyst fluid and the subdural collection. Ultimately, the evolution of hemorrhage within arachnoid cysts likely depends on a multitude of factors, including both the mechanism of hemorrhage and the composition of the cyst. Further investigation of the structure and physiology of arachnoid cysts may elucidate the etiology of intracyst hemorrhages and their sequelae. This knowledge may allow for anticipation of complications associated with intracyst hemorrhages and provide an avenue for potential prophylactic intervention.

Hemorrhagic Venous Infarction in a Patient with an Enlarged Developmental Venous Anomaly and New Apparent Stenosis of the Distal Outflow Vein.

J Lantos¹, R Zimmerman², A Tsiouris¹
¹New York-Presbyterian Hospital/Weill Cornell Medical Center, New York, NY, ²New York Presbyterian Hospital, New York, NY

Purpose
Stenosis of the outflow vein of a developmental venous anomaly (DVA) has been proposed as a mechanism whereby isolated DVAs cause hemorrhagic venous infarction. We describe the imaging of a patient who presented with an acute hemorrhagic venous infarction in the setting of apparent new outflow stenosis of a known DVA. We then discuss other relevant current concepts of DVAs. Additionally, our patient had multiple sclerosis (MS), and initial clinical presentation and imaging mimicked MS flare; we discuss imaging features that help distinguish the two entities.

Materials and Methods
A 34-year-old female with rapidly progressive MS and a known DVA was admitted after experiencing right arm paralysis and right leg weakness for one day, unable to ambulate.
Intravenous steroids and plasmapheresis were initiated for a presumed MS flare. Subsequent MR imaging (MRI) revealed a venous infarction and new apparent stenosis of the outflow vein of the DVA. The patient was treated with heparin and transitioned to warfarin and improved over several days. She regained near full-strength of her right lower extremity and was able to ambulate with assistance. She was transferred to an acute rehabilitation facility in stable condition.

Results
MR imaging three months prior to admission demonstrated an uncomplicated left frontoparietal DVA draining into the left lateral thalamostriate vein. The DVA was uniform in caliber throughout its course. MR imaging after admission showed new heterogeneous T2 hyperintense signal along the course of the DVA with surrounding vasogenic edema. On sagittal FLAIR images, ovoid high signal was oriented perpendicular to the lateral ventricle. There was no peripheral leading edge of enhancement. The DVA (Figure 1A arrow) was increased in size proximally compared to the prior study. New multifocal ill-defined, serpentine parenchymal enhancement along the course of the DVA (Figure 1A arrowheads) was compatible with venous congestion. Same day follow-up MRI was performed to include susceptibility-weighted imaging (SWI) and MRV. Low signal on SWI was consistent with petechial hemorrhage. MRV images demonstrated a new apparent distal stenosis of the draining vein (Figure 1B arrow). Together, findings were interpreted as hemorrhagic venous infarction possibly caused by a new stenosis of the draining vein of the DVA.

Conclusions
Our case supports the concept that outflow vein stenosis is a mechanism whereby DVAs cause hemorrhagic venous infarction. We illustrate a DVA with a new apparent stenosis of the outflow vein with associated venous infarction, with no stenosis or venous infarction on imaging three months prior. Absence of a leading edge of enhancement and presence of petechial hemorrhage supported venous infarction rather than tumefactive MS. The patient improved after thrombolytic therapy.

High-Grade Dural Arteriovenous Fistula Causing Subarachnoid Hemorrhage with Direct Visualization of the Rupture Site on CT Angiography.

V Daruwalla¹, B Patel¹, A Honarmand², A Shaibani², S Ansari³, M Hurley¹
¹Northwestern Feinberg School of Medicine, Chicago, IL, ²Northwestern University, Chicago, IL, ³Northwestern Memorial Hospital, Chicago, IL

Purpose
We describe the CT angiographic (CTA) detection of a subarachnoid venous rupture site downstream to a high grade dural arteriovenous fistula (dAVF). CT angiography has replaced conventional digital subtraction angiography (DSA) as the first line angiographic work up of acute subarachnoid hemorrhage in most centers but lacks hemodynamic information compared to MR angiography (MRA) and DSA. This case also illustrates the risk of developing multiple separate dAVFs subsequent to a dural sinus thrombosis.

Materials and Methods
Case Presentation: A 52-year-old right-handed female presented with sudden onset thunderclap
headache, mild drowsiness. Her past medical history was significant for superior sagittal sinus and left transverse sinus venous thrombosis diagnosed in 2008 with repeat sinus venous thrombosis after discontinuing warfarin. Routine coagulopathy screening was negative and she was placed on lifelong warfarin for a presumed coagulopathy. At this presentation, her International Normalized Ratio (INR) was 3.6, which was rapidly reversed. Noncontrast CT brain demonstrated left sylvian subarachnoid hemorrhage and adjacent small discrete left temporal parenchymal hemorrhage. Subsequent CTA showed “arterialized” opacification of an ectatic left superficial middle cerebral vein harboring a prominent saccular outpouching, with a narrow neck favoring pseudoaneurysm over varix. Conventional angiography confirmed a Cognard 2b dAVF centered on the wall of a previously thrombosed and isolated left transverse sinus (TS) segment and draining via the left vein of Labbé and the sylvian vein with a patent pseudo aneurysm. The main arterial supply was from the left middle meningeal artery (MMA) but with contributions also from the left occipital artery, contra lateral MMA and occipital arteries as well as posterior and falx cerebelli meningeal supply arising from the left vertebral artery. A Marathon Micro Catheter (EV3 Irvine, CA) was advanced via the left MMA close to the fistulous network on the dural surface and a total of 4 ml of Onyx-34 (EV3, Irvine CA) was injected with complete penetration of the fistulous network and filling of the isolated fistulized segment of the left TS. A follow-up angiogram two months later showed no recurrent fistula. She subsequently underwent elective embolization and obliteration of the unruptured right orbitofrontal fistula. She will continue surveillance with time-resolved MR angiography (MRA) and time-of-flight (TOF) MRA.

Results

Figure 1: Presenting noncontrast CT head (A) shows subarachnoid hemorrhage in the left sylvian fissure with a more discrete clot over the temporal lobe (arrow) and an axial CTA slice (B) demonstrates a corresponding saccular out pouching (arrow) arising from the left sylvian vein, with size and configuration more consistent with venous pseudo aneurysm than varix.

Conclusions

CT angiography is widely available and provides a rapid, noninvasive assessment in acute intracranial hemorrhage. In the setting of a ruptured dAVF, a discrete pseudo aneurysm should indicate the site of rupture and for a target for treatment. As we demonstrated, the principle goal of treatment is to relieve the ruptured vein of the arterial pressure resulting from the fistula and does not require embolic occlusion of the rupture site itself. Venous pseudonaeurysms should not be confused with the so-called "spot sign", a small (1-2 mm) focus of enhancement on CTA within parenchymal hematomas and extra-axial lesions such as subdural hematomas, which essentially represents a discrete microvascular extravasation without containment as in a pseudoaneurysm. In the setting of DAVF and SAH, careful analysis of the emergent CTA may reveal the exact rupture site as represented by a pseudoaneurysm arising from an arterialized vein. The treatment goal should be to disconnect the arterialization of the ruptured vein, with penetration to the venous side to reduce recurrences, but does not require casting of the rupture site itself.

KEYWORDS: Arteriovenous Fistulas, CT Angiogram
Imaging findings in a patient with PML-IRIS after the discontinuation of Tysabri for the treatment of multiple sclerosis.

A Pal¹, M Post¹, E Sklar¹, R Bhatia¹
¹Jackson Memorial Hospital/University of Miami, Miami, FL

Purpose
Progressive multifocal leukoencephalopathy (PML) is a known complication of patients on Tysabri (natalizumab) for the treatment of relapsing and remitting multiple sclerosis. Withdrawal of this drug subsequently can result in immune reconstitution inflammatory syndrome (IRIS), similar to that seen in HIV patients who recently have started HAART therapy. The purpose of this exhibit is to create awareness of the entity so that a prompt diagnosis can be made and the appropriate treatment be started.

Materials and Methods
A 61-year-old female with a long history of relapsing and remitting multiple sclerosis on treatment with Tysabri (natalizumab). The patient presented with worsening fluctuating symptoms of right hand weakness and loss of coordination with a contrast-enhanced MR imaging (MRI) of the brain at that time demonstrating relative stability in the patient's size and
number of demyelinating plaques, as compared to the prior examination. There was no MR evidence of progressive multifocal leukoencephalopathy (PML) on the initial exam. A lumbar puncture performed at the time of presentation was positive for JC-virus. A diagnosis of PML subsequently was made and the Tysabri was discontinued. The patient presented again six weeks later with worsening neurologic symptoms. Contrast-enhanced MRI of the brain at that time demonstrated new areas of nodular and curvilinear enhancement, as well as worsening FLAIR signal hyperintensity in the white matter. The imaging findings in conjunction with the patient's clinical symptoms were most suggestive of progressive multifocal leukoencephalopathy-immune reconstitution inflammatory syndrome. Corticosteroid therapy subsequently was started and the patient's symptoms have since markedly improved.

Results

MR imaging findings in the first set of images (Figure A) demonstrate patchy areas of flair signal hyperintensity in the white matter compatible with the patient's history of multiple sclerosis. No associated enhancement was seen. MR imaging performed six weeks later (Figure B) after the discontinuation of Tysabri demonstrated new nodular and curvilinear areas of enhancement with worsening FLAIR signal hyperintensity in the white matter, as well as subtle mass effect, compatible with IRIS. Cerebrospinal fluid (CSF) analysis was positive for JC virus at the time imaging was performed.

Conclusions

Tysabri is a monoclonal antibody that prevents binding of leukocytes to the endothelium of brain vasculature and their subsequent migration and attack on the central nervous system. Progressive multifocal leukoencephalopathy secondary to JC virus is a known complication of patient's on Tyasbri (natalizumab) from immunosupression. After discontinuation of therapy, there is improved cellular immunity with a resultant response to a pre-existing infection, which if flagrant, will cause an immune reconstitution inflammatory syndrome (IRIS). This entity should not be confused with relapse or worsening of the already existing infection. On imaging, new nodular and curvilinear areas of enhancement and worsening FLAIR signal hyperintensity in the white matter, as well as subtle mass effect, are highly suggestive of IRIS in a patient with recent discontinuation of Tysabri. These patients often will present with paradoxical worsening of neurological symptoms, and prompt treatment with corticosteroids may aid in clinical recovery.

Intracranial Extraskeletal Chondrosarcoma Mimicking A Meningioma.

A Bhatt\textsuperscript{1}, N Campeau\textsuperscript{1}, D Black\textsuperscript{1}
\textit{\textsuperscript{1}Mayo Clinic, Rochester, MN}

Purpose
To describe the clinical presentation and imaging findings of an unusual primary intracranial extraskeletal chondrosarcoma, which mimicked a meningioma on pre-operative MR imaging (MRI).

Materials and Methods
The patient is a 41-year-old female who presented to the emergency room with an acute TIA-like spell, including scintillating scotomas, numbness involving the bilateral fingertips, and word-finding difficulties. The episode spontaneously resolved. An MRI was performed for further evaluation, and revealed an extra-axial dural-based mass along the tentorium, with the working diagnosis of meningioma. Surgery confirmed origin of the mass along the superior aspect of the left tentorium cerebelli. The intra-operative appearance of the tumor was noted to be unusual and gross total excision was obtained; intra-operative histology confirmed a tumor of cartilaginous origin. A metastatic work up of the rest of the body demonstrated no abnormality. Final pathologic diagnosis was a low grade primary intracranial extraskeletal chondrosarcoma.

Results
MR imaging of the head demonstrated a low T1 and heterogenous T2 signal extra-axial, enhancing lesion along the left tentorium, with no edema in the adjacent parenchyma. No foci of low signal were seen on susceptibility-weighted images to suggest calcification, and there were no areas of restricted diffusion.

Conclusions
Primary intracranial chondrosarcoma is a rare neoplasm. Chondrosarcomas can arise from bone, cartilage, or mesenchymal soft tissue. Due to its close association with the dura and similar MRI characteristics, the imaging findings can lead to the misdiagnosis of meningioma. Correct diagnosis is important because of treatment/management differences; chondrosarcoma is relatively insensitive to radiation treatment, has a propensity for dissemination at the time of surgery, and has a greater rate of local recurrence.

Intracranial Hemorrhage Following Spinal Surgery-Related CSF Leak, an Important Mimiker of PRES.

N Satovick¹, L Shah², R Wiggins²
¹University of Utah Hospitals and Clinics, Salt Lake City, UT, ²University of Utah, Salt Lake City, UT

Purpose
We present two cases of intracranial hemorrhage (ICH) following spinal surgery in which large dural cerebrospinal fluid (CSF) leaks were present, an uncommon but known complication. These cases show intriguing intracranial imaging findings as a result of extreme, acute intracranial hypotension (IH) in which signal abnormalities mimic posterior reversible encephalopathy syndrome (PRES) and may help support a venous pathophysiologic cause of vasogenic edema and remote cerebellar hemorrhage (RCH).
Materials and Methods
Case 1. A 64-year-old woman underwent resection of recurrent sacral chordoma. Postoperative day three (POD#3), there was high lumbar surgical drain output and the patient experienced altered mental status and seizure activity. MR imaging (MRI) of the brain showed intracranial hemorrhage. Myelography confirmed a large pseudomeningocele, at the site of recurrence resection. The pseudomeningocele was repaired and the intracranial hemorrhage was managed medically. Case 2. A 58-year-old woman with prior L4-S1 posterior spinal fusion (PSF) underwent elective, uncomplicated removal of the L4-S1 PSF hardware with decompression and PSF of L3-L4 for recurrent back pain. POD#3 the patient had nausea and vomiting with positional headache and large volume lumbar surgical drain output. MR imaging of the brain showed intracranial hemorrhage. An MRI of the lumbar spine showed a dorsal dural defect. The defect was repaired and the intracranial hemorrhage managed medically.

Results
Case 1. Brain MRI, GRE showed bifrontal, parietal, temporal, putamen and cerebellar hemorrhage. T2 and FLAIR images demonstrated cortical and subcortical hyperintensity, separate from the areas of hemorrhage, in all cerebral hemispheres, with thick pachymeningeal enhancement. Of note, there was a relative lack of brain stem slumping and no subdural hemorrhage. Lumbar spine MRI showed a large CSF intensity fluid collection in the subcutaneous tissues at the operative site in the lumbar spine. This filled with contrast at myelography, confirming a connection with the thecal sac. Case 2. Brain MRI, GRE showed cerebellar and putamen/globus pallidus hemorrhage, and patchy T2/FLAIR hyperintensity in the cortical and subcortical hemispheric white matter, the bilateral caudate heads, and thalami. There were small bilateral subdural hemorrhages, diffuse pachymeningeal enhancement, and crowding of the perimesencephalic and prepontine cisterns. Lumbar spine MRI demonstrated a dorsal dural defect with an associated CSF intensity collection containing neural elements dorsal to the lumbar spine at the site of PSF.

Conclusions
Each of these cases show marked vasogenic edema in a pattern commonly associated with PRES, however, in the clinical setting of intracranial hemorrhage with large CSF leaks following spinal surgery. There is presumed profound intracranial hypotension and there are imaging findings to support that etiology. To our knowledge, this is the first report of PRES-like imaging features in this clinical scenario. There are case reports of central brain structure vasogenic edema in IH as well as one case report of more classic PRES-like findings in the setting of IH. A case of cerebellar hemorrhage with IH was reported, and PRES with ICH and IH in a post partum patient has been reported. There is a postulated venous congestion theory with respect to IH rooted in the Monro-Kelli hypothesis; however, most patients with IH present with chronic, compensated physiology. Decreased subcortical FLAIR signal intensity due to parenchymal deoxyhemoglobin has been shown in IH. In our cases, the rapid pressure changes with acute CSF loss and venous hypervolemia likely resulted in venous congestion, vasogenic edema and hemorrhage. These findings also help to support a venous cause etiology of the PRES-like appearance and RCH post spinal surgery with dural CSF leak. Practitioners should be aware of imaging findings in the setting of RCH and IH that mimic PRES, and if the clinical scenario warrants, search for CSF leak.

KEYWORDS: Hemorrhage, Intracranial Hypotension, Posterior Reversible Encephalopathy
Intraosseous Hemangioma of the Middle Turbinate: Case Report of a Rare Entity and Review of the Literature

R Goff¹, S Weindling¹, V Gupta¹, A Nassar¹
¹Mayo Clinic Florida, Jacksonville, FL

Purpose
Hemangiomas are ubiquitous benign vascular tumors or malformations commonly seen within the head and neck region. Lesions arising within the nasal cavity and paranasal sinuses are uncommon, and intraosseous hemangiomas arising from the nasal turbinate are exceedingly rare with only a few reported cases in the literature. We present a case of an intraosseous hemangioma of the middle turbinate with both computed tomography (CT) and MR imaging (MRI), and histologic correlation. While the nasal turbinate is a rarely reported site of occurrence, the characteristic imaging appearance of this intraosseous hemangioma allowed the correct diagnosis to be proposed prospectively by the interpreting neuroradiologist which had direct clinical and surgical implications. We believe the neuroradiology community would benefit from our experience through this case report presentation.

Materials and Methods
A 61-year-old male was referred to our otorhinolaryngology department for intermittent right epistaxis for approximately two - three years. Sinonasal endoscopy revealed a right nasal cavity mucosal ulceration, likely responsible for the epistaxis. On the left, edematous intact nasal mucosa was noted between the left middle turbinate and nasal septum. Subsequent sinus CT and MRI demonstrated an expansile left nasal cavity mass. Imaging features (as described below) suggested a benign lesion, and intraosseous hemangioma was included within the differential diagnosis on the basis of internal bony trabecular network seen at CT. The patient underwent uncomplicated, complete endoscopic resection of the mass which was confirmed to represent an intraosseous cavernous hemangioma of the middle turbinate pathologically. Patient did well postoperatively without recurrent symptoms at follow up.

Results
Sinus CT demonstrated a 3.6 cm expansile left nasal cavity mass with internal honeycomb bony trabeculations causing secondary remodeling of the left maxillary antrum, medial orbital wall, and rightward deviation of the nasal septum. The mass obstructed the left frontal sinus outflow
tract. Subsequent MRI, performed for assessment of lesion vascularity and operative planning, demonstrated the mass to be T2 hyperintense and T1 hypointense. The mass avidly enhanced postcontrast but lacked internal "flow-voids," allaying concerns of hypervascularity and obviating the need for pre-operative embolization. The CT and MR appearance was suggestive of an intraosseous nasal cavity hemangioma, confirmed to be arising from the middle turbinate both intraoperatively and histologically. Representative sagittal bone window CT image and coronal T1-weighted postgadolinium MRI image are shown below.

Conclusions
Hemangiomas are uncommon within the nasal cavity and paranasal sinuses, making up less than 20% of benign nasal cavity lesions. Nasal cavity and paranasal sinus hemangiomas most frequently originate from the mucosa, and are rarely intraosseous with few cases arising from the nasal turbinate previously reported. Despite this unusual location, the characteristic CT and MR appearance suggested this diagnosis and was in keeping with intraosseous hemangiomas found elsewhere in the musculoskeletal system. Additional diagnostic considerations for a nasal cavity mass with internal calcifications would include squamous cell carcinoma, sinonasal undifferentiated carcinoma, inverted papilloma, ossifying fibroma, esthesioneuroblastoma, and chondrosarcoma. While a differential diagnosis typically is required when encountering a nasal cavity mass, the internal honeycomb trabecular network present in our case allowed for confident diagnosis of intraosseous hemangioma, thereby avoiding unnecessarily aggressive treatment for this benign lesion.

Intravascular B cell lymphoma: A diagnostic challenge

C Hilditch¹, C Gall¹, P Pal¹, P Cooper¹, G Potter¹
¹Salford Royal Foundation NHS Trust, Salford, UK

Purpose
To demonstrate the diagnostic difficulties in a case of intravascular B cell lymphoma presenting with a progressive multifocal neurological syndrome and multifocal radiological lesions.

Materials and Methods
A 66-year-old male retired mail worker of Indian origin presented to the neurology clinic with progressive diplopia, ataxia, muscle wasting and lower limb weakness. Examination revealed right internuclear ophthalmoplegia, limb wasting, fasciculations, proximal leg weakness, ataxia and impaired sensation to the knees. The patient had emigrated to the UK in his 20s and had recently travelled to rural India and Kenya. Past history included diabetes, Crohn's disease and cervical lymph node tuberculosis. He was taking regular Azathioprine. Viral, immunological and inflammatory markers were unremarkable. Tests for TB were negative. Nerve conduction studies were consistent with a polyneuropathy with demyelinating features. MR imaging (MRI) brain revealed multiple infra- and supratentorial lesions with mild enhancement of some of the lesions. Spine MRI spine showed abnormal high T2 signal in the conus medullaris and enhancement of the left cauda equina, unusual rounded lesions in the left L2 and L3 transverse processes, and paraspinal soft tissue edema. Differential diagnosis included neoplasia including lymphoma, infection including TB, and inflammatory conditions such as neurosarcoidosis. Skin and bone biopsy and CT body were negative. The patient was started on Prednisolone which improved his symptoms and radiological findings. Three months later, he was admitted to hospital after a fall. Examination revealed flaccid paraparesis and marked apathy. This coincided with a reduction in dose of Prednisolone from 60 mg od to 40 mg od. During admission, the patient declined rapidly and required ICU admission. He developed 'pin-pong gaze', indicative of bilateral hemispheric damage. The patient continued to decline and died eight weeks later. Post-mortem examination revealed intravascular B cell lymphoma.

Results
Noncontrast CT brain was normal. STIR sequences demonstrated left paraspinal soft tissue edema at L2-L3 level (not shown). Axial and sagittal T1+C sequences showed unusual rounded left L2 (left image) and L3 transverse process lesions and asymmetric left cauda equina nerve root enhancement. T1+C sequences of the brain postcontrast demonstrated a subtly enhancing left corpus callosum lesion (right image) and further multifocal subtly enhancing infra- and supratentorial lesions (not shown).

Conclusions
This case demonstrates diagnostic difficulties which may be encountered in intravascular B cell lymphoma. Radiologists should include intravascular B cell lymphoma in the differential diagnosis in patients with a multifocal neurological syndrome and multifocal lesions of the neuraxis.
Intraventricular Obstructive Hydrocephalus and Subependymal Nodules; a Case of Anaplastic Astrocytoma with Subependymal Spread.

T Metz¹, S Al-katib², J Harb¹
¹Beaumont Health System, Royal Oak, MI, ²Beaumont Health System, Farmington Hills, MI

Purpose
Subependymal lesions have a variety of etiologies including inflammatory, congenital and
neoplastic causes. We present an unusual case of anaplastic astrocytoma presenting with intraventricular obstructive hydrocephalus and multiple subependymal masses.

Materials and Methods
A 66-year-old female with past medical history of sarcoidosis and diabetes presented to the emergency department with headache, gait imbalance, visual disturbance and difficulty concentrating. Neurological physical examination showed no abnormality. A noncontrast computed tomography (CT) of the head was obtained in the ER and based on the results, an MR imaging (MRI) of the brain with contrast subsequently was performed. The patient underwent additional work up in the outpatient setting, although her condition continued to deteriorate. She was admitted to the hospital a few weeks later with altered mental status and underwent ventriculostomy placement. This was followed by endoscopic third ventriculostomy with biopsy of the third ventricular mass and left lateral ventricular subependymal lesion. Histopathology of the biopsy specimens revealed both lesions to be consistent with anaplastic astrocytoma WHO grade 3. The patient underwent treatment with radiation and concurrent Temodar.

Results
The initial noncontrast CT examination of the brain demonstrates enlargement of the lateral and third ventricles with periventricular low attenuation consistent with transependymal cerebrospinal fluid (CSF) flow. An ill-defined hyperdense lesion is seen in the posterior third ventricle. Additionally, four hyperdense subependymal nodules are seen in the lateral ventricles ranging in size from 6 mm to 15 mm. MR imaging examination of the brain with contrast confirms obstructive hydrocephalus with transependymal CSF flow on FLAIR imaging. An ill-defined nonenhancing lesion is seen in the posterior third ventricle with isointense T1 and mildly increased T2 and FLAIR signal. The MRI also confirmed multiple subependymal nodules in the lateral ventricles show patchy enhancement and are isointense on T1 and T2.

Conclusions
The differential diagnosis of multiple subependymal nodules includes neoplastic, congenital and inflammatory conditions. We present an unusual case of anaplastic astrocytoma presenting with a third ventricular mass causing acute obstructive hydrocephalus and multiple subependymal nodules.

KEYWORDS: Anaplastic Astrocytoma, Obstructive Hydrocephalus, Subependymal
Intraventricular Pilomyxoid Astrocytoma: Unusual Presentation of Rare Tumor.

S Thota

\[Suny Upstate Medical University, Syracuse, NY\]

**Purpose**

**Case Report**

**Materials and Methods**

A 11-year-old female presented to the emergency room with uncontrollable nausea and vomiting. In the ER, she became very lethargic and later developed seizure with generalized tonic movements. Her neurological exam demonstrated dilated pupil on the right side. Stat computed tomography (CT) of her head showed a large right intraventricular lesion with acute hydrocephalus. Significant midline shift and uncal herniation was noted. An emergent external ventriculostomy was placed in the ER and she was taken urgently to the operating room for resection of the intraventricular lesion. Patient underwent right parietotemporal craniotomy.
Brain appeared very tense after the flap was elevated and the dura irrigated. Blood clot and tumor were identified upon entering the right lateral ventricle in the region of trigone. The tumor was resected in small pieces using suction and bipolar dissection. The tumor was followed into the temporal horn. The tumor was resected until the ependymal liming was seen. Intra-operative ultrasound was used to confirm that there is no gross residual tumor present. As the brain was pulsatile after the tumor was resected and did not seem to be under pressure, bone flap was placed back.

Results
Emergent noncontrast CT head demonstrated 6.0 x 3.4 x 2.0 cm lobulated heterogenous, predominantly hyperdense intraventricular mass with intraventricular hemorrhage. The lesion is centered around the trigone of the right lateral ventricle with extension into the body and temporal horn of the lateral ventricle. Hyperdense material also was identified within the third ventricle which may represent hemorrhagic tumor or hemorrhage. Associated vasogenic edema was noted in the peritrigonal white matter. Four mm leftward midline shift was noted.

Conclusions
Pilomyxoid astrocytomas were described fairly recently as biological relatives of the more common pilocytic astrocytoma with which it shares many histopathological features. Pilomyxoid astrocytomas however, are notable for their abundant myxoid matrix and the tendency of their cellular constituents to arrange themselves agiocentrically forming pseudosarette. PMAs are known to perform less favorably than pilocytic astrocytomas, with higher rate of recurrence and leptomeningeal dissemination. Accordingly, they have been designated as grade 2 in the most recent WHO classification scheme.

Intraventricular Schwannoma: A Rare Cause of Ventricular Entrapment.

S Curran-Melendez, M Fukui, D Oliver-Smith
Allegheny General Hospital, Pittsburgh, PA

Purpose
We present a rare case of an intraventricular schwannoma in a 20-year-old male.

Materials and Methods
A 20-year-old male presented with a two-year history of intermittent blurry vision and a burning sensation involving the top of his head, which had increased in frequency and intensity over the past several months. Physical exam did not reveal any physical abnormalities or neurologic deficits. Initial evaluation with MR imaging (MRI) demonstrated an enhancing right-sided intraventricular mass. The patient underwent complete tumor resection through a right-sided transparietal approach with a right parietal craniotomy. A light pink, well-encapsulated mass, adherent to the medial ventricular wall, was removed. Pathologic analysis revealed a S100-positive tumor which was rich in reticulin and type IV collagen, consistent with a schwannoma.

Results
Contrast-enhanced brain MRI revealed a 2.6 x 2.1 x 1.9 cm T1 and T2 hypointense mass centered within the atrium of the right lateral ventricle. There was a large amount of T2-FLAIR
signal within the adjacent white matter of the right parietal and temporal lobes, consistent with edema. Dilatation of the temporal horn of the right lateral ventricle was consistent with ventricular entrapment. Susceptibility artifact was suggestive of calcification. After administration of gadolinium, the mass demonstrated homogeneous enhancement.

Conclusions

Schwannomas associated with peripheral nerves account for 8% of all intracranial neoplasms. Intraventricular schwannomas are rare neoplasms with only 23 cases previously reported. These lesions most often are found in the lateral ventricles (70%) but also can be located in the fourth (26%) and third (4%) ventricles and most often are seen in males (65%). Intraventricular schwannomas have been found in a wide range of age groups, 7 to 78 years of age, with a median age of 31. The most common presenting symptom is headache with or without nausea and vomiting, although lesions may be asymptomatic (detected due to papilledema seen on ocular exam). They also may present with visual changes, neurological deficits, or seizures. These lesions are most often benign, with only two malignant cases being reported. Although a definite etiology has not been determined, theories include neoplastic transformation of pluripotent mesenchymal cells into Schwann cells, neoplastic transformation of ectopic neural crest cells from disorganized embryogenesis, or hyperplastic transformation of Schwann cells from the peripheral nerve fibers located within the choroid plexus. Inclusion of schwannoma in the differential diagnosis for intraventricular lesions is important as these lesions may lead to life-threatening complications such as hydrocephalus, but often can be treated successfully with total surgical resection.

¹Henry Ford Health System, Detroit, MI

Purpose
Langerhans cell histiocytosis (LCH) is a rare disease, which can present with a broad range of clinical and radiologic manifestations. Although involvement of the central nervous system (CNS) is not uncommon, lesions are typically extra-axial with secondary involvement of the cerebral parenchyma. This excerpt describes an unusual presentation of LCH as an isolated intra-axial lesion.

Materials and Methods
We present a case of a 31-year-old male presenting with a recent history of frontal headaches and new onset partial-complex seizures. The patient was otherwise neurologically intact without
evidence of focal neurologic deficit. Following imaging evaluation, the patient underwent a right pterional temporal osteoplastic craniotomy with microsurgical debulking and subtotal resection of the intraparenchymal lesion. No lesion was seen to originate from the meninges of the middle cranial fossa. Pathology demonstrated a nodular infiltrate of atypical epithelioid histiocytes. Within the histiocytic nodules were occasional multinucleated giant cells, many polymorphonuclear neutrophilic granulocytes and abundant eosinophils. Immunohistochemical staining was strongly and diffusely positive for CD1a and S100 protein. Findings were consistent with LCH. Following surgery, the patient reported improvement in headaches without seizure recurrence.

**Results**

Head computed tomography (CT) demonstrates a large area of vasogenic edema within the right temporal lobe with an intact adjacent calvarium. Contrast-enhanced MR of the brain demonstrates a T2 heterogeneous, avidly enhancing and infiltrative lesion within the right temporal lobe with marked surrounding vasogenic edema.

**Conclusions**

Langerhans cell histiocytosis is a rare disease, which can present with a broad range of clinical and radiologic manifestations. The disease process, which is of unknown cause, is a dendritic cell-related disorder characterized by tumor and tumor-like masses composed of histiocytes. Manifestations of LCH in the central nervous system (CNS) can have a variety of imaging presentations, including involvement of the hypothalamic-pituitary axis, which is the most commonly involved intracranial site. Other imaging patterns include neurodegenerative gray-matter changes in the cerebellum, leukoencephalopathy-like pattern changes in the white matter, meningeal lesions and choroid plexus lesions. Isolated intra-axial LCH lesions without extracranial involvement are rare; however, the diagnosis should be considered in young patients presenting with isolated intra-axial lesions demonstrating marked vasogenic edema.

Isolated Involvement of the Substantia Nigra in West Nile Virus Encephalitis

D Lukins¹, S Berl¹, E Escott¹
¹University of Kentucky, Lexington, KY

Purpose
West Nile virus (WNV) is a well known cause of encephalitis, and demonstrates variable findings on brain imaging. We report a case of West Nile virus encephalitis with an MR imaging (MRI) of the brain showing isolated involvement of the bilateral substantia nigra. Although involvement of the substantia nigra in conjunction with other sites has been reported previously in patients with WNV encephalitis, isolated involvement has not. We also review the clinical presentation and imaging findings of West Nile virus encephalitis as well as the differential diagnosis for the imaging findings seen in this case.

Materials and Methods
A 55-year-old man with multiple comorbidities was admitted to the hospital with a four-day history of abdominal pain, fever, and altered mentation. Laboratory analysis showed marked leukocytosis with 80% lymphocytes. Bone marrow biopsy revealed chronic lymphocytic leukemia, a new diagnosis. Evaluation for infection and broad-spectrum antibiotic coverage were initiated. Over the first several days, the patient progressively deteriorated neurologically. Computed tomography (CT) of the head with and without intravenous contrast was negative. The patient continued to have intermittent fever despite broad-spectrum antibiotic coverage. No clear source of infection was discovered. Results of HIV testing were negative. On hospital day seven, lumbar puncture was performed, showing results suspicious for viral meningitis. The patient's mental status continued to wax and wane. On hospital day 13, the infectious disease service was consulted because of persistent fever and abnormal findings on repeat LP. Brain MRI showed abnormally increased signal in the substantia nigra on T2-weighted and FLAIR images. On hospital day 15, West Nile virus serology was positive in both the cerebrospinal fluid and serum. The patient was given supportive therapy for West Nile virus encephalitis, and was discharged 4.5 weeks later neurologically intact.

Results
Computed tomography of the head with and without intravenous contrast performed on hospital day five was negative. MR imaging of the brain with and without intravenous contrast performed on hospital day 14, showed increased signal in the substantia nigra bilaterally on FLAIR and T2-weighted sequences, and no other abnormalities.

Conclusions
We report a case of West Nile virus encephalitis with isolated involvement of the substantia nigra on MRI. Imaging findings of West Nile virus encephalitis are nonspecific, but include abnormally increased signal in the deep gray nuclei, brainstem, and cerebral white matter on T2-weighted images. Hyperintensity in the substantia nigra on T2-weighted images should suggest the possibility of WNV encephalitis or other flavivirus encephalitis.

Low Grade Tumor Arising in Focal Cortical Dysplasia: Understanding the Spectrum of Pathology Through Examples of a New Subtype (IIIb)

C Reilly¹, E Bit-Ivan¹, Q Mao¹, B Liu¹
¹Northwestern Memorial Hospital, Chicago, IL

Purpose
To present two cases of low grade tumor arising in focal cortical dysplasia (FCD) in adult patients, and review the new International League Against Epilepsy (ILAE) classification system of FCDs.

Materials and Methods
Case 1. A 38-year-old man had an MR imaging (MRI) to evaluate tension headaches that discovered an abnormality in the left superior parietal lobule read as "nonenhancing infiltrating glioma." His headaches never returned, and the patient remained asymptomatic during MRI monitoring for one year. Due to concern for tumor, the lesion was resected. Case 2. A 50-year-old woman with history of migraines presented with visual changes, left hand paresthesias, nausea, and imbalance. Her MRI revealed a left parietal lobe lesion, which was subsequently resected. In both cases, surgical pathology demonstrated low grade neoplasm arising in focal cortical dysplasia. Histologic evaluation revealed cortical dyslamination, dysmorphic neurons, and ectopic neurons (arrowheads) in the white matter with abundant balloon cells (arrows) in both gray and white matter, consistent with FCD. Additionally, the parenchyma was hypercellular due to an atypical, neoplastic astrocytic population (circles), consistent with a low grade tumor (Figure 1a).
Results
In both cases, a 1 to 2 cm nonenhancing left parietal T2/FLAIR hyperintense lesion with blurring of the gray-white junction was identified. Gyral expansion suggested a low grade tumor. T2/FLAIR hyperintensity in the subcortical white matter tapering towards the ventricle suggested FCD (Figure 1b).

Conclusions
The imaging, surgical and pathological features of two cases of FCD type IIIb lesions are presented. Focal cortical dysplasia is the most common neuropathological finding in surgical specimens from drug-resistant epilepsy patients. Focal cortical dysplasia is uncommon in older and nonepileptic patients. Low grade tumor arising in FCD in adults is particularly rare. MRI imaging is excellent for detection of these lesions. However, distinguishing a low grade primary neoplasm, FCD, and/or their combination is challenging for radiologists and pathologists. To allow for accurate diagnosis, radiologists must include FCD type IIIb in the imaging differential diagnosis to inform surgeons and pathologists when there is a possibility of multiple abnormal cell lines in the pathological sample. Incorrect/incomplete diagnosis risks inappropriate management. The new 2011 ILAE classification system of FCDs is reviewed to explain why the two cases presented herein are classified as FCD IIIb and how older terminology was incorporated into the new schema. Radiologists should be familiar with these lesions and their classification.

Metastases to the Pituitary Gland from Parotid Gland Carcinoma.

N Guha-Thakurta1, L L1, (Debnam2
1MD Anderson Cancer Center, Houston, TX. 2The University of Texas MD Anderson Cancer Center, Houston, TX

Purpose
Metastases to the pituitary gland are rare with an incidence of 1-3.6%. The most common malignancy to metastasize to the pituitary is breast, followed by lung cancer. Herein, we report a case of a primary parotid gland cancer metastasizing to the pituitary gland.

Materials and Methods
A 51-year-old man presenting with a recent onset of progressive fatigue was investigated with an endocrine panel and found to have hyperprolactinemia, hypocortisolemia, and hypothyroidism. His past history was significant for carcinoma ex-pleomorphic of the parotid gland treated 5 years ago with resection and radiation therapy.

Results
Magnetic resonance imaging (MRI) of the brain demonstrated a homogeneously enhancing mass within the sella with suprasellar extension, approximating the optic nerve and chiasm, inseparable from the cavernous internal carotid arteries bilaterally (Figure 1). The primary imaging diagnostic consideration was a pituitary macroadenoma. During endoscopic surgery, the tumor extending anteriorly into the sphenoid sinus was biopsied. On visual inspection, the mass was vascular and more firm than a pituitary adenoma. Frozen section diagnosis was that of a carcinoma, and not a primary pituitary neoplasm. The surgery was terminated. The final histopathology was consistent with myoepithelial carcinoma with squamous differentiation, the same as the primary salivary gland tumor.

Conclusions
Metastases to the pituitary gland are unusual and most often originate from primary cancer of the breast, followed by the lung. They are predominantly clinically silent and occur mostly in the posterior pituitary. Rarely lymphomas, leukemia, plasmacytoma, renal cell carcinoma, thyroid cancer and gastrointestinal primary tumours can metastasize to the sella. The metastases are usually invasive and can be heterogeneous in appearance. We present a primary parotid gland carcinoma metastasizing to the pituitary gland mimicking a pituitary adenoma on imaging, five years following treatment of the primary and without any evidence of recurrent disease in the neck. Our report highlights the fact that although metastases to the pituitary gland are atypical, they should be considered in the differential diagnosis in patients with a prior history of malignancy exhibiting new pituitary dysfunction and enlargement.

KEYWORDS: Metastases, Parotid Gland, Pituitary Gland
MRI findings of acute crossed cerebellar diaschisis in the setting of status epilepticus

J Tisnado\textsuperscript{1}, J Chazen\textsuperscript{1}
\textsuperscript{1}Weill Cornell Medical College, New York, NY

Purpose
To highlight the MR imaging (MRI) findings in prolonged status epilepticus with secondary crossed cerebellar diaschisis.

Materials and Methods
An 82-year-old female with past medical history of hypertension and left parietal infarct approximately nine months prior was found unresponsive in her home after last seen in her normal state of health two days prior. The EMS team that brought the patient to the hospital reported possible seizure activity at the scene. The patient had a GCS of 3 at the hospital and was urgently intubated. A head CT was performed followed by a brain MRI. Following the brain
MRI findings, continuous EEG monitoring was initiated which demonstrated findings suggestive of status epilepticus.

Results
Noncontrast head CT showed no acute findings. Noncontrast brain MRI demonstrated diffuse gyriform reduced diffusion throughout the left cerebral hemisphere with associated T2 hyperintensity and gyral swelling. There was also reduced diffusion in the right cerebellar hemisphere with associated T2 hyperintensity. A region of encephalomalacia secondary to a left parietal infarct also was seen, probably representing the seizure nidus.

Conclusions
It is important for the radiologist to be aware of MRI findings in crossed cerebellar diaschisis, as it can be an indicator that active seizures are occurring in an altered or unresponsive patient. These findings must be differentiated from other causes of gyral edema and reduced diffusion including acute ischemia and infection. The radiologic findings then can be correlated with clinical findings as well as EEG monitoring to help the clinician come to a definitive diagnosis.

KEYWORDS: Crossed Cerebellar Diaschisis
Purpose
Multisystem atrophy is a sporadic neurodegenerative disorder of unknown etiology which occurs secondary to degeneration of the basal ganglia and the olivopontocerebellar system. The disease is not uncommon but may be underrecognized on MR imaging (MRI) as the imaging findings may be subtle. We present a case report and two companion cases with MR imaging demonstrating the unique findings of MSA-C and MSA-P, the two main subtypes of the disease. The third type, MSA-A is the autonomic variant which has no specific imaging findings. Recognizing the findings of MSA will lead to prompt diagnosis for the patient and may prevent unnecessary interventional procedures.

Materials and Methods
(Case 1) A 56-year-old female presented with postural hypotension and dizziness. Her blood pressure fluctuated significantly in the emergency department and on physical exam she was found to have slow speech, generalized severe hypotonia, and significant cogwheel rigidity involving all four extremities, left greater than right. Her past medical history included chronic dysautonomic symptoms and associated complications. (Case 2) A 58-year-old male with chronic dizziness and gait ataxia presented after sustaining a fall secondary to poor balance. The patient had a history of falls with increasing frequency recently. (Case 3) A 64-year-old female was referred for brain MRI secondary to progressive gait ataxia. The patient previously had undergone anterior cervical diskectomy because her symptoms had been misattributed to cervical spondylosis. Her spinal surgery resulted in no improvement in her symptoms.

Results
(Case 1) Axial T2*-weighted gradient echo sequence demonstrates bilateral decreased signal in the putamina. (Case 2) An axial T2-weighted MR demonstrates linear increased T2 signal intersecting in the pons, the so-called "hot cross bun" sign. (Case 3, not shown) Sagittal T1-weighted MR image demonstrates significant interval atrophy of the olivopontocerebellar structures compared to a study performed four years previously.

Conclusions
Following the review of this exhibit, the reader will be familiar with the types of MSA, the clinical presentation and unique neuroimaging findings. We present three patients diagnosed with MSA with the hallmark MR imaging findings of this disorder. Multisystem atrophy is a sporadic, progressive neurodegenerative disorder which shares many clinical features of other disease processes such as Parkinson's disease, progressive supranuclear palsy, and spinocerebellar ataxia. Correct identification of MSA as the diagnosis will likely aid in treatment planning as well as prognosis. Therefore, the radiologist plays an integral role in the diagnosis of this often obscure and debilitating disease.
Not all that's white is blood! – Leukemia mimicking acute subarachnoid hemorrhage

M Diogo¹, S Dias¹, P Branco¹, I Fragata¹, I Lucio¹, M Mafra¹, L Cerqueira¹
¹Centro Hospitalar Lisboa Central, Lisboa, Portugal

Purpose
To present an educational case where continued misdiagnosis of acute subarachnoid hemorrhage (SAH) on computed tomography (CT) delayed further work up and treatment of a meningeal leukemia. A short review of patterns and imaging evolution of SAH and a brief illustrated review of SAH mimics also is presented.

Materials and Methods
A 21-year-old previously healthy male presented to a secondary care hospital with a three-week history of progressively worsening headaches. A head CT was performed and the diagnosis of diffuse acute SAH was made. He was admitted for observation and sequential imaging studies were performed; however the headaches increasingly worsened and he developed bilateral
amaurosis, deafness, right proptosis and progressive weight loss. Six weeks after admission the patient was transferred to our institution for further investigation. Additional imaging studies were performed. Despite all efforts the patient continued to deteriorate and died three days later. Autopsy results and histopathological findings were consistent with diffuse leukemic infiltration of the meninges.

Results
Serial CT scans showed diffuse hyperdensity of the subarachnoid spaces, with progressive and irregular erosion of the skull vault and base. Computed tomography on admission to our institution showed identical findings, plus herniation of the frontal lobe through the skull base into the right orbit, causing exophthalmos. Magnetic resonance imaging demonstrated the same filling of all cerebrospinal fluid (CSF) spaces by a T1-hypointense, T2-hyperintense component with restricted diffusion and strong enhancement after IV gadolinium. Additionally a pineal mass with the same characteristics was identified. Secondary encephaloceles were clearly visible protruding into the right orbit and through the middle cerebral fossa on the left.

Conclusions
We present a case of a 21-year-old man misdiagnosed with acute SAH in order to illustrate a rare case of aggressive meningeal leukemic dissemination, and present a brief differential diagnosis of SAH mimics. Subarachnoid hemorrhage patterns and mimics should be familiar to the neuroradiologist, in order to direct clinicians towards the right investigation and diagnosis.

Post Carotid Endarterectomy Cerebral Hyperperfusion Syndrome Mimicking Stroke

R Hernandez, V Kalra, A Malhotra

Yale University School of Medicine, New Haven, CT

Purpose
Review a case of cerebral hyperperfusion syndrome status postcarotid endarterectomy highlighting findings of CT perfusion.

Materials and Methods
A 69-year-old gentleman with history of multiple punctate left cerebral infarcts and ipsilateral high grade carotid stenosis underwent uncomplicated left carotid endarterectomy (CEA). On postoperative day two the patient developed headache and right hemiplegia. Noncontrast computed tomography (CT) and MR imaging (MRI) of the brain demonstrated no stroke. Computed tomography angiography (CTA) of the neck showed expected postoperative changes related to CEA with no evidence of dissection or thrombosis. Computed tomography perfusion performed at that time revealed increased left cerebral blood flow and decreased mean transit times. Findings were considered diagnostic of cerebral hyperperfusion. By postoperative day six the patient had recovered completely without persistent deficit.

Results
MR imaging/MRA of the brain demonstrated multiple punctate left cerebral infarcts involving the left middle and posterior cerebral artery territories with a fetal configuration of the left posterior cerebral artery. Computed tomography angiography (CTA) of the neck revealed greater
than 70% stenosis of the proximal left internal carotid artery. Postoperatively, there was no acute hemorrhage or infarction on CT or MRI of the brain. Computed tomography angiography of the neck revealed expected changes related to recent CEA with no dissection or thrombosis. Increased cerebral blood flow and decreased mean transit times were noted in the left cerebrum with CT perfusion imaging.

Conclusions
Cerebral hyperperfusion syndrome (CHPS) is a known complication status postcarotid endarterectomy. It is characterized clinically by headache, seizure, and cortical neurologic deficit occurring with reperfusion in the absence of cerebral ischemia. Early identification is critical, with aggressive blood pressure control necessary to prevent intracranial hemorrhage. The majority of neurologic complications following carotid endarterectomy are ischemic in etiology with clinical features that are often indistinguishable from those of CHPS. In the setting of postoperative hemiplegia, the diagnosis traditionally has been one of exclusion primarily utilizing routine MRI and CT to rule out infarction. However, cerebral CT perfusion imaging provides the opportunity to proactively suggest the diagnosis in this clinical dilemma.

Primary Trigeminal Nerve Germinoma: Case Report

D Leake¹
¹Austin Radiological Association, Austin, TX

Purpose
To describe neuroradiologic findings in a rare case of primary intracranial trigeminal nerve germinoma.

Materials and Methods
A 19-year-old male presented to the emergency room with a three-month history of headache. He described numbness of his entire left face. He also complained of double vision and inability to open his left eye completely. Physical exam revealed a left fifth and third cranial nerve palsy. Computed tomography (CT) and MR imaging (MRI) demonstrated a left cavernous sinus/sella mass extending into the left middle cranial fossa. Subsequent surgical resection demonstrated an extraaxial mass of the middle cranial fossa with infiltration of the left trigeminal nerve, CN5, including cisternal segment and divisions V2 and V3. Oculomotor nerve, CN3, was severely compressed, but not infiltrated. Pathology revealed high grade germinoma.

Results
Computed tomography brain revealed a large homogenous enhancing mass of the left cavernous sinus/sella region with left middle cranial fossa extension. There was enlargement of left foramen ovale. MR imaging also demonstrated the mass, but with inhomogenous enhancement. There was enlargement of left trigeminal nerve, CN5, cisternal segment and divisions V2 and V3. The mass showed restricted diffusion. Cerebral catheter DSA with selective left internal carotid artery injection demonstrated an enlarged inferolateral branch supplying the mass and prolonged vascular "stain" of the mass. Selective left external carotid artery injection did not show enlargement of arterial branches or a prolonged vascular "stain". MR imaging of entire
neuraxis demonstrated two enhancing nodular masses of the lumbar subarachnoid space compatible with cerebrospinal fluid (CSF) disseminated metastases. Computed tomography chest, abdomen, pelvis and testicular ultrasound examinations were normal.

Conclusions
Germinomas make up about 0.5% to 3% of primary intracranial tumors. They occur in children and young adults. Most germinomas involve the pineal and suprasellar regions, and uncommonly the thalamus and basal ganglia. Our germinoma occurred in a young adult originating in a rare location, the trigeminal nerve. The skull base and trigeminal origin of germinoma has been reported only rarely. Although rare, germinoma should be considered in the differential diagnosis in children and young adults when a cavernous sinus/sella mass with trigeminal perineural extension is found.

Retrograde Cerebral Venous Air Embolism

C Toh¹, H Wong¹
¹Chang Gung Memorial Hospital, Taoyuan, Taiwan, Province of China

Purpose
To report the imaging findings of cerebral venous air embolism after removal of central venous catheterization.

Materials and Methods
A 63-year-old male with right lung cancer was admitted to the hospital for surgery. His postop course in ICU was stable. Before transferring to general ward, the patient had his central venous catheter removed. Immediately after the catheter removal, the patient was found to be unconscious. Brain CT showed air collection in bilateral cavernous sinuses, straight sinus and bilateral cerebral cortical veins, suggesting cerebral venous air embolism. MR imaging (MRI) obtained 10 hours later showed no residual air in the venosinus system, but subtle cortical swelling in the bilateral high frontal and left parietal lobe. Follow-up MRI of brain done 12 days later revealed bilateral subacute infarctions with pseudolaminar cortical necrosis. He received supportive treatment with gradual return of consciousness despite remained to be paralysis.

Results
Noncontrast-enhanced CT of brain revealed air bubbles in the bilateral cavernous sinus, straight sinus and cerebral veins in bilateral high frontal and left parietal sulci. Axial T2-weighted MR image obtained 10 hour after to the CT scan show no residual air in the bilateral cerebral veins. Axial T1-weighted MR image with gadolinium enhancement obtained 12 day later demonstrated gyral enhancement in the bilateral high frontal and left parietal cortex suggesting subacute infarctions with pseudolaminar cortical necrosis. Diffusion-weighted image showed diffusion restriction in the affected cortex.

Conclusions
In conclusion, cerebral venous air embolism is an extremely rare complication after removal of central venous catheter. Radiologists should be aware of the imaging findings of this potentially serious complication.

KEYWORDS: Venous Infarction
Rotational Vertebral Artery Stenosis Secondary to Transverse Mega-Apophysis: an Uncommon Finding

B Bartolini¹, P Favrole², R Blanc¹, S Pistocchi¹, H Redjem¹, M Piotin¹
¹Fondation A. de Rothschild, Paris, France, ²Hôpital Tenon AP-HP, Paris, France

Purpose
We describe one case of rotational vertebral artery severe stenosis associated with a transverse mega-apophysis at C6.

Materials and Methods
A 59-year-old female was admitted with vertigo. MR imaging (MRI) and MR angiography (MRA) showed a small vertebrobasilar thromboembolic stroke without intracranial occlusion. She was discharged without symptoms. One week later, she was readmitted with similar symptoms; MRI and MRA showed an acute left PICA stroke, without intracranial occlusion. Neck CT and CTA revealed a dissection of left V2 and a bone condensation. A functional occlusion of the left vertebral due to extrinsic compression was suspected. Digital subtraction angiography (DSA) was performed, with dynamic angiograms that revealed a dissection of left V2 and a subocclusive stenosis in the left head rotation.

Results
Catheter angiography of the affected vertebral artery was performed in AP and lateral views, with dynamic angiograms (right head rotation, neutral and left head rotation). Angiograms in neutral and right head rotation revealed a dissection of left V2 segment, at the level L5-L6, that induced a 60% stenosis. Angiograms in left head rotation showed a subocclusive stenosis with hemodynamic effects. Three-dimensional images acquired with rotational angiography revealed a transverse C6 left mega-apophysis at the level of the dissection.

Conclusions
Rotational vertebral artery occlusion is a rare syndrome that can be revealed by vertigo, nystagmus and syncope during head rotation. Multiple etiologies have been described in the literature. We report a case of cervical mega-apophysis, with emphasis on angiographic findings.

KEYWORDS: Vertebral Artery Dissection, Vertigo
Purpose
To report an unusual case of multiple small adjacent venous angiomas with venous shunting mimicking arteriovenous malformation.

Materials and Methods
A 21-year-old presenting with acute onset of headache and left-sided weakness in an outside hospital. Patient then was transferred to our institution. MR imaging (MRI) was performed followed by catheter cerebral angiography to rule out arteriovenous vascular malformation. Patient showed progressive improvement during short hospital observation.

Results
MR imaging showed right thalamic remote hemorrhage. There also was typical appearance of
Multiple adjacent venous angiomas in the bilateral anterior and right posterior thalami with a large peri-thalamic draining vein constituting a large venous angioma. Typical "caput medusa" or "spider" appearances were present. Catheter angiography confirmed the venous angiomas but with additional finding of arteriovenous shunting on both right internal carotid and right vertebral artery selective injections. No AVM nidus identified.

Conclusions
Venous angiomas with arteriovenous shunting is a rare occurrence. This has been termed as "Arterialized Venous Angiomas". There are few reported cases in the literature. Our case is distinguished by virtues of multiple small venous angiomas draining into the same vein with separate anterior and posterior arterial feeding in the anterior and posterior thalamus, respectively. Also, associated hemorrhage further helped the case to masquerade as AVM. The treatment is generally conservative.

KEYWORDS: Arteriovenous Malformation, Venous Malformations

Thrombosis of a Drainage Vein in Developmental Venous Anomaly (DVA) Leading to Venous Infarction:

A Agarwal1, S Kanekar2, K Thamburaj3
1Penn State University, Hummelstown, PA, 2Penn State Milton S Hershey Medical Center, Hershey, PA, 3Penn State University, Hershey, PA

Purpose
Developmental venous anomaly (DVAs) are fairly common and generally benign congenital
vascular abnormalities, present in approximately 2.6% of the general population. Thrombosis of a DVA is extremely rare, and most symptomatic complications arise from DVAs that are arterialized or associated with other vascular malformations, like cavernomas or arteriovenous malformations. In this exhibit, we report imaging findings in a case of DVA with a thrombosed drainage vein in the left cerebellar hemisphere along with a review of the relevant literature.

Materials and Methods
A 61-year-old man presented to an emergency room with sudden loss of consciousness and syncope. He had experienced a headache, progressive dizziness, and nausea persisting for two weeks. He denied previous seizure and had no cardiovascular risk factors. Laboratory values, including coagulation tests, were within normal limits. Cranial computed tomography (CT) scan revealed a large tubular hyperdense structure in the left cerebellar hemisphere converging toward the left transverse sinus (Figure 1). Additionally, mild left-sided cerebellar edema was present. Magnetic resonance imaging (MRI) performed subsequently revealed areas of hyperintense subcortical venous infarction on T2-weighted images in the left cerebellar hemisphere (Figure 1). Unenhanced T1-weighted images demonstrated a hyperintense tubular structure in the left cerebellum. Gadolinium-enhanced T1-weighted images showed the nonenhanced thrombosed drainage and enhanced medullary veins with caput medusa appearance confirming the diagnosis of DVA. Four-vessel cerebral angiography during the venous phase demonstrated lack of opacification in the territory of the thrombosed DVA. The patient's neurological status improved gradually with anticoagulation therapy over a period of 10 days with residual mild left-sided ataxia and he was discharged on coumadin and antihypertensive medication. Follow-up MRI after seven months showed recanalization of the thrombosed vein and resolution of cerebellar edema. No underlying cavernoma or AVM was identified in the region.

Results
Head computed tomography (CT) scan revealed a large tubular hyperdense structure in the left cerebellar hemisphere converging toward the left transverse sinus (Figure 1a). Additionally, mild left-sided cerebellar edema was present. Magnetic resonance imaging performed subsequently revealed areas of hyperintense subcortical venous infarction on T2-weighted images in the left cerebellar hemisphere (Figure 1b). Unenhanced T1-weighted images demonstrated a hyperintense tubular structure in the left cerebellum. Gadolinium-enhanced T1-weighted images showed the nonenhanced thrombosed drainage and enhanced medullary veins with caput medusa appearance confirming the diagnosis of DVA.

Conclusions
In summary, DVAs occasionally give rise to significant symptoms due to thrombosis of the draining vein. We evaluated comprehensive imaging findings in a challenging case of DVA associated with nonhemorrhagic infarction. The familiarity with imaging findings of complicated DVAs is essential for accurate diagnosis and appropriate management.

KEYWORDS: Developmental Venous Anomalies, Thrombosis
Unusual Necrotic Cerebral Prostate Metastasis

J Johnson¹, C Carr¹, T Kaufmann¹
¹Mayo Clinic, Rochester, MN

Purpose
To present an unusual case of necrotic prostate cancer metastasis to brain parenchyma mimicking a high grade glioma, in the absence of other hematological metastases; and to review the spectrum of intracranial findings of prostate cancer metastasis.

Materials and Methods
A 62-year-old man with a history of prostate cancer treated with prostatectomy and radiotherapy had no close follow up for the ensuing nine years. He then presented in 2011 with cystitis, hematuria and an elevated prostate specific antigen (PSA). However, subsequent bone scan and abdominopelvic computed tomography (CT) were negative. He was started on leuprolide and his PSA normalized. In late 2012, he developed progressive fatigue, vague cognitive changes, and left foot drop. Subsequent brain MR imaging (MRI) showed a right-sided cerebral mass, which was resected with pathology showing poorly differentiated prostate adenocarcinoma.

Results
Brain MRI depicted a large right necrotic temporal lobe mass with a heterogeneous avidly enhancing peripheral rim with no restricted diffusion, which resulted in marked mass effect including uncal and subfalcine herniation. The enhancing rim showed patchy T1 shortening and T2* dephasing on susceptibility-weighted imaging, suggestive of intratumoral hemorrhage. Spread of tumor around the trapped right lateral ventricular temporal horn (arrow) and possibly into it also was suggested, given the layering of intraventricular blood products. Dynamic susceptibility contrast perfusion imaging depicted elevated tumoral blood volume with a mean
percentage signal recovery of 69%, compatible with a high grade glioma. A subcentimeter enhancing left frontal lesion also was present, possibly representing a second focus of tumor versus subacute enhancing infarction. No abnormal pachymeningeal or osseous enhancement was present. Overall findings were deemed suspicious for a high grade glioma with periventricular spread, versus less likely, an atypical metastasis. However, an abdominopelvic CT scan demonstrated retroperitoneal and iliac partially necrotic presumed lymphatic metastases, despite normal PSA. No imaging studies ever demonstrated hematogenous bone, liver or lung metastases.

Conclusions
This unusual case of a large prostate adenocarcinoma brain metastasis mimicking a high grade glioma provides the opportunity to review the pathophysiology and neuroradiological manifestations of prostate cancer metastases, which are more typically dural or osseous. This case is particularly unusual given its primarily cystic/necrotic appearance as well as the lack of hematogenous metastases elsewhere in the body and a normal PSA, which had lowered the index of suspicion for metastasis. Ultimately, the neuroradiologist should remain aware of the different presentations of metastatic tumors to the brain, including atypical ones.

KEYWORDS: Brain, Metastases, Prostate
A Case of Refractory Trigeminal Neuralgia: Relevant MR Techniques and Anatomy

C Wanamaker¹, M Hughes¹, B Branstetter¹, A Frederickson², R Sekula¹
¹University of Pittsburgh Medical Center, Pittsburgh, PA, ²University of Pittsburgh, Pittsburgh, PA

Purpose
Trigeminal neuralgia is a debilitating disorder which affects approximately 4.5/100,000 people per year. We will review anatomy of the trigeminal nerve focusing on the imaging findings of vascular compression causing trigeminal neuralgia. The MR techniques that best depict the trigeminal nerve and arteries to evaluate for neurovascular compression are reviewed. We present a case of trigeminal neuralgia caused by vascular compression at the root entry zone to illustrate the critical role imaging plays in identifying the culprit vessel and guiding surgical management.

Materials and Methods
A 72-year-old male presented with a 20-year history of left facial pain (sharp and electric) that worsened over the last two months leading to decreased oral intake and a 50-pound weight loss. Until recently the patient was managed with narcotics. On the most recent admission, the patient initially was successfully medically managed, but developed an allergy to the medication (carbamazepine) and failed subsequent attempts at medical management. After microvascular decompression of the left trigeminal nerve the patient reported complete resolution of symptoms.

Results
Initial routine brain MR did not elucidate a cause for facial pain. Follow-up MR protocled to include thin section multiplanar steady-state free precession (FIESTA) MR images revealed the left superior cerebellar artery contacting and deforming the left trigeminal nerve at the superior margin of the root entry zone (approximately 4 mm anterior to the pons). The more vulnerable segment of the trigeminal nerve is the centrally myelinated posterior portion when compared to the more resistant peripherally myelinated anterior portion. An imaging approximation is used to measure the cisternal segment of the trigeminal nerve from the pons to the porous trigeminus. The posterior 50% of the nerve roughly corresponds to the centrally myelinated portion and the anterior 50% roughly corresponds to the peripherally myelinated portion.

Conclusions
In this presentation, we report a case of medically recalcitrant trigeminal neuralgia caused by compression of the root entry zone of the nerve by the superior cerebellar artery successfully treated with microvascular decompression. Knowledge of the anatomy and more susceptible portion of the nerve as well as utilization of tailored MR protocols is necessary to correctly diagnose these patients.
Anomalous origins of bilateral anterior cerebral arteries (ACA) from the cavernous internal carotid arteries (ICA) with associated anomalies of the circle of Willis: MRA and CTA demonstration.

M Omolola¹, M White¹, S Pedavally¹
¹University of Nebraska Medical Center, Omaha, NE

Purpose
The purpose of our presentation is to describe a rare case of anomalous origins of the bilateral anterior cerebral arteries (ACAs) from the cavernous internal carotid arteries (ICAs) and associated anomalies of the circle of Willis demonstrated by CT angiography (CTA) and MR angiography (MRA) and review the clinical implications and embryologic reasons for such anomalies.

Materials and Methods
The ACA conventionally is a branch of the supraclinoid ICA emanating as one of the two terminal branches of the ICA. Very rarely, the ACA arises from the ICA at the level of the ophthalmic artery as the ‘infraoptic course of the ACA’. Bilateral anomalous origins are unusual and we present a case of anomalous origins of bilateral ACAs from the bilateral cavernous ICAs well below the origins of the ophthalmic arteries. This is a case report of anomalous origins of bilateral ACAs from the cavernous ICAs in a 68-year-old female being investigated for the cause of a subarachnoid hemorrhage. These anomalies were incidental and have nothing to do with the subarachnoid hemorrhage. The subarachnoid hemorrhage was due to a right vertebral artery aneurysm. Other associated anomalies include fenestration of the right A1, fenestration of an accessory A2, direct origin of the left PCA from the supraclinoid left ICA or MCA and conjoint origins of the left superior cerebellar artery and the hypoplastic left P1. We discuss possible clinical implications and embryologic origins of these anomalies.

Results
Initial noncontrast CT revealed a predominantly basal subarachnoid hemorrhage with mild intraventricular hemorrhage and hydrocephalus. CTA angiography at the same time revealed a right vertebral artery pear shaped aneurysm measuring 5.4 x 4.3 mm just distal to the origin of the PICA with attenuation of the terminal right vertebral artery. In addition, the bilateral anterior cerebral arteries originated from the distal cavernous ICA proximal to the origins of the ophthalmic arteries. The distal right A1 was fenestrated. An accessory A2 also showed a fenestration. The left posterior cerebral artery emanated from the left supraclinoid ICA (technically the left MCA since the ACA already originated more proximally than usual). There was a common origin of the left hypoplastic P1 and the left superior cerebellar artery. Digital subtraction angiography (DSA) confirmed the CTA findings. Follow-up MRA following treatment of the aneurysm confirmed the infraoptic course of the bilateral ACAs, the fenestrations on the right A1 and the accessory A2 as well as the left PCA anomalies (Figure).

Conclusions
This is a case of a 68-year-old patient with subarachnoid hemorrhage. During the course of the
investigation for the hemorrhage, it was discovered that she had a combination of rare anomalies that included infra-optic course of the bilateral ACA, fenestrations of the anterior cerebral arteries, direct origin of the left PCA from the left MCA and conjoint origin of the left hypoplastic P1 and the left superior cerebellar artery. The discussion centers around the clinical implications of these anomalies and embryologic origins of such anomalies.

Atypical Cortical Restricted Diffusion in Tacrolimus-Associated Neurotoxicity: A Report of Two Cases

K Amuluru¹, C Filippi²
¹Columbia University, New York, NY, ²Columbia University Medical Center, New York, NY

Purpose
Tacrolimus (FK-506) is an immunosuppressant drug discovered in 1984 by Fujisawa Pharmaceutical Co., Ltd. This drug belongs to the group of calcineurin inhibitors, which has been proven highly effective in preventing acute rejection after transplantation of solid organs. However, tacrolimus-induced neurotoxicity is a rare, yet documented, complication. The findings on MR imaging (MRI) are similar to those in cyclosporin A (CsA) toxicity and typically present in a pattern of posterior reversible encephalopathy syndrome (PRES). To the best of our knowledge, tacrolimus-induced neurotoxicity causing cortical restricted diffusion is an extremely rare imaging presentation. We report two cases thereof.

Materials and Methods
(Case 1) A 13-year-old female with aplastic anemia status post-bone marrow transplant in 2011, cryptogenic cirrhosis complicated by portal hypertension, thrombocytopenia and
hepatopulmonary syndrome was admitted for living donor liver transplant. She was started on FK-506 on postoperative day number one at a dosage of 2.5 mg twice daily. On postoperative day number four, her FK-506 level was supratherapeutic at 28.6 ng/mL. On postoperative day number five, she developed acute bilateral upper extremity shaking and eye deviation to the left. An MRI of her brain showed abnormal gyriform restricted diffusion involving the cortices of the bilateral frontal, parietal and posterior temporal lobes. The differential diagnosis was cortical ischemia, meningoencephalitis or medication-induced toxicity. Her Tacrolimus was held for three days, with a repeat level of 6.9 ng/mL. A repeat MRI of the brain done on postoperative day number 16 showed complete resolution of the gyriform cortical restricted diffusion. She was discharged on postoperative day number 30. (Case 2) A 70-year-old female with a history of hepatitis-C, cirrhosis and hepatocellular carcinoma status postliver transplant in 2001 with recurrence and repeat transplant in 2005 was admitted for increased confusion and weakness resulting in multiple falls. Her initial lab testing including basic metabolic panel, complete blood count and urinalysis were unremarkable. Her FK-506 level was measured to be 6.0 ng/mL. A noncontrast CT of the head showed no acute process. An MRI of the brain showed gyriform-restricted diffusion involving the cortices of the bilateral parietal, occipital lobes and the right temporal lobe.

Results
(Case 1) Axial diffusion-weighted sequence shows gyriform-restricted diffusion involving the cortices of the bilateral frontal, parietal and posterior temporal lobes in a symmetric distribution. (Case 2) Axial diffusion-weighted sequence shows gyriform-restricted diffusion involving the cortices of the bilateral parietal, occipital lobes and the right temporal lobe.

Conclusions
Tacrolimus-induced neurotoxicity after solid organ transplantation is a rare but known complication with an incidence of approximately 0.4 – 0.5%. It usually can be diagnosed on the basis of a characteristic clinical and radiographic pattern. Prior reports have described neurotoxicity with the development of a posterior reversible encephalopathy syndrome (PRES) imaging pattern. However, to our knowledge, cortical restricted diffusion is not a typical presentation of Tacrolimus-associated PRES. Many studies have shown that the neurotoxicity associated with tacrolimus may occur at therapeutic levels. In prior cases of tacrolimus-induced neurotoxicity, medication withdrawal often results in alleviation of toxicity, which was the case in one of the patients presented here. We present these cases in an effort to educate the neuroradiology community on the rare but varied patterns of tacrolimus-induced toxicity.

Fatal Outcome of Tissue Plasminogen Activator Administration in a Stroke-like Syndrome

S Cherian1, J Ginos1, R Suss1, M Pinho1, M Pezhouh1, R Fetzer1, A Whittemore1

1University of Texas Southwestern Medical Center, Dallas, TX

Purpose
To illustrate the potential insensitivity of computed tomography (CT) in detecting subacute subarachnoid hemorrhage (SAH), the importance of considering vasospasm as a possible cause for neurologic deficits, and the risk of tissue plasminogen activator (tPA) administration in the misdiagnosis of thrombotic stroke.

Materials and Methods
A 47-year-old Hispanic woman arrived to the emergency room with slurred speech and confusion that began two hours earlier. Her husband mentioned that she had been complaining of a headache for the last eight days. A noncontrast head CT obtained for "aphasia and headache"
revealed effacement of the left sylvian fissure and questionable left temporal lobe hypodensity without visible intracranial hemorrhage. The treating neurologist administered tPA and within 15 minutes the patient developed worsening headache, extreme hypertension, and subsequently became unresponsive and apneic. After intubation, a CT angiogram revealed SAH, diffuse cerebral edema, and lack of intracranial arterial perfusion. Autopsy revealed SAH concentrated near a 3mm aneurysm at the left internal carotid artery bifurcation.

Results
Noncontrast head CT images revealed subtle low attenuation of the left temporal lobe, effacement of the left sylvian fissure, and no convincing evidence of hemorrhage. Computed tomography angiography performed two hours later demonstrates diffuse subarachnoid hemorrhage with an asymmetric larger amount of blood in the left paraclinoid region. No intracranial vascular enhancement was present above the cavernous ICAs.

Conclusions
A large prospective study revealed that the sensitivity of a noncontrast CT for detecting SAH drops from nearly 100% within the first six hours of headache onset to 85.7% after six hours. (1) Cerebral vasospasm is most likely to occur four to 12 days after onset of SAH, and 35% of those with aneurysmal SAH experience neurologic symptoms associated with brain ischemia secondary to vasospasm. (2) We suspect that our patient's onset of headache eight days prior to her presentation was due to a sentinel aneurysmal bleed, that the patient's aphasia was secondary to vasospasm, and that subsequent tPA administration resulted in catastrophic aneurysmal rebleed. This case demonstrates the importance of considering an aneurysmal hemorrhage in a stroke-like syndrome with a negative CT. If radiologists are provided with a history of several days of headache, it may be prudent to inform clinicians of the decreased sensitivity of a CT head to detect nonacute SAH.

Imaging Beyond Common Neoplasms of the Sinonasal cavity.

J Nair\textsuperscript{1}, C Torres\textsuperscript{1}, P Zhiyu\textsuperscript{1}, M Zhang\textsuperscript{1}, J Chankowsky\textsuperscript{1}, R del carpio\textsuperscript{1}
\textsuperscript{1}McGill University Health Centre, Montreal, Quebec, Canada

Purpose
To revisit two very rare entities [(1) Nasal polyps with metaplastic ossification and (2) Respiratory epithelial adenomatoid hamartoma (REAH)] involving the sinonasal cavity and their characteristic imaging findings.

Materials and Methods
Case 1: A 67-year-old female presented with rhinorrhea, nasal obstruction and headache. She is a known case of nasal polyp for the past 18 months. Case 2: A 63-year-old male presented with two-year history of anosmia and posterior rhinorrhea, not relieved by antibiotic treatment.

Results
Case 1: Multiplanar computed tomography (CT) scan of the sinuses with bone and soft tissue
window reveal a mucosal mass with central linear calcification in the posterior aspect of the right nasal cavity. The lesion extended through the posterior choana into the nasopharynx, associated with obstruction of drainage of the right posterior ethmoid air cells. The CT findings were consistent with a nasal polyp with metaplastic ossification. Case 2: Multiplanar CT scan of the sinuses with bone and soft tissue window reveal widening of the left nasal vault by the presence of a soft tissue lesion, which extends posteriorly into the left sphenoid sinus through the sphenoethmoidal recess. The lesion fills the olfactory recess, obstructs the left cribriform plate, also displaces the septum towards the contralateral side with obstruction of the right cribriform plate accounting for the patient's anosmia.

Conclusions
1) Although rare, metaplastic ossification can occur within nasal polyps and possibility should be raised when one visualizes benign-looking sinonasal mass with centrally located radiodensity on CT scans. 2) REAH though rare, should be included in the differential diagnosis of a symptomatic sinonasal mass to prevent unnecessary aggressive surgical intervention of this benign lesion. 3) Finally the radiologist should be familiar with the imaging findings of these two rare entities involving the sinonasal cavity.

Imaging of Supraclavicular Nerve Perineural Spread with Operative Correlation.

L Alsarraf¹, K Shah², A Hessel², M Williams², L Ginsberg²
¹Baylor College of Medicine, Houston, TX, ²University of Texas MD Anderson Cancer Center, Houston, TX
Purpose
To describe a novel case of perineural spread (PNS) along the intermediate branch of the supraclavicular nerve, correlated with operative findings. Relevant anatomy of this branch of the cervical plexus is reviewed.

Materials and Methods
A 61-year-old man who had prior excision of skin cancer on the upper anterior chest, noticed growth of a painless left lower anterior neck mass over three months. Biopsy revealed poorly differentiated carcinoma. Perineural spread was proven by surgical excision and histopathologic examination.

Results
Left, contrast-enhanced axial CT scan of the neck showed an irregularly marginated subcutaneous tumor implant (asterisk) lateral to the left sternocleidomastoid muscle and external jugular vein. A curvilinear, cord-like structure (arrow) extended medially from the tumor implant, traversing the posterior triangle of the neck and coursing towards the left C3-C4 neural foramen. The cord-like structure corresponded anatomically to the abnormally thickened intermediate branch of the supraclavicular nerve. Right, hematoxylin and eosin section at 70x shows normal wavy nerve fibers and their spindled nuclei (between arrows) interspersed with perineural invasion by poorly differentiated carcinoma cells that have large round nuclei (arrowheads). The asterisk shows surrounding desmoplastic reaction.

Conclusions
Anatomy Review: The cervical plexus is formed from C1-C4 nerve roots. The ventral rami of C3-C4 contribute to the supraclavicular nerve. The supraclavicular nerve emerges from beneath the posterior border of the sternocleidomastoid muscle and divides into an anterior (or medial) branch, a posterior (or lateral) branch and an intermediate branch. The intermediate branch provides sensory innervation to the skin over the clavicle, anteromedial shoulder, and proximal chest. Perineural extension is a well described mode of head and neck cancer spread, generally along branches of cranial nerves. Perinural spread along spinal nerves is uncommon, with prior reports of only the great auricular branch of the cervical plexus being involved. We report the first case of PNS along the supraclavicular nerve branch of this plexus. Recognition of this type of spread requires knowledge of the relevant neuroanatomy, as well as the typical imaging features of perineural tumor spread.

Inadvertent MRI/MRV Imaging Following Administration of Intravenous Ferumoxytol (Superparamagnetic Iron Oxide Nanoparticles) Resulting in Profound Vascular Signal Artifacts

T Kaufmann¹, C Carr¹, N Campeau¹
¹Mayo Clinic, Rochester, MN

Purpose
To describe the confounding brain MR imaging (MRI) findings in a patient who recently had received intravenous ferumoxytol for treatment of iron deficiency, the administration of which was unknown to the interpreting radiologist.

Materials and Methods
A 38-year-old female patient with history of total gastrectomy with esophagojejunostomy, iron deficiency, and clotting disorder underwent routine head MRI and MRV for chronic headaches and action tremor. Head imaging was essentially normal except for the gradient echo and susceptibility-weighted imaging, which were very unusual, as described below. These findings were initially a diagnostic dilemma. After discussing with the referring neurologist, who then conferred with the patient's gastroenterologist, it was realized that the patient had received IV ferumoxytol (Feraheme) for iron deficiency (plasma ferritin 7 mcg/L) two days prior to MRI. Ferumoxytol consists of superparamagnetic iron oxide nano particles and is an approved treatment for iron deficiency in individuals with chronic renal disease, but it is not yet approved
as an MRI contrast agent. The imaging findings were fully consistent with this history of recent intravenous ferumoxytol administration, which caused very exaggerated susceptibility-related signal loss in intracranial blood vessels.

Results
Standard clinical T1-weighted, T2-weighted (Figure 1A), T2-weighted FLAIR, and post-gadolinium contrast T1-weighted MRI as well as gadolinium bolus MRV of the head were performed on a 1.5 T scanner and were judged to be completely normal. However, a gradient echo T2*-weighted (GRE) sequence also was performed, which showed abnormally very prominent signal loss throughout the subarachnoid spaces reminiscent of superficial siderosis, versus in subarachnoid blood vessels, but also in small parenchymal veins. This GRE appearance was similar to that seen normally with susceptibility-weighted imaging (SWI). The GRE was repeated and was unchanged. Susceptibility-weighted imaging then was also performed (Figure 1B), and the degree of signal loss throughout the superficial and deep cerebral vasculature also was much more profound than usual. Superficial siderosis did not seem likely, as there seemed to be a diffuse vascular abnormality uniformly throughout the intracranial compartment. Findings were, however, compatible with an exaggerated loss of signal intensity on T2*- and susceptibility-weighted images from an intravascular USPIO (ultrasmall super paramagnetic iron oxide) nanoparticle such as ferumoxytol.

Conclusions
Ferumoxytol is a USPIO which is FDA-approved for the treatment of iron deficiency anemia in patients with renal failure, as it is not renal excreted (1). It also has high r1 and r2 relaxivity values of 15 and 89, respectively, and so it has been used in brain imaging as an experimental contrast agent (2, 3). It persists in the vasculature longer than gadolinium-based contrast agents, affecting MRI scans for up to three months following IV infusion for iron deficiency, though effects are maximal at 1-2 days. It only slowly traverses the disrupted blood-brain barrier, an advantage in first pass T2*-weighted dynamic susceptibility contrast (DSC) perfusion. It also is gradually taken up by inflammatory cells such as macrophages, which provides unique information on delayed T1-weighted imaging in inflammatory and neoplastic diseases. However, there has not been much description of the T2*- or susceptibility-weighted imaging appearance of intracranial ferumoxytol. Its very strong effect on transverse relaxivity creates a predictable, very exaggerated signal loss throughout the vasculature on these pulse sequences, such as in this present case. Awareness of the MRI appearance of intravenous ferumoxytol is important to avoid additional imaging or unnecessary medical intervention. Very exaggerated and diffuse intravascular paramagnetic effects on T2*- or susceptibility-weighted imaging should prompt one to consider prior iron oxide nanoparticle infusion such as for iron deficiency anemia.

Inflammatory Pseudotumor of the Nasopharynx: A Case Report

J Nair¹, J Chankowsky¹, C Torres¹, S Lam¹, M Robichaud¹, H Remy¹, R del carpio¹
¹McGill University Health Centre, Montreal, Quebec, Canada

Purpose
1) To describe the imaging findings of inflammatory pseudotumors (IPTs) involving the nasopharynx. 2) To differentiate IPTs from nasopharyngeal carcinoma (NPC).

Materials and Methods
A 87-year-old male presented with severe unrelenting headaches and recent onset facial numbness and facial palsy. Review of the database revealed similar stable findings on previous computed tomography (CT) scan of the brain done for trauma.

Results
Computed tomography scan of the brain and base of skull reveals nasopharyngeal soft tissue predominantly involving the left side and extending across the midline with destruction of the clivus and left carotid canal. Significant narrowing of the petrous segment of left internal carotid artery also noted. There was complete opacification of the left mastoid air cells. MR imaging (MRI) redemonstrated soft tissue mass lesion in the left posterolateral aspect of the
nasopharynx with destruction of the clivus, left petrous apex and narrowing of the petrous segment of left internal carotid artery. Important points to differentiate IPTs from NPC are: 1) Hpointense mass lesion compared to brain parenchyma while NPC are more hyperintense, 2) Internal carotid artery encasement and resultant narrowing are common features in cases of IPT but not NPC.

Conclusions
Inflammatory pseudotumor of the nasopharynx is a great mimicker of nasopharyngeal carcinoma. The clinician should be aware of this disease process and investigate patients, combining clinical presentation, imaging characteristics and possible histological evidence to arrive at a correct diagnosis.

Magnetic Resonance Imaging Findings of Infantile Myofibromatosis

P Naidu¹, J Egelhoff³
¹Phoenix Childrens Hospital, Phoenix, AZ

Purpose
We describe the magnetic resonance imaging (MRI) features of infantile myofibromatosis involving the neck and paraspinal soft tissues to familiarize other radiologists with this rare condition.

Materials and Methods
A 7-week-old with expanding right lateral temporal and left posterior neck masses underwent MRI for further delineation of the abnormality. Following MRI, the lesion in the right temporal region was biopsied and the left posterior neck lesion was surgically excised. Histopathologic findings were consistent with a diagnosis of myofibromatosis.

Results
MR imaging demonstrated an expansile oval mass within the right suprazygomatic masticator space. The mass was T1 hypointense, T2 centrally hyperintense, peripherally hypointense, and peripherally enhancing on subsequent contrast-enhanced examination. It measured 2.7 x 1.5 x 2.4cm and was difficult to separate from adjacent musculature. An additional mass with similar signal characteristics was present in the left posterior cervical triangle, measuring up to 1.0cm. A lesion within the left thoracic paraspinal soft tissues had slightly different characteristics-central mild T1 hyperintensity, T2 hypointensity with peripheral T1 hypointensity, and T2 hyperintensity. This abnormality decreased in size on subsequent examination.

Conclusions
Infantile myofibromatosis is part of the spectrum of musculoskeletal fibromatoses. While some authors describe it as the most common fibrous tumor of infancy, the entity rarely is encountered in daily practice. Myofibromas may be solitary or multifocal, with well defined or infiltrative margins; they spontaneously regress in about 30% of patients. The head, neck, and trunk are common areas of involvement. Lesions may be found in multiple organ systems, including skin, bone, muscle, viscera, and, rarely, the central nervous system. Visceral involvement is a poor prognostic indicator, carrying a mortality rate of up to 75%. The overall mortality rate for
infantile myofibromatosis approximates 15%. The recognition of myofibromatosis may guide management by prompting further imaging to delineate the extent of systemic involvement, particularly of the viscera.

Perineural Spread of Adenoid Cystic Carcinoma Mimicking a Cavernous Sinus Meningioma

D Dunaway¹, P Gidley², P Brown², L Ginsberg², S Ahmed²
¹Baylor College of Medicine, Houston, TX, ²MD Anderson Cancer Center, Houston, TX

Purpose
We present a case of intracranial perineural spread of nasopharyngeal adenoid cystic carcinoma mimicking cavernous sinus meningioma.

Materials and Methods
A 62-year-old female presented with a five-year history of left ear discomfort and discharge, thought to be secondary to Eustachian tube dysfunction and treated with repeated myringotomy and tubes. She subsequently developed numbness and tingling in the V2 distribution of her face as well as decreased sensation over the left eye while applying makeup. She reported a lack of tearing in the left eye, requiring eye drops. Brain MR imaging (MRI) at an outside facility demonstrated a mass lesion involving Meckel's cave and the cavernous sinus, and interpreted as either meningioma or schwannoma. The patient was referred to our institution for radiation therapy options for a presumed benign lesion. Physical examination revealed left nasopharyngeal soft tissue fullness and a left tympanic membrane perforation and a middle ear mass. Cranial nerve testing revealed deficits in all three branches of the trigeminal nerve. Extraocular movements and facial nerve function were normal.

Results
MR imaging obtained for treatment planning purposes confirmed a mass in the left Meckel's cave and the cavernous sinus, with retrograde extension along the main trunk of the left trigeminal nerve. Based on the concern that this was not a meningioma, further high-resolution skull base imaging was obtained and revealed abnormal enhancement in foramen ovale, and enhancing submucosal fullness in the upper masticator space and submucosa of the left nasopharynx. Additionally, from Meckel's cave, there was posterolateral perineural enhancing tumor spread along the greater superficial petrosal nerve to involve the geniculate ganglion and the labyrinthine segment of the left facial nerve. The patient underwent biopsy of the left middle ear mass revealing adenoid cystic carcinoma with cribriform and solid patterns. Given the overall extent of tumor spread, the patient was not a candidate for surgical resection. She was dispositioned to definitive chemoradiation with proton therapy and cisplatin-based chemotherapy.

Conclusions
Perineural spread of tumor, particularly adenoid cystic carcinoma, can mimic other head and neck lesions. Submucosal malignancy of the nasopharynx, specifically, may spread by this mechanism to the cavernous sinus or Meckel's cave, and be misdiagnosed as nerve sheath tumors.
or meningioma. If treatment for a benign lesion is undertaken without histologic sampling, the primary cancer may go undiagnosed with disastrous consequences, and so accurate imaging is of critical importance.

Pterygoid Hamulus Syndrome: Imaging Findings in an Unusual Cause of Soft Palate Pain.

L Wing¹, T Matys², N Antoun², T Massoud³
¹John Radcliffe Hospital, Oxford, UK, ²Cambridge University Hospitals NHS Foundation Trust, Cambridge, UK, ³Stanford University School of Medicine, Stanford, CA

Purpose
We report a rare case of an abnormally elongated pterygoid hamulus in a patient presenting with soft palate pain (pterygoid hamulus syndrome). We review this curious entity and present an imaging review of other pathologies of the soft palate with reference to the anatomy of this region.

Materials and Methods
A 63-year-old male patient presented to the Maxillofacial Surgery clinic with a seven-month history of bilateral pain in the lateral aspects of the soft palate. On examination, prominent bilateral bony structures were palpable with keratinization of the overlying mucosa. A diagnosis of pterygoid hamulus syndrome was made following CT imaging of facial bones. The patient was treated conservatively with oral anti-inflammatory drugs and local steroid injections.

Results
We performed spiral CT acquisition through facial bones with high resolution bone algorithm axial reconstruction and multiplanar reformats. This revealed bilateral enlarged hamuli of the pterygoid bones, each measuring 14mm in length (normal length 5-6mm). These hamuli were oriented towards the midline and hooked in configuration. The differential diagnoses of soft palate pain is wide. In this exhibit we demonstrate and review the computed tomography (CT) and MR imaging (MRI) appearances of peritonsilitis, malignancy, impacted teeth and trauma.

Conclusions
Pterygoid hamulus syndrome is rare with approximately 40 cases reported to date. Conservative treatment usually is sufficient, but persistent symptoms warrant surgical management which involves exposure of the hamuli by blunt dissection or resection of the hamuli. This case demonstrates the importance of recognizing abnormal anatomical structures in a region often overlooked on CT.

KEYWORDS: CT Anatomy, Oropharynx, Pain
Revisiting the Utility of the "Open-Ring" Sign in the Diagnosis of Demyelinating Disease.

A Golombeck¹, M Kinon¹, J Graber¹, P Lasala¹, T Miller², J Farinhas¹
¹Montefiore Medical Center, Bronx, NY, ²Albert Einstein College of Medicine, Bronx, NY
Purpose
Multiple sclerosis (MS) is the most common demyelinating disease, classically presenting as multiple ovoid periventricular white matter hyperintensities perpendicular to the corpus callosum on T2-weighted MR imaging (MRI). This characteristic appearance often locks in the diagnosis of MS. A solitary lesion in the cerebral hemisphere of a patient without a history of demyelinating disease results in a diagnostic dilemma; the differential diagnosis then includes infectious, inflammatory, and neoplastic entities. Additionally, the open-ring enhancement pattern on postgadolinium MR imaging is highly specific for the diagnoses of demyelinating lesions and extremely useful in atypical cases. We report a case of glioblastoma multiforme (GBM), with the "open-ring" pattern of enhancement, mimicking a demyelinating lesion.

Materials and Methods
A 55-year-old previously healthy male presented with a postconcussive syndrome. Initial neurologic examination revealed no focal deficits or other abnormalities. A head CT and brain MRI were obtained for further evaluation.

Results
MR imaging demonstrated a 1.5 cm lesion in the right periventricular white matter of the temporal lobe. There is minimal surrounding edema and mass effect. Postcontrast imaging demonstrated an open-ring enhancement pattern.

Conclusions
The patient's clinical status worsened; repeat imaging demonstrated marked enlargement of the lesion and closed-ring enhancement, along with multiple satellite lesions. The patient underwent biopsy and debulking of the lesion. Neuropathology revealed GBM. Although the open-ring sign is highly specific for demyelination, high-grade neoplasms may demonstrate this finding. Therefore, advanced imaging modalities such as perfusion imaging and spectroscopy should be entertained, along with follow-up imaging in these atypical cases, even when the open-ring sign is appreciated.

Sacral nerve root neurocytoma.

N Guha-Thakurta, L Langford
MD Anderson Cancer Center, Houston, TX

Purpose
Neurocytomas typically are well differentiated tumors of the central nervous system (CNS) and predominantly arise intracranially within the lateral ventricles. They occur in young and middle-aged adults, and have no sex predilection. Herein we report the first case of a sacral nerve root neurocytoma and its management.

Materials and Methods
A 49-year-old man presented with a seven-month history of back pain and right S1 radiculopathy diagnosed on EMG.

Results
Magnetic resonance imaging (MRI) of the spine demonstrated an extramedullary enhancing lesion at the right S1 level with the primary imaging diagnostic consideration of a nerve sheath tumor. The patient subsequently underwent surgery with a final histopathological diagnosis of a neurocytoma of the S1 nerve root.

Conclusions
Neurocytomas in the spinal cord are extremely rare. They appear to have a propensity for the
male population and can present at ages ranging from eight to 72 years. Majority of spinal cord neurocytomas present as an intramedullary cord lesion. Its occurrence along a sacral nerve root has not been described before and on such occasions it can be mistaken for a schwannoma. The treatment of choice is surgery with adjuvant radiotherapy advocated only in cases with anaplastic features and high MIB-1 labeling index.

Spinal subdural space enlargement with subdural enhancement in adults after craniocervical surgery.

R Samant¹, R Fitzgerald¹, R Ramakrishnaiah¹, M Kumar¹, R Van Hemert¹, E Angtuaco¹ ¹University of Arkansas for Medical Sciences, Little Rock, AR

Purpose
Spinal subdural space enlargement and enhancement after suboccipital craniotomy is a known observation in the pediatric neuroradiology literature. This benign postoperative MR imaging (MRI) finding also can be seen in adults who have undergone intrathecal surgery at the cranio-cervical junction. The aim of this exhibit is to discuss the proposed physiologic mechanism responsible and acquaint radiologist of this finding to prevent misdiagnosis.

Materials and Methods
Case Report: We present two cases of patients who underwent intrathecal surgery at craniocervical junction and upper cervical spine and were noted to have an enlarged enhancing subdural space throughout the cervical and thoracic spine on immediate postoperative MRI. The findings resolved within 10 days in both the cases. Case 1: A 58-year-old male patient who presented with neck stiff and shoulder pain underwent an MRI of the C-spine, which revealed a 2cm enhancing lesion in the lower half of the 4th ventricle. An ependymoma was in the differential. The immediate postsurgical MRI for extent of resection evaluation revealed an enlarged subdural space with diffuse enhancement throughout the spinal canal. There was no T1 hyperintensity. The patient was asymptomatic and there was no signal abnormality in the cord. A postsurgical subdural hematoma was included in the provisional diagnosis. A follow-up scan on day eight demonstrated complete resolution of the findings. Case 2: A 40-year-old male patient with a history of NF-1 presented with gradually progressing weakness in all four extremities. Postcontrast MRI of the cervical spine revealed a 3.5cm neurofibroma at C3-4 causing significant mass effect on the cord with intramedullary T2 hyperintensity. An emergent cervical decompression with neurofibroma resection was performed. The immediate postsurgical MRI revealed subdural space enlargement and enhancement throughout the lower cervical and thoracic spinal canal. Even though there was no T1 hyperintensity on noncontrast imaging, a postsurgical subdural hematoma was considered. A repeat postcontrast MRI on day six after surgery demonstrated resolution of the findings.

Results
Immediate postsurgical postcontrast Sag and Axial T1 images of the cervical and thoracic spine demonstrate enlargement of the subdural space with diffuse uniform enhancement. There is mild
to moderate narrowing of the spinal subarachnoid cerebrospinal fluid (CSF) space. On the follow-up scan (not uploaded at this time), there is complete resolution of the findings.

Conclusions
Enlargement with diffuse enhancement of the spinal subdural space on immediate postoperative scans after suboccipital craniotomy is a described finding in the literature (1). Posterior fossa neoplasms are common in children and radiologists working with pediatric scans are aware of this finding. This finding may be obscure to radiologist working mainly with adult patient imaging and this may result in misdiagnosis and unnecessary further evaluation with a potential of unrequired surgery. Educating radiologist of this benign finding will result in appropriate patient management.

A Rare Case of a Retromandibular Varix Presenting as a Parotid Mass

G Reddy¹, A Naidu², P Torrei³

¹Rutgers-Robert Wood Johnson University Hospital, Jersey City, NJ, ²Rutgers-Robert Wood Johnson University Hospital, New Brunswick, NJ, ³University Radiology Group, East Brunswick, NJ

Purpose
To describe a rare case of a retromandibular varix presenting as a parotid mass in a patient with locally advanced supraglottic carcinoma.

Materials and Methods
An 88-year-old male with a history of supraglottic squamous cell carcinoma presented with an enlarging and asymmetric left parotid mass concerning for metastatic spread of disease. The patient underwent a contrast-enhanced computed tomography (CT) of the soft tissue neck as well as a subsequent sonogram of the mass with Doppler to complete the work up of the suspicious mass. Upon confirming the diagnosis of a retromandibular varix, the patient completed his outpatient treatment without the need for tissue sampling of his parotid mass.

Results
A contrast-enhanced CT of the soft tissues of the neck through the level of the parotid glands demonstrates a 4.2cm tubular low attenuating mass in the deep left parotid gland. There is an enhancing and dilated left retromandibular vein contiguous with the posteromedial aspect of the mass. Subsequent color Doppler images of the palpable left parotid mass demonstrate a dilated vessel that corresponds to the mass seen on the prior CT and therefore represents a varix of the left retromandibular vein. A follow-up PET/CT two weeks later as part of the patient's routine cancer work up confirmed the nonhypermetabolic nature of the left retromandibular varix.

Conclusions
A varix of the retromandibular vein (posterior facial vein) presenting as a parotid mass is a very rare entity that to our knowledge has been reported only once in the otolaryngology literature. Varices of the cervical and facial regions are particularly rare given the low pressure system and are seen more typically in patients with thoracic outlet syndrome or following trauma. Identifying a suspicious parotid mass as a vascular structure is an important diagnosis in order to prevent potentially disastrous complications upon biopsy. Slow flow through the varix can hinder diagnosis on contrast-enhanced studies due to lack of enhancement. Therefore, implementing appropriate radiological imaging, such as a Doppler sonogram, becomes an essential component of the diagnostic work up to prevent unnecessary and potentially harmful interventions.

An Unusual Case of Cholesterol Granuloma of the Orbit

W Chwang¹, P Doshi¹
¹Henry Ford Hospital, Detroit, MI

Purpose
Orbital masses can be difficult to diagnose, as they often have overlapping clinical and imaging features. We present an unusual case of cholesterol granuloma of the orbit, a common radiographic lesion occurring in an uncommon location. Understanding the imaging
characteristics of a cholesterol granuloma will help the radiologist include it appropriately in the differential diagnosis.

Materials and Methods
An 80-year-old male was referred to Ophthalmology clinic with progressive left eye proptosis over one year. The patient had a history of blunt injury to the left eye 20 years ago, after which he has been able to see only shadows. However, during the past year he has had increasing proptosis along with pain and redness of the left eye. The patient was placed on steroid eye drops, and was told he has a tumor behind the left eye. So far he had declined surgical options, but now with worsening symptoms the patient wished to reevaluate his tumor and undergo surgery. The patient was taken to the operating room for a left ocular enucleation, anterior orbitotomy, resection of the mass, and placement of an orbital implant. The patient tolerated the procedure well. The pathology result from the surgical specimen was reported as cholesterol granuloma.

Results
Computed tomography (CT) images demonstrate a well-defined soft tissue mass arising from the superolateral postseptal left orbit, causing adjacent mass effect and proptosis as well as smooth bony remodeling of the left lateral orbital wall and orbital roof. MR images demonstrate homogeneously high T1 signal and heterogeneous T2 signal within the mass, with few areas of curvilinear low T2 signal and a well-defined low T2 rim. There is no significant enhancement within the mass. The findings are compatible with a slow-growing hemorrhagic lesion of the postseptal orbit. The differential diagnosis includes cholesterol granuloma, cavernous hemangioma, hemorrhagic mesenchymal tumor, and hemorrhagic nerve sheath tumor.

Conclusions
Cholesterol granuloma of the orbit is an uncommon cause of an orbital mass. Recognizing the features of internal hemorrhage, no enhancement, and smooth, expansile bony remodeling is important for suggesting this diagnosis, especially since the orbit is an atypical location for this lesion.

Coexisting Papillary Thyroid Carcinoma (PTC) and Primary Thyroid Large Cell Lymphoma

S Ahmed1, S Parrada Orego2, H Elamir3, E Grubbs1, M Williams1
1The University of Texas MD Anderson Cancer Center, Houston, TX, 2US Teleradiology, Atlanta, GA, 3The University of Texas Health Science Center at Houston, Houston, TX

Purpose
We present an unusual case of coexisting PTC and thyroid lymphoma with lateral compartment lymphadenopathy (LAD) from both entities. The typical ultrasound (US) and computed tomography (CT) findings of these two entities are reviewed.

Materials and Methods
A 64-year-old male presented with cervical lymphadenopathy, night sweats, and 35 lb weight loss.

Results
Computed tomography showed a large left thyroid mass with tracheal deviation, and bilateral, multilevel, LAD with both cystic and solid nodes. Fine-needle aspiration (FNA) of the left thyroid mass and left neck node revealed large cell lymphoma. Following three cycles of chemotherapy, the patient self-referred to MDACC for an enlarging right neck mass. Positron emission tomography (PET)-CT demonstrated resolution of the left thyroid mass and improved lymphadenopathy, without residual FDG avid disease. However, a cystic right neck node had increased in size. Fine-needle aspiration and core biopsy of the cystic node were both nondiagnostic. Thyroid ultrasound demonstrated hypoechoic masses in both lobes. Repeat FNA of the right cystic neck node for assessment of the FNA cyst fluid for thyroglobulin (Tg) level (Result Tg=152590) also demonstrated PTC on this repeat cytology. Patient underwent total thyroidectomy and bilateral neck dissection, demonstrating multifocal PTC with multiple metastatic lymph nodes.

Conclusions
Coexisting thyroid lymphoma and papillary thyroid carcinoma (PTC) is very rare. Cystic nodes and microcalcification within nodes are not associated with lymphoma, and raise the concern for coexisting PTC. While preferred in cases of lymphoma, core biopsy can be nondiagnostic when dealing with cystic nodes from PTC. Fine-needle aspiration can be acellular with cystic nodes, and Tg assay is essential to establishing a diagnosis of metastatic PTC.

Cutaneous Angiosarcoma Presenting With Dermal and Parotid Invasion.

J Bapuraj¹, J Gudjonsson¹, R Egbers¹, I Meesa¹, L Lowe¹, A Srinivasan¹
¹University of Michigan Health System, Ann Arbor, MI
Purpose
To highlight an unusual imaging and clinical presentation of a facial angiosarcoma, a rare neoplasm of the head and neck.

Materials and Methods
A 54-year-old man presented to the ER room with a nonhealing facial lesion and acute right-sided facial swelling. The lesion appeared four months prior as a "sore" in the middle of his forehead. Approximately a week before the ER visit, he began to have swelling in his right jaw, which progressed significantly to prompt him to seek immediate medical assistance. On clinical evaluation the patient showed a swelling along the right face from the pre-auricular region to the submandibular area. A purpuric vascular midline lesion with central ulceration and erythema was noted on the forehead. Ill-defined erythema was present surrounding this lesion and extending along the right face to the submandibular region. A soft subcutaneous mass was palpable in the latter location. A punch biopsy of the ulcer and computed tomography (CT) of the head and maxillofacial region was performed. Biopsy from the ulcerated portion of lesion showed a high grade angiosarcoma.

Results
The CT studies showed contiguous soft tissue edema, fat stranding, and streak-like linear densities limited to the superficial portion of the right parotid gland and surrounding subcutaneous tissues extending to the forehead. Focal soft tissue stranding with excavation at the site of the forehead ulcer was observed. A presumptive diagnosis of dermal and parotid gland involvement was made.

Conclusions
The CT studies showed contiguous soft tissue edema, fat stranding, and streak-like linear densities limited to the superficial portion of the right parotid gland and surrounding subcutaneous tissues extending to the forehead. Focal soft tissue stranding with excavation at the site of the forehead ulcer was observed. A presumptive diagnosis of dermal and parotid gland involvement was made.

Cutaneous head and neck angiosarcoma mimics hematoma after neck mass biopsy

T Ng¹, D Parker¹, R Beck¹, E Paplomata¹, A Fountain¹, S Dehkharghani²
¹Emory University, Atlanta, GA, ²Emory University Hospital, Atlanta, GA

Purpose
To illustrate an unusual and previously unreported manifestation of head and neck angiosarcoma mimicking soft tissue hematoma following biopsy of a presumed venolymphatic malformation (VLM).

Materials and Methods
A 61 year old African American female presented with a painless, 1 cm right neck mass. Past history was significant for 40-pack-year tobacco use. CT demonstrated an ill-defined fluid collection, which following biopsy revealed benign lymphocytes without evidence of malignancy. Clinical, radiologic, and histopathologic features at presentation and follow up were favored to represent a VLM. Three weeks following biopsy, the mass had dramatically enlarged, extending beyond the right ear and towards the eye. CECT was favored to represent an enlarging periprocedural hematoma. Despite non-healing, multidisciplinary ENT, dermatologic, vascular surgical, and infectious disease consultation again supported the diagnosis, and the patient was discharged with a presumptive diagnosis of procedural hematoma following VLM biopsy. Two weeks later, the mass had grown and became increasingly purpuric and hemorrhagic, and the right eye was increasingly edematous. Repeat CECT suggested cellulitis, myositis and fasciitis.
MRI followed, and findings were compatible with an evolving chylous collection. Repeat biopsy revealed marked atypical, ecstatic vascular channels diffusely infiltrating tissue consistent with angiosarcoma. Unfortunately, the patient was not a candidate for surgical resection and began palliative doxorubicin/ifosfamide. She passed away one month after diagnosis due to a large pulmonary embolism.

Results
CECT at presentation (Fig. 1) demonstrated a discrete fluid collection abutting the thyroid and enveloping the cervical vessels. Vague adjacent edema extended towards the supraclavicular soft tissues. Follow up CT showed multiple ill-defined pockets of fluid and soft tissue stranding extending from the right supraclavicular region to the right facial soft tissues and scalp. No aggressive osseous findings were present at the calvarial interface. A rim enhancing fluid collection in the deep cervical fascia was believed to represent VLM, possibly with superimposed infection. Findings were overall favored to represent a hematoma secondary to VLM biopsy. Fat-suppressed T2-weighted MRI (Fig. 2) exhibited a transpatial, multi-cystic fluid intensity tracking along the posterior right neck fascial planes into the face. Foci of signal loss were believed to reflect venous channel rather than flow voids. No definite fluid-fluid levels. Imaging features were felt to be compatible with presumptive mixed malformation. Post-contrast T1-weighted images showed vague areas of enhancement, which were more confluent overlying the upper cervical and scalp soft tissues. While greater than expected for VLM, superimposed reactive or inflammatory enhancement was favored.

Conclusions
Head and neck angiosarcoma is a rare and highly aggressive vascular proliferative neoplasm. Most cases occur in geriatric Caucasian patients with only 4% of cases in African-Americans. Angiosarcomas are often diagnosed late; prognosis is poor. Typical imaging features are characterized as an enhancing mass with hypervascular flow voids. Hemorrhage following biopsy is well-described, and clinical and imaging features generally indicate aggressiveness. The rare manifestation reported within this case mimicked the presence of a far less sinister process, suggesting VLM at presentation, with presumed periprocedural hematoma on multiple subsequent examinations. The confounding features in this case, including the paucity of distinct flow voids, and absence of a discrete mass or aggressive features, in the setting of recent biopsy, resulted in misdiagnosis over four hospital admissions and delayed treatment. The findings in this case emphasize the need for careful inspection and surveillance of atypical or slow-healing head and neck lesions, and illustrate a potential diagnostic pitfall in clinical ENT imaging.

Ecchordosis Physaliphora Meningocele with CSF leak

J Choi

University of Texas Houston Health Science Center, Houston, TX

Purpose
Few cases of meningocele and cerebrospinal fluid (CSF) leak related to the notochordal remnant ecchordosis physaliphora (EP) have been described (1-3). MR imaging characteristics of EP have been described previously in the neuroradiological literature (4). A description of MRI findings of CSF leak related to EP in the neuroradiological literature however, is useful to reinforce this differential consideration in a patient with CSF leak emanating from a defect in the sphenoid sinus.

Materials and Methods
A 47-year-old female presented with several month history of profuse clear rhinorrhea. She denied a history of trauma and showed no meningeal signs. Computed tomography scan showed a defect in the posterior wall of the right sphenoid sinus with suggestion of a bony stalk and a fluid filled sinus. MR imaging showed a lobulated gelatinous lesion protruding through the sinus wall defect with CSF communicating between the intracranial compartment and sinus. The patient was taken for endoscopic repair where a meningocele was found at the site of defect and reduced back into the intracranial compartment. Unfortunately, no tissue sampling was performed. Dural graft with overlying mucosal graft was used to cover the defect and the patient has since had no recurrence of rhinorrhea.

Results
Sagittal T2 sequence shows a lobulated T2 hyperintense lesion extending from the posterior aspect of the clivus through the sphenoid sinus wall defect. Cerebrospinal fluid communicates freely between the intracranial compartment and sinus.

Conclusions
Cerebrospinal fluid leak related to EP and associated meningocele is reported rarely. Although no histologic confirmation was obtained in this case, the imaging findings are consistent with
those reported in similar cases in the neurosurgical and otolaryngological literature. Imaging features presented in the neuroradiological literature hopefully will be a ready aid for the practicing radiologist in forming a differential diagnosis in a patient presenting with CSF leak emanating from the sphenoid sinus.

Ectopic External Auditory Canal and Ossicular Formation in Goldenhar Syndrome

N Supakul¹, C Ho¹
¹Indiana University School of Medicine, Indianapolis, IN

Purpose
To demonstrate previously unreported finding of ectopic external auditory canal and rudimentary ossicular formation in a case of Goldenhar syndrome.

Materials and Methods
A 4-year-old girl with a diagnosis of Goldenhar syndrome, presents with right hemifacial and auricular microsomia, associated with hearing deficit. She also exhibited congenital progressive scoliosis with multiple vertebral segmental anomalies as well as radial hypoplasia and
underdeveloped thumbs. A CT of the temporal bone without contrast was performed to evaluate for potential reconstruction of the right ear with hearing aid placement.

Results
CT temporal bone demonstrated ectopic location of a small, malformed right pinna and external auditory canal, terminating in a hypoplastic temporomandibular joint. Rudimentary ossicle formation is noted within the hypoplastic temporomandibular joint. At the expected location of the middle ear cavity, there is a hypoplastic aerated cavity without visualization of typical mesotympanic structures, including the ossicles. The right inner ear and internal auditory canal are within normal limits. In addition, there is hypoplasia of the right zygomatic arch, mandible and mandibular condyle, consistent with hemifacial microsomia. Figures: Coronal CT of the temporal bone demonstrates a hypoplastic right temporal mandibular joint articulating with a hypoplastic condyle and zygomatic arch. A medial rudimentary ossicle (white arrow) can be seen within the joint. Axial oblique reformats show the rudimentary ossicle (white arrow) with a small focal aeration (black arrow) connected to a severely atretic and ectopic external auditory canal with malformed pinna (black arrows). The expected posterior location of the left middle ear cavity is hypoplastic.

Conclusions
Goldenhar syndrome (aka oculoauricolovertebral dysplasia) is a rare condition, presenting at birth and has a wide range of clinical manifestation involving the eye, ear and spine. The characteristic facial phenotype defined as hemifacial microsomia, occur due to abnormal development of the first and second pharyngeal arch derivatives. Goldenhar disease may also affect the heart, lungs, kidneys, and central nervous system. The underlying cause of the condition remains unknown. A wide variety of ear/temporal bone deformities can be seen in Goldenhar as a spectrum from mild to severe from isolated preauricular appendages, fistulae, to abnormal formation of the external auditory canal with malformation of the middle and inner ear cavities. A review of embryological development of the ear will be discussed to help understand the wide spectrum of ear deformities in Goldenhar syndrome. However, all reported cases in the literature report typical location of the hypoplastic external auditory canal. This is the first report to our knowledge of Goldenhar syndrome with ectopic location of the ear pinna, external auditory canal and rudimentary ossicular formation associated with the temporomandibular joint.

KEYWORDS: Congenital Anomalies, ENT, Hearing Loss
Extraspinal Meningioma Presenting as a Neck Mass

S Cantrell¹, D Bell², L Ginsberg²

¹University of Texas Health Science Center at Houston, Houston, TX, ²MD Anderson Cancer Center, Houston, TX

Purpose
We present a case of extraspinal meningioma presenting as a neck mass.

Materials and Methods
A 59-year-old man presented with vague right-sided neck and jaw discomfort. The patient denied any weakness or symptoms suggestive of radiculopathy. Computed tomography (CT) and MR imaging (MRI) of the cervical spine revealed a right paraspinal mass.

Results
Contrast-enhanced CT demonstrated a heterogeneously enhancing lobulated 3.5 cm right-sided paraspinal mass extending from the C1 to C3 levels without internal hemorrhage or calcification. The mass abutted the adjacent C1-2 and C2-3 neural foramina, without apparent intraforaminal extension or osseous destruction. On MRI, the lesion was T1 isointense with heterogenous
enhancement. Ultrasound-guided core biopsy was performed with histology revealing meningioma. 

Conclusions 
Extrapinal meningioma is a rare entity that may be confused with other paraspinal soft tissue masses, such as sarcoma, neurofibroma or metastases in the appropriate clinical setting. It has been postulated that these lesions may arise from meningocytes or dural fibroblasts that accompany exiting nerve roots or from developmental cell rests. Although our patient's lesion demonstrated no obvious extension into the adjacent neural foramina by imaging, Ibrahim et al reported attachment to the nerve root sleeve on microscopic examination following resection of extrapinal extradural meningioma (1). One reported case by Christopherson, et al demonstrated purely extraspinal meningioma without attachment to the dura or nerve root sleeve on microscopy (2). Additional paraspinal sites mimicking neck mass include parapharyngeal location reported by Taori et al and Possanzini et al (3, 4). Correct diagnosis and tissue sampling is essential for treatment planning.

Iatrogenic Masticator Space Abscess: an Infrequent but Important Cause of Pain and Trismus Following Inferior Alveolar Nerve Block for Routine Dental Procedures.

N Pierson\textsuperscript{1}, R Wiggins\textsuperscript{2}

\textsuperscript{1}University of Utah Health Science Center, Salt Lake City, UT, \textsuperscript{2}UHSC, Salt Lake City, UT

Purpose
Persistent postprocedural pain and trismus are among the most common complications of inferior alveolar nerve block for elective dental procedures. This is thought to be secondary to multiple or forceful injections, injury to muscles, or hematoma formation (1). Uncommonly, iatrogenic infection can occur at the site of injection presenting as pain and trismus 2-3 days following the procedure and should not be confused with benign post procedural pain (2). Clinical evaluation of these patients reinforced by contrast enhanced CT is important in correctly guiding clinical management (3-5).

Materials and Methods
We report 2 cases of iatrogenic deep masticator space abscesses following routine elective dental procedures. Patient 1, a 14 year old male, presented to a pediatric emergency department with trismus and pain 4 days following filling placement. The patient was found to have an abscess in the infratemporal fossa anterior and superior to the lingula of the mandible. This patient was treated with antibiotics and recovered well. Patient 2, a 48 year old male presented to the emergency department 5 days following left central incisor extraction with trismus and pain. He reported the dentist having had difficulty in obtaining anesthesia during the procedure, requiring multiple injections. A masticator space abscess was found centered at the left mandibular foramen (Figure 1). Needle aspiration was performed returning purulent material positive for Streptococcal infection. The patient was treated with incision and drainage and antibiotics, subsequently recovering well.

Results
Classic CT imaging findings of a masticator space abscess were demonstrated, however without an odontogenic source. Conventional masticator abscess formation is described on imaging as periodontal disease leading to infection of the mandible and dehiscence or direct spread into the masticator space (6). These conventional findings were not seen in these patients. The abscesses were centered in the masticator space demonstrating central soft tissue or fluid density with peripheral enhancement. Enlargement and edema within the adjacent muscles was seen in addition to stranding and obliteration of adjacent fat plains.

Conclusions
Iatrogenic masticator space abscesses are an uncommon but important consideration in a patient with late presenting postprocedural pain and trismus following inferior alveolar nerve block. Patients with this history are best evaluated with contrast enhanced CT for appropriate guidance of clinical management. Imaging findings are that of classic masticator space abscess, however without apparent odontogenic source.

KEYWORDS: Abscess, Deep Space, Iatrogenic
Maxillary Mass with Loss of the Maxillary and Mandibular Cortical Lamina Dura: A Diagnostic Clue

A Betts¹, H Morales¹, T Tomsick¹
¹University Hospital/University of Cincinnati College of Medicine, Cincinnati, OH

Purpose
We describe a case of an expansile mass of the maxilla with an additional finding of diffuse loss of the cortical lamina dura of the maxillary and mandibular teeth. The significance of loss of the lamina dura is discussed, and how this finding can be used to suggest the diagnosis of the maxillary mass.

Materials and Methods
A 59-year-old female was referred for maxillofacial computed tomography (CT) for evaluation of a right maxillary mass that had been enlarging over the course of the previous three months. On clinical examination, there were areas of ulceration of the mucosa maxillary gingival mucosa. Biopsy of the overlying oral mucosa showed ulceration with underlying proliferation of osteoclasts. She then underwent right maxillectomy with fibular free flap reconstruction. Pathology findings were consistent with a giant cell granuloma, without evidence of malignancy. During postoperative inpatient admission, she had steadily increasing serum calcium levels up to 12.5 mg/dL, and parathyroid hormone level of 725 pg/mL. On follow-up examination, an ultrasound of the neck was performed, and a mass deep to the right lobe of the thyroid gland was visualized. Patient was later taken for parathyroidectomy, and pathologic evaluation of the specimens demonstrated a right superior parathyroid adenoma. Serum parathyroid hormone and serum calcium levels subsequently normalized.
Results
Axial CT image through the maxilla in soft tissue algorithm shows a lucent expansile mass in the right paramedian alveolar ridge of the maxilla with erosion of the anterior cortex, and an associated soft tissue mass. Axial CT image in bone window shows loss of the cortical lamina dura of the maxillary teeth. There was also diffuse loss of the lamina dura involving the mandibular teeth (not pictured here).

Conclusions
The differential diagnosis of lucent mass lesions of the maxilla involving the alveolar ridge include both odontogenic and nonodontogenic lesions. Odontogenic neoplastic lesions include ameloblastoma, odontogenic myxoma, and rarely odontogenic carcinomas. Odontogenic cystic lesions include radicular cysts, dentigerous cysts, and odontogenic keratocysts. Nonodontogenic lesions include benign etiologies such as osteitis fibrosis cystica (brown tumor), aneurysmal bone cysts, and fibrous dysplasia. Malignant nonodontogenic osseous lesions may manifest in the maxilla or mandible, including plasmacytoma or metastatic disease. Osteitis fibrosa cystica is a diffuse process of bone resorption in response to hyperparathyroidism (primary or secondary). With long-standing hyperparathyroid states, focal non-neoplastic proliferations of multinucleated giant cells and fibrovascular tissue can develop within a bone. This is known as a "brown tumor," due to hemosiderin staining that results from its tendency to hemorrhage. On imaging, brown tumor usually presents as a lucent or cystic expansile mass. It may occur within any bone, including the mandible and maxilla. Brown tumors may be monostotic or polyostotic. Other radiographic findings associated with hyperparathyroidism include phalangeal subperiosteal bone resorption, osteolysis of the distal clavicle, and "salt and pepper" appearance of the calvarium. Loss of the cortical lamina dura is another established radiographic finding in hyperparathyroidism that was described on dental radiographs prior to the introduction of computed tomography. On modern CT imaging, loss of the lamina dura also can be seen with multidetector CT (MDCT) or cone-beam CT (CBCT), although CBCT has been shown to be more sensitive in evaluation of the lamina dura. In this patient, the anatomical location of the focal osseous lesion within the maxilla allowed simultaneous visualization of this finding and provided an important diagnostic clue.

KEYWORDS: Bone, Hyperparathyroidism
Ocular Hemorrhage in a Patient with Ruptured Cerebral Aneurysm (Terson's syndrome)

A Agarwal¹, S Kanekar²
¹Penn State University, Hummelstown, PA, ²Penn State Milton S Hershey Medical Center, Hershey, PA

Purpose
Terson's syndrome (vitreous hemorrhage) and other ocular hemorrhages (retinal hemorrhages) have been reported to occur in up to 40% of patients with ruptured cerebral aneurysms. The mechanism of Terson's syndrome is controversial. The vitreous hemorrhage may be caused by a large amount of blood, originally formed by Terson's syndrome, entering the subarachnoid space around the optic nerve and from there infiltrating the intraocular space through the perivascular space around the central retinal vessels within the optic nerve. Here we report magnetic resonance imaging (MRI) findings of Terson's syndrome in a patient with ruptured aneurysm who developed acute unilateral vision loss.

Materials and Methods
A 51-year-old man had acute onset of severe headache, weakness, and depressed consciousness and was admitted to the hospital. He had no significant past medical or ocular problems and was not taking any medication. The preoperative computed tomography (CT) scan clearly depicted extensive subarachnoid hemorrhage in the basal cisterns and mild ventricular dilatation. Lumbar puncture confirmed a subarachnoid hemorrhage. Cerebral angiography demonstrated an aneurysm arising from the origin of the right anterior choroidal artery. The patient underwent emergency external ventriculostomy and later endovascular coil treatment of the aneurysm. Patient developed acute onset of vision loss in the left eye within three hours of endovascular treatment. Patient underwent a MRI and MR angiogram of the brain to rule out infarcts or findings of vasospasm. MR imaging study revealed diffuse subarachnoid hemorrhage, seen as bright signal within the sulci and cisterns. The scan also revealed increased T1 signal in the left globe with loss of signal suppression on the FLAIR images. Fundoscopic exam done subsequently revealed extensive viterous hemorrhage. Patient underwent emergency vitrectomy. His condition improved with medical and surgical therapy and his vision returned to normal with absorption of the blood. This patient had Terson syndrome, intraocular hemorrhage due to acutely elevated intracranial pressure usually associated with subarachnoid hemorrhage or severe head trauma. To our knowledge, neuroimaging of ocular hemorrhage in Terson's syndrome has not been reported previously.

Results
The preoperative CT scan clearly depicted extensive subarachnoid hemorrhage in the basal cisterns and mild ventricular dilatation. Lumbar puncture confirmed a subarachnoid hemorrhage. Cerebral angiography demonstrated an aneurysm arising from the origin of the right anterior choroidal artery. The patient underwent emergency external ventriculostomy and later endovascular coil treatment of the aneurysm. Patient developed acute onset of vision loss in the left eye within three hours of endovascular treatment. Patient underwent a MRI and MR angiogram of the brain to rule out infarcts or findings of vasospasm. MR study revealed diffuse subarachnoid hemorrhage, seen as bright signal within the sulci and cisterns. The scan also
revealed increased T1 signal in the left globe with loss of signal suppression on the FLAIR images (Figure 1). Bright signal also was noted in the dilated optic nerve sheaths on both sides.

Conclusions

Ophthalmological screening of patients with histories of transient or prolonged comas after ruptured cerebral aneurysms very sensitively identifies patients with ocular hemorrhages, which are relatively common in patients with subarachnoid hemorrhage treated in an academic neurosurgical practice. The present case depicts the imaging findings of Terson's syndrome in a patient who presented with acute onset vision loss within hours of endovascular treatment of aneurysm. Vitrectomy for patients who do not exhibit spontaneous improvement in vision results in a dramatic reversal of blindness.

Osseous Metaplasia of the Laryngeal Cartilage Mimicking Tumor Invasion

B Wang\textsuperscript{1}, L Ginsberg\textsuperscript{1}
\textsuperscript{1}MD Anderson Cancer Center, Houston, TX

Purpose

To illustrate the imaging findings of metaplasia of the laryngeal cartilage mimicking tumor invasion. Our purpose is to raise awareness of the neuroradiology community concerning this rare entity so that unnecessary extensive surgery may be avoided.

Materials and Methods

A 50-year-old white male presented with a one-month history of hoarseness. He was treated by his PCP for an upper respiratory infection, which did not resolve the hoarseness. He was referred to an ENT, who performed a laryngoscopy, which revealed a left vocal cord mass. A biopsy was obtained which revealed squamous cell carcinoma with a probable invasive component. He was
referred to our institution for further treatment. Laryngoscopy showed normal vocal fold mobility, epiglottis rotated to the right, left vocal fold with hyperkeratotic lesion at anterior commissure, erythematous lesion extending to left posterior cord, and not involving the arytenoids. Patient underwent a total laryngectomy based on the imaging findings described below, which appears to show extensive tumor that goes far beyond that which is suspected clinically. Gross specimen of total laryngectomy showed a tumor (1.3 x 0.6 x 0.3 cm), grossly limited to the left true vocal cord without crossing the midline. On serial sectioning the tumor does not appear to involve cartilage or extend into the prelaryngeal soft tissue. The right true vocal cord shows an area of edema with submucosal hemorrhage. The underlying soft tissues are soft without discrete lesions. The thyroid and cricoid cartilages are partially ossified without fibrosis. There is marked osseous metaplasia of the cartilages with hematopoiesis. Gram stain and GMS to evaluate the inflammation in the anterior soft tissues are negative for microorganisms.

Results
With respect to the larynx, the patient has a most unusual appearance. The left aryepiglottic fold appears somewhat hypoplastic. The left arytenoid and normal vocal cord are not seen. Rather the inferior aspect of the anterior thyroid cartilage appears to be involved with tumor and largely replaced. This finding extends more inferiorly where the cartilage appears to be heavily consumed and replaced by tumor. There is a question that tumor is extending posteriorly in the location lateral to the left side of the cricoid and medial to the left thyroid lobe. Base on imaging, there is far more than a relatively low-grade or early stage tumor that is the clinical impression and rather one that has replaced many of the normal structures including much of the thyroid cartilage.

Conclusions
Osseous or chondroid metaplasias are uncommonly found adjacent to laryngeal squamous cell carcinoma (SCC) and may resemble an osteosarcoma (1). This particular case has extensive osseous metaplasia of the laryngeal cartilage adjacent to the real SCC, mimicking cartilage invasion on imaging, and therefore possibly contributing to a total laryngectomy for T4 disease that may not have been. To our knowledge, this has yet to receive attention in the neuroradiology literature. Although relatively rare, neuroradiologists should be aware of this entity and consider it in the differential diagnosis when the characteristic features are encountered, possibly avoiding unnecessary extensive surgery.

KEYWORDS: Cancer, Head And Neck, Larynx
Papillary Thyroid Carcinoma in a Thyroglossal Duct Cyst: A Rare Occurrence

A Naidu\textsuperscript{1}, G Reddy\textsuperscript{2}, S Schonfeld\textsuperscript{3}
\textsuperscript{1}Rutgers-Robert Wood Johnson University Hospital, New Brunswick, NJ, \textsuperscript{2}Rutgers-Robert Wood Johnson University Hospital, Jersey City, NJ, \textsuperscript{3}University Radiology Group, East Brunswick, NJ

Purpose
To present a case of papillary thyroid cancer in a thyroglossal duct cyst and to allow the reader to consider thyroid carcinoma in the differential of a calcified midline neck mass.

Materials and Methods
A 56-year-old male presented with a midline anterior neck mass as noted by his primary care physician. The patient reported a history of gout and denied any significant family history of cancer. Imaging demonstrated a partially calcified mass anterior to the thyroid cartilage, suspicious for a thyroid carcinoma in a thyroglossal duct cyst. The patient went on to fine needle aspiration of the mass, which yielded malignant cells. The patient subsequently proceeded to surgery with resection of the mass as well as thyroidectomy. The surgical biopsy results came back as papillary thyroid carcinoma.

Results
Axial computed tomography (CT) image through the level of the neck shows a midline partially calcified mass along the anterior margin of the thyroid gland.
Conclusions
Thyroglossal duct cysts are formed after failure of the thyroglossal tract to involute during embryologic development and occur in approximately seven percent of the population. Malignant changes within a thyroglossal duct cyst are very rare with the incidence of malignancy occurring in less than one percent of cases. Papillary thyroid carcinoma is the most common type of cancer occurring in a thyroglossal duct cyst; however there have been reports of squamous cell carcinoma and anaplastic thyroid carcinoma. Thyroid carcinoma in a thyroglossal duct cyst may be clinically indistinguishable from a benign thyroglossal duct cyst. Therefore, it is important to include thyroid carcinoma in the differential diagnosis of midline neck lesions with suspicious CT findings. Other differential considerations for a calcified midline neck mass include a calcified anterior cervical node, dermoid cyst, tophaceous gout, and tuberculosis. The preoperative diagnosis of thyroid carcinoma in a thyroglossal duct cyst can greatly affect surgical planning and further management.

KEYWORDS: Cancer, Neck Masses, Thyroid
Post-traumatic sinus pneumocele formation relating to long-term intracranial hypotension.

M Young¹, M Hagiwara¹, Y Lui¹
¹New York University Langone Medical Center, New York, NY

Purpose
Skull pneumoceles are extremely uncommon. Though they are associated with prior head trauma, it is not known why or how this complication occurs. Here we illustrate this rare and important entity and suggest a possible mechanism by which it occurs.

Materials and Methods
A 29-year-old man with a history of prior severe traumatic brain injury relating to a motor vehicle accident was treated during his initial injury for severe hydrocephalus requiring placement of a ventricular shunt catheter. Noncontrast head CT and brain MR were performed five years later after a fall and showed bilateral complex sinus pneumoceles. A decision was made to surgically excise the lesions due to potential risk of obstruction and infection with extremely thin bone separating the intracranial compartment from the sinuses. The patient underwent a bifrontal craniectomy, and exenteration of the frontal sinuses with resection of complex sinus pneumoceles and placement of pericranial grafts. The patient clinically did well.

Results
Noncontrast head CT performed shortly after the traumatic injury confirms the presence of moderate to severe hydrocephalus and placement of a right frontal ventricular catheter. In addition, areas of prior contusional injury are present in the frontal lobes bilaterally. A follow-up noncontrast head CT performed during the patient's most recent admission redemonstrated the ventricular catheter with marked decrease in ventricular size compared with the prior study. There were new bilateral, bubbly, loculated and septated air-filled osseous spaces communicating with the paranasal sinuses projecting intracranially. These demonstrated mass effect on the frontal lobes and had extremely rarefied bone surrounding them, consistent with complex pneumoceles (Figure 1). MR imaging (MRI) performed at the same time also showed findings compatible with intracranial hypotension including diffuse, smooth pachymeningeal thickening and enhancement, dilated superior sagittal sinus, inferior displacement of the midbrain, and a prominent pituitary gland. In addition, CT confirmed thickening of the inner table of the calvarium in keeping with intracranial hypotension.

Conclusions
We present a dramatic case of acquired sinus pneumoceles occurring years after significant head trauma. There are concomitant findings of cerebrospinal fluid (CSF) overshunting leading to chronic intracranial hypotension. Prior trauma previously has been cited as a risk factor for pneumocele formation, though the mechanism by which this occurs is unknown. We suggest here a possible mechanism related to intracranial hypotension for the development of sinus pneumoceles after head injury.

Pott's Puffy Tumor: Imaging Findings from Ultrasonography to Magnetic Resonance Imaging

H Kalkan, M Eryılmaz, D Kıreşi, H Arbağ, A Yeşildağ

1 Necmettin Erbakan University, Meram School of Medicine, Konya, Turkey, 2 Necmettin Erbakan University, Meram School of Medicine, Department of Otolaryngology, Konya, Turkey, 3 Necmettin Erbakan University Meram School of Medicine, Department of Radiology, Konya, Turkey, 4 Necmettin Erbakan University, Meram School of Medicine, Department of Radiology, Konya, Turkey

Purpose
Pott's Puffy tumor is a complication of acute sinusitis and occasionally trauma. It is an uncommon presentation of acute sinusitis in pediatric population (1). It's characterized by subperiosteal abscess and osteomyelitis of frontal bone. Clinical findings are fluctuant swelling of scalp, headache, periorbital edema. We aimed to present imaging findings (ultrasound (US),
computed tomography (CT), magnetic resonans imaging (MRI)) of a 14 year old boy with Pott's Puffy tumor.

Materials and Methods
14 year old boy applied for 2 months history of headache and 1 week history of swelling of his forehead. His forehead swelling was tender, warm and erythematous. His laboratory values were no suspicious of infection. For diagnosis, CT (64 slices, multi-detector CT), MRI(1.5 T,Siemens, Erlangen, Germany) and then after US was performed.

Results
First US was applied to understand the nature of swelling. Transverse sonogram of the frontal swelling demonstrates the subperiosteal abscess and discontinuity of frontal bone (figure 1a). CT was performed to reveal sinusitis, to confirm the bone defect and abscess. Contrast enhanced CT revealed pansinusitis, epidural abscess in frontal area, frontal bone osteomyelitis, abscesses in diploe and subgaleal spaces. To see clearly if there was any brain parenchyma involvement which could be overlooked by CT, patient underwent contrast enhanced MRI. There was erosion and destruction of frontal bone (osteomyelitis) on the right, soft tissue and epidural abscesses with their rim enhancements (figure 1b) and no parenchymal involvement. With those imaging and clinical findings, the diagnose was Pott's Puffy tumor, a rare complication of acute sinusitis today, thanks to broad-spectrum antimicrobial coverage. The patient was recommended surgery for abscesses. Patient was underwent surgery by otolaringology and neurosurgery at the same time. Right frontal bone and sinus anterior wall destruction were seen. Abscesses were drained from frontal sinus. Then neurosurgery team attended the operation. Craniotomy was performed to left frontal side and epidural abscess was drained. At the end of the operation, frontal sinus was obliterated with the fat from the left groin. Microbyologic results were negative under the antibiotic supression. Pathology result was active chronic inflammation.

Conclusions
Pott's Puffy tumor is a surgical emergency. Imaging methods have an important role in the diagnosis of it(2). Nowadays we have forgotten this entity under the broad spectrum antibiotic therapis for sinusitis. In the literature US findings of Pott's Puffy tumor was rarely adverted. In this presentation we also mentioned sonographic images addition to CT and MRI findings. US is helpful in diagnosis of osteomyelitis (3).

Silent cranium syndrome: A rare and unique imaging and clinical entity

M Heran¹, D Sobh¹, P Dolman¹
¹University of British Columbia, Vancouver, BC, Canada

Purpose
Describe the clinical and imaging characteristics of silent cranium syndrome. Two cases are presented with discussion of their clinical concerns and CT findings.

Materials and Methods
Two female patients presented to the Orbital Surgery service with severe bilateral enophthalmos. Both patients had longstanding histories of hydrocephalus requiring ventriculoperitoneal (VP) shunting. A 53-year-old female was referred with a history of ocular irritation and left eye discharge. This patient had a remote history of VP shunting for late onset hydrocephalus at the age of 13 years, with shunt revision at the age of 24 years. Clinical examination revealed marked enophthalmos with lack of lid corneal contact, left inferior corneal scar and erosions, and upper lid entropy with lagophthalmos. Her visual acuity was 20/40 (right eye) and 20/70 (left eye). A 55-year-old female was referred with a history of chronic headache, persistent eye irritation and discharge. At the age of three months, she was diagnosed with obstructive hydrocephalus and had VP shunt surgery followed by shunt revision at the age 22 years. She developed progressive enophthalmos at the age of 39 years with a right corneal ulcer identified seven years later. Computed tomography (CT) scan of the orbits was reviewed for each patient, and bony orbital, orbital soft tissue, and orbital fat volumes were calculated for each orbit. These were compared with a single normal case control.

Results
Computed tomography orbits of both patients showed marked superior bowing of the orbital roof into the anterior cranial fossa with severe enophthalmos, lack of appropriate contact between the eye lids and globes and resultant air entrapment as illustrated in the provided CT image. We found an increase in these patients' calculated total orbital volumes (47 cm³, patient 1; 38 cm³, patient 2) compared with control (30 cm³). There also was a decrease in their orbital fat volumes (22.4 cm³, patient 1; 17 cm³, patient 2) compared with control (24 cm³).

Conclusions
Silent cranium syndrome refers to bilateral severe progressive enophthalmos developing in the setting of longstanding VP shunting. This syndrome has been recognized recently in some patients who had history of hydrocephalus early in life requiring VP shunt. This longstanding shunting results in bony remodeling of the thin orbital roof, with characteristic clinical and radiologic appearance. Silent cranium syndrome represents a previously undescribed unique clinical and radiologic entity.

Small Cell Neuroendocrine Tumor of the Paranasal Sinuses

R Rios¹, A Spiro¹, J Bello², K Shifteh¹
¹Montefiore Medical Center, Bronx, NY, ²Montefiore Med. Ctr., Bronx, NY

Purpose
Primary small cell neuroendocrine carcinoma (SNEC) of the paranasal sinuses are extremely rare neoplasms. Similar to SNEC of the lung, SNEC of the paranasal sinus demonstrates aggressive clinical behavior and poor prognosis. The tumor exhibits early local recurrence, widespread dissemination and paraneoplastic syndromes. Primary SNEC of the paranasal sinus has not demonstrated a strong linkage with smoking as opposed to its pulmonary counterpart. Clinical symptoms are nonspecific and generally attributed to involvement of the adjacent cranial nerves, nasal and orbital cavities. Common symptoms include epistaxis, diplopia, proptosis, pain, nasal obstruction and paraneoplastic syndromes. We report a case of paranasal sinus small cell neuroendocrine carcinoma in a 78 year old male.

Materials and Methods
78 year old male presented to the Emergency Department with a painful hard mass in the right cheek which he first noticed 2 weeks prior. He described pain radiating to the right eye accompanied by swelling and increased lacrimation. Over the prior 2 days he noticed decreased hearing and vision on the right. He also reported difficulty chewing on the right: with 3-4 daily episodes of intermittent bleeding from the mouth. Over the prior 2 weeks he lost approximately 8 pounds. Laboratory results were significant for hyponatriemia, (Na:119).

Results
CT of the Orbits demonstrated a large destructive soft tissue mass within the right maxillary sinus that eroding adjacent bony structures. The mass extended through the floor of the right orbit causing proptosis and encasing the inferior rectus muscle. Involvement of the pterygoid plate with expansion of the pterygopalatine fossa was noted. The mass extended laterally into the buccal and masticator spaces with involvement of the right premalar soft tissues. No intracranial extension was present.

Conclusions
Surgical biopsy of the right maxillary sinus was positive for primary small cell neuroendocrine
carcinoma. Nephrology concluded that the patient's hyponatremia was a result of SIADH from the sinonasal neoplasm. Primary small cell neuroendocrine tumor of the paranasal sinuses is an uncommon, extremely aggressive neoplasm that carries a poor prognosis. Clinical symptoms are nonspecific pain, epistaxis, diplopia, proptosis and nasal obstruction. Patients may experience paraneoplastic syndromes which are a unique feature of these neuroendocrine tumors, and when present in conjunction with a sinonasal mass should raise suspicion for a primary SNEC.

Sudden onset hearing loss in the setting of a Chronic Myelogenous Leukemia Blast Crisis: Inner Ear Leukemic Infiltrate

M Franke\textsuperscript{1}, J Handwerker\textsuperscript{1}, R Venkatesh\textsuperscript{1}

\textsuperscript{1}University of California Irvine, Orange, CA

Purpose
To review the imaging findings of leukemic inner ear infiltrate/hemorrhagic labryrinthitis, a rare cause of sudden-onset sensorineural hearing loss.

Materials and Methods
A 36-year-old male with a past medical history of chronic myelogenous leukemia (CML) presented with sudden-onset left greater than right sensorinerral hearing loss, dizziness, and vertigo. The patient was treated initially for presumptive otitis media without improvement. Three weeks after initial presentation the patient was admitted for CML blast crisis (WBC >700,000), at which time persistent vertigo and hearing loss prompted an MR imaging (MRI) examination of the cranial nerves.

Results
MR imaging of the internal auditory canals demonstrates T1 hyperintense fluid within the bilateral inner ear structures, more pronounced on the left. Findings are consistent with subacute
hemorrhage, leukemic infiltrate and proteinaceous material. Asymmetric prominence on the left is concordant with the patient's symptoms of left greater than right sensorineural hearing loss. 

Conclusions

Labryrinthine hemorrhage has been described previously in association with anticoagulant therapy, sickle cell disease, and chronic myelogenous leukemia among others. It is a rare cause of sudden onset sensorineural hearing loss. Careful attention to the labyrinth on T1-weighted images may reveal vestibulocochlear high signal, which can be differentiated from intralabyrinthine lipoma with fat saturation sequences. The detection of labyrinthine hemorrhage has important clinical and prognostic implications.

The Enlarging Neck Mass: A Rare Case of Metastatic Papillary Thyroid Cancer

J Lee1, B Yoo1

1David Geffen School of Medicine at UCLA, Los Angeles, CA

Purpose

We describe a rare case of metatastatic papillary thyroid carcinoma presenting as a slowly enlarging, multicystic neck mass. Papillary thyroid cancer should be recognized as a possible differential diagnosis in the setting of a multicystic neck mass, especially when specific imaging characteristics are present.

Materials and Methods

41-year-old man without significant past medical history presented to an outside institution with an enlarging left neck mass. His symptoms included dysphonia with an increased raspiness to his voice and globus sensation upon swallowing. Cervical physical examination revealed a large, firm mass just above the left clavicle and adjacent to a normal-feeling thyroid gland. Flexible fiber-optic laryngoscopy showed normal vocal cord mobility. Fine needle aspiration returned a diagnosis of metastatic papillary thyroid cancer. A total thyroidectomy revealed the primary cancer to be in the thyroid isthmus.
Results
MRI showed an 8.3 cm multiloculated cystic mass in the left neck extending from the level of C3 inferiorly to the clavicular head. The mass was located posteromedial to the left sternocleidomastoid muscle and was noted to abut the left common carotid artery without displacement of the carotid or parapharyngeal spaces. The mass included cystic components (T1 hypointense, T2 hyperintense) and more complex material (T1 iso- to hyperintense and T2 hyperintense). There was no associated enhancement. In addition, an 8-mm intrinsically T1 hyperintense nodule was seen immediately medial to the left common carotid artery. By imaging, the thyroid gland appeared unremarkable.

Conclusions
Multicystic neck masses carry a wide differential diagnosis, which can be divided into congenital and acquired categories. Congenital neck masses include branchial cleft cysts and venolymphatic malformations. Acquired neck masses include complex lymph nodes and multicystic peripheral nerve sheath tumors. The age of the patient and clinical presentation of a slowly enlarging neck mass suggests an acquired etiology. The presence of T1 and T2 hyperintense components in both the enlarging multicystic neck mass and the adjacent T1 hyperintense nodule suggests increased thyroglobulin content. With the appropriate clinical scenario and imaging characteristics, metastatic papillary thyroid cancer should be suspected as a possible cause of a slowly enlarging neck mass.

KEYWORDS: Cystic Lymph Node, Cystic Neck Mass, Thyroid
Purpose
Occlusive carotid dissections occur in around 30% of cases of carotid dissection. If revascularization is considered, most cases are treated with stent and balloon angioplasty. In this young stroke population, the use of a stent implies life-long antiplatelet medication. Our purpose is to describe a technical use of a balloon guide catheter in the revascularization of occlusive internal carotid artery (ICA) dissection.

Materials and Methods
Three patients were admitted in our stroke unit for acute ischemic stroke of the carotid circulation. All three patients were eligible for endovascular thrombectomy. In two patients, spontaneous proximal carotid occlusion with the characteristic signs of dissection was documented, both in noninvasive studies and in conventional angiography. In one patient, iatrogenic dissection while manipulating the intermediate catheter for thrombectomy caused an ICA occlusion.

Results
A balloon guide catheter was advanced into the common carotid artery. A 0.014” microguidewire and a microcatheter were advanced through the guide catheter, and across the proximal ICA occlusion, until the cavernous segment of the ICA was reached. Multiple contrast injections were done through the microcatheter, confirming its position inside the true lumen of the vessel. The balloon guide catheter then was advanced over the microcatheter and positioned distally to the dissection. The balloon was inflated to its nominal pressure, and the guide catheter then was pulled proximally, until the common carotid was reached, keeping the balloon inflated. The inflated balloon, while crossing the true lumen, collapsed the false lumen, and re-established patency of the vessel. In all three cases, the occlusion resolved, and anterograde flow was achieved. No stent was needed in any of the cases. There were no embolic Complications of the procedure.

Conclusions
A new technique for revascularization of occlusive ICA dissections is described, where a balloon guide catheter can be used, in the setting of thrombectomy, to re-establish the patency of the true lumen of the ICA.

Differential Considerations for Vascular Preauricular Lesion in a Young Wrestler

S Sundararajan¹, S Roychowdhury², C Gribbin², I Iacobas³, M Kaufman⁴
¹Robert Wood Johnson University Hospital, New Brunswick, NJ, ²University Radiology Group, East Brunswick, NJ, ³St. Peter's University Hospital, New Brunswick, NJ, ⁴The Plastic Surgery Center, Shrewsbury, NJ

Purpose
The term 'Vascular Malformation' is routinely employed to describe varying manifestations of vascular pathology. There can be confusion in distinguishing malformation types, especially in the pediatric population. Multispecialty vascular teams composed of clinicians, surgeons, radiologists, and pathologists often are needed to sort through complex differentials. The following case exemplifies how such a team allows for streamlined healthcare delivery to these patients.

Materials and Methods
A 17-year-old high-school wrestler presented with a progressively worsening aching soft tissue abnormality overlying the right pre-auricular region during the course of a year. Physical exam demonstrated a warm, partially compressible 2 cm pink-green lesion with palpable thrill and audible bruit. No associated neurological deficits or additional lesions were noted. Computed tomography angiography (CTA) and MR angiography (MRA) exams confirmed the lesion's vascular etiology, having opacified on arterial phase and rapidly washed out on venous phase. Differential considerations at the time included AV Fistula, pseudoaneurysm, or AV Malformation.

Results
Cerebral angiogram performed two weeks later demonstrated no readily filling aneurysm, arteriovenous shunting, significant stenosis, or occlusion of internal/external carotid systems. Hypervascularity of both pinnae and preauricular regions was noted. Ultrasound of the lesion was performed following cerebral angiography. A 20 mm hypoechoic nodule corresponding to the patient's palpable abnormality was noted. Color Doppler revealed trace peripheral flow at its cephalad aspect, and a focal triangularly shaped area color flow at its caudal aspect related to a feeding native vessel. Findings were most consistent with a progressively thrombosed pseudoaneurysm, with only minimal thrombosis at time of initial noninvasive imaging. Residual neck of pseudoaneurysm was treated via ultrasound-guided thrombin injection in order to minimize bleeding during planned resection. Resection confirmed thrombosed pseudoaneurysm arising from the anterior division of the superficial temporal artery.

Conclusions
Vascular malformations encompass a wide range of manifestations. Classification consists of either developmental (high flow AVM, slow-flow venous, congenital mixed syndromes, vascular tumors, lymphatic) or acquired (pseudoaneurysm, traumatic AVF). The anterior division of the superficial temporal artery is prone to injury, with pseudoaneurysm typically seen in young males with history of acute/repetitive facial trauma. In our case, the patient's history of high-school wrestling and hyperemic pinnae complement this presentation. Associated physical symptoms include ear pain, headache, or rarely facial nerve palsy. In summary, a combined physician approach aided in proper diagnosis and treatment of this superficial temporal artery pseudoaneurysm. Such multidisciplinary clinics are a great resource for providing quality
healthcare, and could potentially become the standard of healthcare delivery in the treatment of vascular malformations.

SUCCESSFUL USE OF THE AMPLATZER VASCULAR PLUG II IN THE SETTING OF ACUTE SIMULTANEOUS TRANSECTION OF THE CERVICAL INTERNAL CAROTID AND VERTEBRAL ARTERIES.

D Murph\textsuperscript{1}, D Hsu\textsuperscript{2}, A DeNardo\textsuperscript{2}

\textsuperscript{1}Indiana University, Indianapolis, IN, \textsuperscript{2}Goodman Campbell Brain and Spine, Indianapolis, IN

Purpose
The Amplatzer Vascular Plug II, a self-expanding Nitinol mesh occlusion device, provided safe, rapid, and complete parent artery occlusion in an exceptional case of simultaneous traumatic transection of the right cervical internal carotid and vertebral arteries.

Materials and Methods
A 49-year-old male presented with penetrating trauma to the midface and right neck by a wooden board after rotary saw accident. Transection of the cervical segments of the right ICA and right VA was suspected and confirmed by CT imaging. Neuroangiography was performed with subsequent embolization of the right ICA and right VA above and below the level of transection. The Amplatzer plug II was utilized proximally, having the advantage of prompt deployment and total occlusion in potentially high-flow lesions. Microcoils were deployed distally. The patient underwent surgical removal of the wooden board. Follow-up MR imaging (MRI) demonstrated no evidence of ischemia, infarct, or intracranial hemorrhage. At three month follow up, the patient demonstrated no neurologic sequelae as a consequence of this near fatal injury.
Results
Computed tomography (CT) head without contrast and CT angiogram of the head and neck: A wooden board with accompanying streak-like artifact extended dorsally along the right lateral mass of C1 with transection of the right vertebral and right internal carotid arteries at the C1 level. There were no findings of acute intracranial hemorrhage or ischemia. Digital subtraction angiography (DSA) and endovascular therapy: Right VA injection demonstrated patency to the C1-C2 level transection. Subsequently an Amplatzer plug measuring 8mm in diameter was placed in the right vertebral artery at the C4 level. Right CCA injection demonstrated patency of the distal right CCA with a patent right carotid bifurcation, with complete occlusion approximately 1.5cm past right ICA origin. Subsequently a 12mm Amplatzer plug was placed in the right ICA extending to the right CCA. Left ICA injection demonstrated patency of the left intracranial arterial vasculature, robust filling of the right ACA and the right MCA across a patent anterior communicating artery, and filling of the right ICA terminus. Left VA injection demonstrated wide patency of the intracranial left VA, basilar artery, and bilateral PCAs. Retrograde filling of the right vertebral artery supplied the right PICA. A microcatheter was advanced over a microwire across the vertebrobasilar junction and into the right VA just above the transection where multiple microcoils were packed. Next, the microcatheter was advanced from the left VA, through the basilar artery and right posterior communicating artery, into the cervical right ICA above the transection. Similarly, microcoils were packed into the right ICA cervical segment. MR imaging of the brain without contrast (post-embolization): No evidence of acute ischemia, infarct, or acute intracranial hemorrhage.

Conclusions
The Amplatzer Vascular Plug II is a self-expanding Nitinol mesh occlusion device shown to provide safe, rapid, and complete parent artery occlusion in the peripheral vasculature. In this unique case of complete simultaneous transection of the right cervical internal carotid and vertebral arteries, successful endovascular embolization was attained.

A case of ADEM with multiple reversible foci on T1-weighted images without hemorrhage on T2*-weighted images.

K Ando¹, R Ishikura¹, Y Kawanaka¹, Y Igarashi¹, T Katsuura¹, Y Wakata¹, Y Takada², J Ono², S Hirota¹
¹Hyogo College of Medicine, Nishinomiya, Japan, ²Meiwa Hospital, Nishinomiya, Japan

Purpose
Acute disseminated encephalomyelitis (ADEM) is an inflammatory demyelinating disorder of the central nervous system that usually occurs in children after viral infection or vaccination. Clinical prognosis of ADEM is usually good. Common imaging finding of ADEM is multiple subcortical and deep white matter lesions with hyper intensity on T2-weighted images and hypo intensity on T1-weighted images of MRI. ADEM with hyper intense areas on T1-weighted images is rare. Hyper intensity areas on T1-weighted images, which reflect hemorrhagic necrosis, are reported in acute hemorrhagic encephalomyelitis (AHEM), which is severe acute variant of ADEM with poor prognosis. We herein report an unusual case of ADEM with multiple reversible foci on T1-weighted images without hemorrhage on T2*-weighted images.
Materials and Methods
A Japanese two-year and 8-month old boy presented with one-week history of low fever with headache and vomiting, one month after vaccination of polio. He was mildly mentally disabled although was developmentally normal before onset. The blood test and the examination for cerebrospinal fluid were normal. T2-weighted images and FLAIR images of brain magnetic resonance imaging (MRI) demonstrated multiple high signal foci in subcortical white matter and basal ganglia. Under the diagnoses of ADEM, he underwent high-dose intravenous steroid therapy. On MRI of 14 days after admission, lesions with hyper intensity on T2-weighted and FLAIR images were reduced, but multiple hyper intense lesions on T1-weighted images with contrast enhancement appeared in subcortical white matter and basal ganglia. None of these lesions showed low intensity on T2*-weighted images. Hyper intense lesions on T1-weighted images increased on MRI of one month after admission, but gradually decreased in one-year follow up. The patient recovered with mild developmental delay.

Results
MR imaging on admission showed multiple hyper intense lesions in subcortical white matter and basal ganglia on T2-weighted images and FLAIR images of MRI. On MRI of 14 days after admission, lesions with hyper intensity on T2-weighted and FLAIR images were reduced, but multiple hyper intense lesions on T1-weighted images with contrast enhancement appeared in subcortical white matter and basal ganglia. Hyper intense lesions on T1-weighted images increased on MRI of one month after admission, but gradually decreased in one-year follow up.

Conclusions
Hyper intense lesions in subcortical white matter and basal ganglia on T1-weighted image without hemorrhage may appear on clinical course of ADEM. These lesions may disappear in follow-up images. Because its clinical prognosis may be good, this state should be distinguished from AHEL.

A Flower in Her Head: A Rare Case of Rosette Forming Glioneuronal Tumor of the Posterior Fossa

R Redwan¹, R Adas¹, A Almehdar¹, A Samkari¹, S Abdullah¹
¹King Abdulaziz Medical City, National Guard Health Affairs, Jeddah, Saudi Arabia

Purpose
Is to present a case of a posterior fossa Rosette forming glioneuronal tumor, and review the spectrum of it's imaging appearance in cross-sectional imaging.

Materials and Methods
A 17-years-old girl was referred to our clinic complaining of persistent headache for six months, along with repeated attacks of nonprojectile vomiting since three months. There was no history of ataxia, vertigo, or blurred vision. She had several trips to the emergency department in the
past, in which she was given symptomatic treatment for her symptoms. On examination, she was vitally stable. Systemic and neurological examinations were negative. There were no neurologic deficits. Her initial lab works were negative. A computed tomography (CT) scan of the brain was obtained initially and showed a posterior fossa mass with supra tentorial hydrocephalus. The patient was immediately admitted and undergone an emergency shunt insertion. The MR imaging (MRI) was obtained later and showed a large heterogeneous mass filling the aqueduct and the fourth ventricle. A few days later the patient had a suboccipital craniotomy for tumor resection. The diagnosis of Rosette forming glioneuronal tumor was made by the pathologist. The patient did well after the operation and only suffered mild nystagmus. One year follow-up studies showed no evidence of recurrence.

**Results**

The initial MRI showed a large partially defined heterogeneously enhancing mass, with combined solid and cystic components. The lesion was centered in the fourth ventricle and extended superiorly to fill and expand the aqueduct. There was no edema of extension into the brain stem. No fluid level, calcification or leptomeningeal enhancement. The mass had a heterogeneous high signal in both T1- and T2-weighted images. Areas of blooming were noted on gradient echo images consistent with hemorrhage. There were no obvious areas of flow voids within the lesion. Although the initial imaging differential diagnosis of the lesion included ependymoma, medulloblastoma and cerebellar pilocytic astrocytoma, the lesion lacked the classic imaging appearance of any of the above lesions. The diagnosis of RGNT was made by pathology.

**Conclusions**

Rosette forming glioneuronal tumor is a rare posterior fossa tumor, that may present in adolescents and young adults, with a wide range of imaging features. Knowledge of this entity and its appearance on imaging studies is essential to guide clinicians and pathologists into making the correct diagnosis.

**Active Venous Bleeding on Intraoperative (IoMRI) Brain MRI Performed During Brain Tumor Resection in a child.**

C Saint-Martin¹, J Farmer¹
¹McGill University Health Center, Montreal, Quebec, Canada

**Purpose**

Review the imaging findings consistent with active venous bleeding on intra-operative MR imaging (IoMRI) obtained during resection of a brain tumor in a child, elaborate hypothesis to explain imaging findings and suggest MRI criteria to suspect active venous bleeding on IoMRI of brain tumors.

**Materials and Methods**

A seventeen-year-old male was diagnosed with a large extra and intra-axial mass lesion involving both of the supra and infratentorial compartments of the posterior right hemisphere whose MRI characteristics initially raised the diagnosis of meningeal hemangiopericytoma or
hypervascular meningioma. He underwent a first resection of the supratentorial component that was subtotal due to extreme large size of the lesion as well as severe peri-operative bleed with acute coagulation disorder and needs for transfusions.

Results
Intra-operative MRI showed expected findings of faintly enhancing tumor residue located superficial to the nonexpected finding of a large heterogeneous grossly round mass lesion occupying most of the surgical bed, showing heterogeneous isointense T1 signal, mixte hypo and hyperintense T2 signal, partial but avid enhancement and T2 shine-through of the hyperintense T2 component, restricted diffusion and absence of enhancement of the hypointense T2 component. Computed tomography (CT) was not performed due to stable clinical condition of the patient. On follow-up MRI obtained 15 days later, the surgical cavity had significantly increased in size, was mainly filled with T1-hyperintense bloody fluid, and was containing a large rounded clot similar in size to the enhancing rounded mass lesion seen during IoMRI; however, it was not showing any residual enhancement. The tumor residue was unchanged. The clinical context of acute peri-operative coagulation disorder and the large amount of methemoglobin content of the fluid filling the surgical cavity seen on follow-up MRI are consistent with organizing subacute bleed within the surgical cavity. In that context, the marked enlargement of the surgical cavity in between the two MRIs obtained 15 days apart raised the suspicion for slow bleeding continuing after the surgical time. In retrospect, avid enhancement of part of the mass lesion occupying the surgical bed on IoMRI is thought to represent active venous bleeding. Isointensity to the adjacent enhanced veins as well as apparent continuity with one of these veins appear the most interesting imaging criteria to suggest active venous bleeding.

Conclusions
Active venous bleeding has not been described previously on IoMRI. In the proper clinical context, it could be suspected based on at least two criteria including continuity with and isointense enhancement to enhancing adjacent vein.

Demonstration of the Retrodural Space of Okada on MRI and Percutaneous Injection in a patient with Axial Low Back Pain

V Lehman¹, T Maus¹, N Murthy¹, J Verdoorn¹
Purpose
Illustration of a potentially under-recognized pattern of spread of fluid and inflammation through the retrodural space of Okada on MR imaging (MRI), which may be associated with axial low back pain or pain related to spinal canal stenosis. The retrodural space allows communication between ipsilateral facet joints, interspinous adventitial bursae, contralateral facet joints, and the posterior paraspinal musculature (1). Access to the retrodural space from a facet joint is facilitated by spondylolysis, although this communication can also be present without spondylolysis (1). Over the past decade, we have encountered a small number of cases of patients with axial low back pain with fluid and inflammation (gadolinium enhancement) present within multiple compartments of the posterior spine, communicating through the retrodural space.

Materials and Methods
We present a 52-year-old male who presented with longstanding axial low back pain with an occasional component radiating down left lower extremity. Given the imaging findings (below) and clinical findings, he was treated with serial computed tomography (CT)-guided bilateral L5 pars interarticularis injections of 6-12 mg of betamethasone over a three-year period with substantial pain relief with each injection.

Results
An MRI of the lumbar spine without gadolinium demonstrated bilateral L5 pars interarticularis defects with slight anterolisthesis of L5 on S1. Joint effusions were present in the bilateral L4/L5 facet joints, in the retrodural space of Okada, and in the L4/L5 interspinous region, all of which were contiguous. During the percutaneous treatment sessions, injection of iodinated contrast material into the bilateral L5 pars interarticularis defects demonstrated contrast opacification of the retrodural space of Okada on CT and the contiguous facet joints and interspinous bursa. This indicated that these contiguous structures in the retrodural space were amenable to percutaneous treatment via the pars interarticularis injections.

Conclusions
There are very few previously reported cases of visualization of the retrodural space of Okada on MRI (2). Recognition of this pattern of involvement can have implications for diagnosis and percutaneous treatment approach. This case demonstrates the MRI appearance of spread of signal abnormality on MRI and directly injected iodinated contrast through the retrodural space.

Documented 8 year development of a pediatric olfactory schwannoma

P Cornejo1, J Egelhoff1, J Miller1, P Dickman1, R Bhardwaj1, R Towbin1

Phoenix Children's Hospital, Phoenix, AZ

Purpose
We report a rare case of olfactory groove schwannoma in a 16-year-old female with a normal
MR imaging (MRI) evaluation eight years before the lesion diagnosis. In this report, we discuss the presentation, histopathology and controversial origin of these unusual tumors.

Materials and Methods

Olfactory groove schwannomas are rare lesions with 35 prior reported cases in the literature. Only five of these cases were of patients less than 18 years old. We report a case of a 16-year-old female with a long history of migraine headaches and seizures who presented with mental status changes. The computed tomography (CT) of the head at the time of presentation showed a large, peripherally calcified mass in the anterior cranial fossa extending into the ethmoid sinus and nasal cavity. MR imaging showed a solid, T2 heterogeneous lesion, avidly enhancing after contrast. A remote MRI of the brain performed eight years earlier was normal. The lesion was resected via bifrontal craniotomy. On pathologic examination, the tumor was a bland spindle-cell lesion with palisading nuclei (Antoni A pattern) and positivity on S100 immunohistochemistry, features characteristic of benign schwannoma. In this report, we discuss the presentation, histopathology and the controversial origin of these tumors including the enigmatic cranial nerve 0.

Results

Head CT without contrast: Large, peripherally calcified extra-axial mass in the anterior cranial fossa with extension into the frontal, sphenoid, ethmoid sinuses and nasal cavity. MR imaging brain without and with contrast: The mass is lobulated, well defined, extra-axial, T1 hypointense, T2/FLAIR iso-hyperintense and shows avid postcontrast enhancement.

Conclusions

We report a rare case of olfactory nerve schwannoma in a young patient which developed in an 8-year interval period. The clinical presentation, imaging characteristics, histopathologic analysis as well as the controversial origin of these tumors will be discussed.

Extra-skeletal Ewing’s Sarcoma of the Scalp

P Cornejo¹, J Egelhoff¹
¹Phoenix Children’s Hospital, Phoenix, AZ

Purpose
Extra-skeletal Ewing's sarcomas are rare soft tissue tumors, first described in 1975. These lesions occur predominantly in adolescents and young adults between the ages of 10 and 30 years and are indistinguishable from Ewing's sarcomas of the bone by histologic analysis. We report a two-year-old patient with extra-skeletal Ewing's sarcoma of the scalp with a complicated past medical history that include prematurity, neonatal intracranial hemorrhage with previous craniotomy for evacuation, hypoxic ischemic encephalopathy, hydrocephalus and developmental delay.

Materials and Methods
A two-year-old male presented with focal swelling of the scalp that rapidly increased in size over a three- to four-week period prior to admission. The lesion was not tender on palpation. Computed tomography (CT) scanning of the head without contrast and magnetic resonance imaging (MRI) of the brain and showed a scalp soft tissue mass over the right vertex. The patient underwent embolization before surgical resection. A small, pink to gray rubbery soft tissue mass was resected. Histopathologic analysis revealed a cellular tumor composed of polygonal cells with round nuclei and moderate amounts of cytoplasm. The cells were present in sheets within a rich network of blood vessels. Ultra-structural examination of the specimen revealed evidence of striated muscle differentiation in the neoplastic cells. Immunohistochemistry analysis demonstrated that the tumor cells were positive for vimentin. The patient was discharged home and no further work up or treatment was pursued by patient's family due to his complex medical history and poor prognosis secondary to his underlying comorbidities.

Results
Computed tomography head without contrast showed a solid, heterogeneous mass in the scalp dermal and subcutaneous tissues near the vertex. On MRI the mass was iso-hypointense on T1 and heterogeneous on T2 with minimal restricted diffusion and heterogenous enhancement. The subjacent parietal bone was thin and irregular without frank cortical disruption. The mass was supplied by the right superficial temporal artery and multiple branches on MR angiography (MRA). Cerebral angiogram confirmed vascular supply from superficial temporal artery vessels.

Conclusions
Primary scalp lesions are unusual in the pediatric population. We present a rare case of extra-skeletal Ewing's sarcoma of the scalp in an infant. The differential diagnosis for soft tissue neoplasms in the pediatric age group includes: neuroblastoma, rhabdomyosarcoma, lymphoma, neuroepithelioma, extra-skeletal Ewing's sarcoma and other round cell sarcomas. In our case, the appropriate immunohistochemical analysis was critical to rule out other diagnostic possibilities.

KEYWORDS: Pediatric Neoplasms
Familial Incidence of the Congenital Torcular Dural Arteriovenous Shunt.

A Honarmand¹, S Schoeneman², M Hurley³, S Ansari⁴, T Alden², A DiPatri², A Shaibani¹
¹Northwestern University, Chicago, IL, ²Ann & Robert H. Lurie Children's Hospital of Chicago, Chicago, IL, ³Northwestern Feinberg School of Medicine, Chicago, IL, ⁴Northwestern University Feinberg School, Chicago, IL

Purpose
There are several hereditary disorders that are well known to be associated with arteriovenous malformations (AVMs) involving the central nervous system including Sturge-Weber, Klippel-Trenaunay-Weber, and Parkes-Weber syndromes as well as hereditary hemorrhagic telangiectasia and hereditary neurocutaneous angiomatosis. Furthermore, familial incidence of AVMs in the absence of congenital hereditary disorders also has been reported. Herein, we describe the occurrence of the giant torcular herophili (TH) dural arteriovenous fistula (AVF) in two pediatric cousins treated with endovascular embolization.

Materials and Methods
Case 1: Five-month-old male with the chief complaint of poor head control, right head tilt, and increasing head circumference with full and pulsatile fontanelle presented and following imaging studies revealing marked venous dilation adjacent to the vein of Galen he underwent multiple sessions of embolization and radiation therapy without significant improvement. Ten months
later the patient presented to our center with significant clinical deterioration with developing seizure and apnea requiring immediate intubation. Case 2: Second case was the third-degree relative (paternal cousin) of case 1. A 20-day-old female was admitted for evaluation of failure to thrive, dysphagia, and enlarged head circumference with bulging fontanelles. Pregnancy history was remarkable for intrauterine diagnosis of an intracranial mass superior to the posterior fossa which was identified on 20-week gestation ultrasound. Amniocentesis with chromosomes and SNP array examinations were reported normal. Mother denied smoking and drinking alcohol during pregnancy and family history was negative for hematological disorders, cardiovascular events and stroke prior to age 50, stroke or frequent miscarriages.

Results
Case 1: Immediate cerebral angiography was performed and venography of the TH demonstrated the filling of the large cavity within the mostly thrombosed TH with retrograde drainage into the superior sagittal sinus (SSS) and subsequently into the deep cerebral vein via a second channel. Embolization of the TH and the distal thirds of the SSS were performed utilizing multiple hydro coils followed by pushable fiber coils and N-butyl cyanoacrylate in multiple sessions. Although complete obliteration of the shunts was achieved, the sequels of the prolonged drainage disturbance remained due to the late diagnosis. Case 2: Fetal MR imaging (MRI) revealed a midline mass in the region of the TH with signal characteristics of blood or blood products that was thought to be consistent with dural sinus thrombosis (Figure). Following presentation, cerebral angiography demonstrated a significant AV shunting from multiple meningeal vessels including bilateral occipital, middle meningeal arteries, and posterior meningeal arteries into a massively enlarged TH either directly or through intermediate dural veins. Subtle opacification of the outflow into the right sigmoid sinus and internal jugular vein and normal venous drainage from the SSS to the TH also was observed. Additionally, there was evidence of venous collateral pathways including the petrygoid venous plexuses due to the venous hypertension. Endovascular embolization was performed in multiple sessions using Onyx resulting in obliteration of the shunt with long-term favorable angiographic and clinical outcome.

Conclusions
Congenital dural sinus malformations (DSMs), as a subgroup of dural arteriovenous shunts, typically are associated with dural AVF shunting into a dilated dural sinus lake. Familial incidence of arteriovenous malformations has been reported in association with several vascular anomalies including cerebral cavernous malformations, dural intracranial arteriovenous fistulas and aneurysms. Although several case-series of DSMs have been reported, no familial incidence was reported in their cohorts. To the best of our knowledge, our case series represents the only reported familial incidence congenital DSMs involving TH in children.

Ganglioglioma mimicking an extra-axial mass

A Golombeck¹, J Goldschmiedt¹, W Gomes¹, J Bello¹, K Shifteh¹
¹Montefiore Medical Center, Bronx, NY

Purpose
Gangliogliomas are rare intracranial neoplasms of the central nervous system. Most of these lesions occur in children and young adults and classically present clinically with seizures. While many sites of the central nervous system can be affected, temporal lobe lesions are overwhelmingly most common. We report a case of ganglioglioma mimicking an extra-axial mass in the left middle cranial fossa.

Materials and Methods
A 13-year-old previously healthy female presents with one year of complex partial seizures that have increased in frequency over several weeks. Initially, seizures were reported once per week and had increased to 2-3 times per day, lasting 30 seconds at a time. Initial neurological
examination revealed no focal deficits or abnormalities. EEG evaluations were inconclusive in evaluation of seizure activity. Patient was referred for MR imaging (MRI) evaluation.

**Results**
MR imaging demonstrates a 5.8-cm well defined mass in the left middle cranial fossa, which appears to be extra-axial in location. The mass has both cystic and solid components with the solid component enhancing heterogeneously. There is mild left uncal herniation secondary to mass effect. There is mild vasogenic edema within the underlying temporal lobe. There is abnormal dural enhancement overlying the mass.

**Conclusions**
Surgical biopsy/resection revealed a dominant extra-axial mass with a thin pedicle of vascular support arising from the temporal lobe. Pathological diagnosis of ganglioglioma was made. Gangliogliomas are uncommon primary central nervous system tumors that often present clinically with seizure in children and young adults. They arise from atypical ganglion cells and astrocytes and are usually found in the temporal lobes. In the setting of a young patient with an apparent extra-axial mass in the middle cranial fossa, ganglioglioma should be considered within the differential diagnosis.

EE-104

**Ganglioglioma on the run: A rare presentation with leptomeningeal spread**

S Dua¹, B Yoo¹

¹David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA
Purpose
We describe a rare case of ganglioglioma presenting with leptomeningeal and subarachnoid spread.

Materials and Methods
A 14-year-old male presented with new onset seizures, described as repetitive behaviors, blank stares and chewing movements lasting two to three minutes and followed by garbled speech. The patient had an EEG performed, which showed focal slowing in the left anterior temporal lobe. A contrast-enhanced MR imaging (MRI) brain examination demonstrated an enhancing solid and cystic lesion in the left temporal lobe with leptomeningeal enhancement. The patient underwent a left frontotemporal craniotomy and resection of the left anterior temporal lobe mass. Pathologic examination revealed low grade glioma with significant ganglion cell component and predominant subarachnoid growth, consistent with ganglioglioma, WHO Grade II.

Results
MR imaging showed a circumscribed, cystic mass with a solidly enhancing mural nodule in the left anterior temporal lobe, with surrounding leptomeningeal enhancement.

Conclusions
Gangliogliomas are well differentiated, low grade neuroepithelial tumors which appear most commonly in the temporal lobe. These are peripheral tumors that tend to occur at the cortical or corticomedullary junction. Most commonly, gangliogliomas present as a circumscribed cyst with a mural nodule. Differential diagnostic considerations include pleomorphic xanthoastrocytoma (PXA), dysembryoplastic neuroepithelial tumor (DNET), pilocytic astrocytoma and oligodendroglioma. While ganglioneuromas are typically nonaggressive, gangliogliomas with leptomeningeal spread can rarely occur, and it is important to be aware of this entity, as the imaging features may mimic more aggressive tumors or infection.

Imaging Findings in a Pediatric Patient With Disseminated Coccidioidomycosis Involving the Spine and Skull

D Leake
1Austin Radiological Association, Austin, TX

Purpose
The purpose of this presentation is to describe the imaging findings in a pediatric patient with disseminated coccidioidomycosis involving the spine and skull.

Materials and Methods
The patient was a 14-year-old African American male. He recently moved to Texas from the San Joaquin Valley, California. He complained of back pain for 1½ years, generalized weakness, and weight loss of 30 pounds. He was in no distress. Physical exam revealed right frontal scalp swelling. Laboratory showed iron deficiency anemia. There also was elevated sedimentation rate and a high C-reactive protein level. Initial chest radiograph demonstrated extensive paraspinal masses of the thoracic region. Subsequent computed tomography (CT) and MR imaging (MRI) spine imaging showed involvement of the cervical, thoracic, lumbar, and sacral spine with paraspinal masses/abscesses. Skull and scalp involvement also was seen. Paraspinal biopsy revealed coccidioidomycosis fungal infection. Patient initially was placed on iv liposomal amphotericin, and later switched to p.o. Voriconazole. The patient demonstrated progressive clinical and imaging improvement over the past year.

Results
Chest radiograph showed extensive bilateral paraspinal thoracic masses. Computed tomography of the entire spine showed extensive mixed sclerotic and lytic changes of the vertebra and noncalcified paraspinal soft tissue masses/abscesses. MR imaging of the entire spine also showed abnormal signal intensity and enhancement of the vertebra and large paraspinal enhancing soft tissue masses/abscesses. Brain MRI showed abnormal signal intensity of the right frontal bone with adjacent scalp swelling/enhancement and intracranial epidural enhancement. There was extension of the infection to involve the temporalis muscles bilaterally.

Conclusions
Our case report describes a pediatric patient with disseminated coccidioidomycosis infection involving the entire spinal neuraxis, as well as the skull and adjacent soft tissues. Coccidioidomycosis is a fungal disease caused by Coccidioides immitis. Recently, the CDC has reported a 10-fold increase in the number of cases since 1998. The infection is endemic in the southwestern United States. The infection may cause a self-limited influenza-like illness or may cause disseminated coccidioidomycosis. The disseminated form is more prevalent in some groups including those of Filipino, African, Native Americans, Hispanic, and Asian descent. Similar to our case, this infection is often misdiagnosed leading to a delay in diagnosis. Awareness of the clinical and imaging findings of coccidioidomycosis will make it possible to diagnose this infection earlier.

Marburg’s Variant of Pediatric Multiple Sclerosis: Clinical Course, Magnetic Resonance Imaging and Histopathology

R Milos¹, R Höftberger¹, K Rostasy², D Prayer¹, R Seidl¹, H Lassmann¹, B Kornek¹
¹Medical University of Vienna, Vienna, Austria, ²Medical University Innsbruck, Innsbruck, Austria

Purpose
Acute multiple sclerosis (MS), also known as "Marburg variant of MS", is a rare but severe form of MS characterized by a fulminant monophasic disease course leading to death or severe disability within weeks to months. Most of the patients who survive develop later a relapsing form of MS. Here we present a five-year clinical and magnetic resonance imaging (MRI) follow up of a 13-year-old patient presenting with Marburg's variant (malignant form) of pediatric MS.
Materials and Methods
The patient was a 13-year-old previously healthy boy. Following an infection of the upper respiratory tract he developed somnolence, neck stiffness and a left-sided hemiparesis. The lumbar puncture displayed no evidence of intrathecal synthesis of immunoglobulins or oligoclonal bands. Despite multiple treatments, including intravenous corticosteroids, plasma exchange and mitoxantrone, we observed a rapid clinical and radiological deterioration (expanded disability status scale, EDSS, 9.5). After onset of cyclophosphamide a slow but steady improvement was noted. Cyclophosphamide was maintained for three and one-half years, followed by intramuscular interferon beta-1a. His current EDSS evaluated five years after disease onset was 5.0.

Results
Serial MRIs were performed. Initial MRI revealed a large tumefactive thalamic lesion without contrast enhancement, but with signs of neuronal dysfunction (reduced NAA peak with an increase in the choline/NAA ratio) in spectroscopy. Additional small lesions were detected in pons and the deep white matter of the cerebral hemisphere. The methionin-PET revealed a moderate increased uptake of the radiotracer within the thalamic lesion. Because these abnormalities were suggestive of a brain tumor, a brain biopsy was performed five days after clinical onset. It revealed an inflammatory demyelinating process accompanied by axonal destruction and gliosis. The MRI controls performed within five months from symptoms onset displayed a massive progression in the number and size of the demyelinating lesions, with new lesions extending in the splenium of corpus callosum, juxtacortical, periventricular and infratentorial. Some of the lesions became confluent, and/or presented with strong contrast enhancement, and/or showed diffusion restriction. The subsequent MRI scans performed afterwards did not show major further cerebral changes.

Conclusions
The imaging presentation of the course of acute multiple sclerosis in children or adolescents has not been described yet in the literature. Here we report the long term follow up of a boy presenting with an acute variant of MS at the age of thirteen. We present the clinical course, MRI findings, histopathology, treatment procedures and outcome in this patient.

Papillary Glioneuronal Tumor

B Wang¹, L Ketonen¹
¹MD Anderson Cancer Center, Houston, TX

Purpose
To illustrate the imaging findings of a case of a solid papillary glioneuronal tumor with MR spectroscopy, which to our knowledge has not been reported in the literature. Our purpose is to raise awareness of the neuroradiology community concerning this rare tumor.

Materials and Methods
Patient is an 11-year-old Asian female who was in her usual state of good health until November 2006 when she had an episode of low-grade headache with associated vomiting. She went to her pediatrician who started medication for the headache and also recommended a CT scan. A CT scan revealed a lesion in the right frontal lobe. The patient went to see a neurosurgeon who felt that this was most likely a tumor, but he recommended an angiogram. An angiogram was performed by a neuroradiologist who suggested that this might be an AV malformation or a vascular lesion potentially in association with a tumor. After this initial episode of headache she did not have any other headache or vomiting episodes until next spring. At that point, she was generally considered to be asymptomatic. She denies any motor or sensory deficits. She was doing very well in school. She was referred to our institution for consideration of surgery. The
family, however, did not want surgery at the time, and she was followed with MRIs until June 2011. Clinically she remained stable with no new symptoms other than progressive migraine-like headaches. Subtotal resection of tumor was performed on June 2011. Pathology was consistent with papillary glioneuronal tumor (PGNT). She has been followed by multiple MR scans, with no progression of residual lesion.

Results
On computed tomography (CT), there is a partially calcified lesion in the right frontal lobe, suggestive of underlying tumor. On MR imaging (MRI), there is a heterogeneously enhancing lesion in the right frontal lobe extending into the frontal horn of right lateral ventricle. There is no significant surrounding T2 FLAIR hyperintensity to suggest edema. Diffusion-weighted imaging (DWI) demonstrates no restricted diffusion within the tumor. On MR spectroscopy (MRS), the choline/creatine ratio is greater 2 with low NAA, which typically is seen in high grade tumors. No lipid is present.

Conclusions
We describe a young female with slowly progressive solid tumor in the frontal lobe. Pathology was consistent with papillary glioneuronal tumor (PGNT), which is a rare brain tumor originally reported in 1998 (1). In 2007 World Health Organization classified the PGNT as a grade I neuronal-glial tumor because of its biphasic neurocytic and glial components and indolent clinical course. Most of the reports have been in pathology literature. There was a report in radiology literature which described the tumor as predominantly cystic with enhancement (2). In our case, the tumor is solid with avid enhancement. We also present unusual MR spectroscopy findings, which to our knowledge has not been reported in the neuroradiology literature. The PGNT has a high choline/creatine ratio with low NAA, which typically is seen in high grade tumors even though it is a low grade tumor. Despite its rarity, neuroradiologists should be aware of this rare brain tumor and consider it in the differential diagnosis when the characteristic features are encountered.

KEYWORDS: MR Imaging Brain, MR Spectroscopy, Pediatric Brain Tumors
Pediatric Patient with Multiple Cerebral Cavernous Malformations and Multiple Cranial Nerve Neurofibromas: Report of a Novel Syndromic Presentation
Purpose
To the best of our knowledge, this is the first reported, pathologically proven case of a patient
with multiple cerebral cavernous malformations (CCMs) and multiple cranial nerve
neurofibromas. Independently, multiple CCMs or multiple neurofibromas can be seen in specific
syndromes (familial multiple CCM syndrome and NF1, respectively), but the combination of the
two findings may represent a novel syndromic presentation.

Materials and Methods
A four-year-old boy presented with left-sided facial weakness that had progressed since 18
months of age. Additionally, a CN VI palsy was noted at birth, for which he had undergone two
prior ocular surgeries. Past medical history and family medical history were otherwise
unremarkable. Physical examination revealed complete left-sided facial paralysis. MR imaging
(MRI) revealed abnormal enlargement and enhancement of the left abducens and facial nerves,
as well as multiple, bilateral CCMs. The patient underwent left transmastoid/middle cranial fossa
craniotomy and resection of CN VI and VII nerve sheath tumors with subsequent left facial
erve interposition graft placement. Histopathology revealed spindle cell tumors of moderate
cellularity with minimal nuclear hyperchromasia and pleomorphism. No mitoses were identified.
Surgical specimens were focally positive for S-100 protein, displayed multifocal positivity for
Collagen IV, and demonstrated axons distributed throughout the tumors on
immunohistochemical stains, compatible with neurofibromas.

Results
Postcontrast T1-weighted imaging demonstrated enlargement and enhancement of the cisternal
portion of the left abducens nerve, as well as enlargement and abnormal enhancement of the
tympanic and mastoid segments of the left facial nerve. The other cranial nerves were normal.
Additionally, numerous foci of "blooming" artifact were present within the subcortical and
periventricular white matter of the bilateral cerebral hemispheres and the left cerebral peduncle
on susceptibility-weighted imaging. Several foci of susceptibility artifact demonstrated markedly
low signal intensity on T2-weighted imaging, but no contrast enhancement.

Conclusions
Cerebral cavernous malformations are relatively common and can be either sporadic or inherited.
Inherited CCMs are much more commonly multiple, whereas sporadic CCMs are typically
solitary. Neurofibromas also can be sporadic or inherited, but to date this patient does not meet
diagnostic criteria for NF1. Review of the medical literature finds three cases of solitary CCM in
an NF1 patient: an acquired cerebellar CCM following radiotherapy for a mesencephalic glioma,
a metachronous medulloblastoma and cavernous malformation in an NF1 child, and an NF1
patient with a solitary sellar CCM. The constellation of multiple CCMs and multiple
neurofibromas has not been reported previously in the medical literature and may reflect a
previously undescribed syndrome. The patient and family have been referred to medical genetics
for further evaluation.

Posterior Mediastinal Lipoblastoma with Intraspinal Epidural Extension: An Atypical Presentation of a Rare Entity

U Barad1, A Taha2, A Douglas2, C Ho1
1Indiana University School of Medicine, Indianapolis, IN, 2Indiana University, Indianapolis, IN

Purpose
To describe imaging features, clinicopathologic correlation as well as surgical management of this uncommon mesenchymal tumor of embryonal fat cells.

Materials and Methods
A ten-month-old female presented with progressive dyspnea and difficulty per oral intake. Plain film of the chest at an outside hospital demonstrated opaque right hemithorax with leftward mediastinal shift. The patient was transferred to our facility for further evaluation, and CT of the chest and abdomen as well as MR imaging of the thoracic spine was performed. A gross total resection was performed, revealing a histopathologic diagnosis of lipoblastoma.

Results
Computed tomography (CT) chest with contrast demonstrated a large heterogeneous lesion within the right hemithorax with complete collapse of right lung and intraspinal epidural...
extension through the neural foramina from T6 through T10 resulting in moderate mass effect and lateral displacement of the spinal cord. In addition there was remodeling of the affected thoracic vertebral bodies and splaying of the ribs. MR imaging (MR) thoracic spine substantiated CT findings and better delineated the extent of the lesion. The large tumor showed internal T1 hyperintensity with suppression on fat saturation and demonstrated heterogeneous enhancement with contrast. The initial differential diagnosis based on MR findings included neuroblastoma, PNET, germ cell tumor such as immature teratoma or pleuropulmonary blastoma. Under image title- T1 postcontrast axial image shows large right hemithorax heterogenous signal intensity lesion extending through neural foramen into spinal canal and displacing the spinal cord to left. Conclusions

Lipoblastomas are rare benign tumors arising from embryonic adipocytes and lipoblasts. Although only 10% of all pediatric soft tissue tumors are adipose in origin, lipoblastoma or liposarcomas should be considered in the differential diagnosis of rapidly growing, large fat-containing masses in infants within the posterior medisatinum. Only three cases of lipoblastoma invading the spine have been reported previously. Imaging is paramount for presurgical planning as treatment of choice is surgical excision. After complete excision the prognosis is excellent with recurrence rate of less than 25%. Caption for image: T1 post-contrast axial image shows large right hemithorax heterogenous signal intensity lesion extending through neural foramen into spinal canal and displacing the spinal cord to left.

Recurrent Subarachnoid Hemorrhage near Occipital Craniectomy site without Angiographic or MRI Source in a Child with Sickle Cell Disease and Past History of Surgical Decompression of a Chiari I Malformation

A Krishnan¹, S Margiewicz¹, A Wang¹, R Silbergleit², B Berman¹
Purpose
1. Present an unusual case of repeated focal subarachnoid hemorrhages near the occipital craniectomy site in a child with sickle cell disease and discuss possible etiologies. 2. Display the imaging findings and review literature pertinent to this uncommon presentation.

Materials and Methods
A 10-year-old girl with history of sickle cell anemia and past uneventful Chiari I decompression (nine months earlier) presented with a second episode of headache, posterior neck pain and nausea and vomiting. Her first episode, which had occurred three months earlier, had been managed with pain medications and was presumed to be a vaso-occlusive crisis. A lumbar puncture performed at that time was bloody but presumed traumatic without xanthochromia and a head computed tomography (CT) was unremarkable except for demonstrating the postoperative site for Chiari decompression. On this second episode, a cervical spine and brain MR imaging (MRI) was performed and showed a triangular focus of hemorrhage at the posterior cervico-medullary junction. This was new from a routine postoperative brain MRI done months earlier. A CT angiogram (CTA) and a cerebral angiogram were performed given this new hemorrhage but failed to show an abnormality. A repeat MRI five days later demonstrated resolution of the hemorrhage and given clinical resolution of symptoms, the patient was discharged. Another three months later, the patient returned with a third similar episode of symptoms. An MRI and MRA of brain and neck were performed and demonstrated a recurrent similar abnormality in the posterior fossa. No aneurysm, arteriovenous malformation was seen on either MRA. An MRI of the cervical spine did not show any additional abnormality. A repeat cerebral angiogram was recommended by neurosurgery and also failed to show an abnormality. Repeat lumbar puncture was technically difficult but performed and showed hemorrhage without xanthochromia.

Results
MR imaging cervical spine (Figure 1) and brain at the second episode demonstrate a triangular (arrow) T2 hypointense and T1 isointense to spinal cord/brain stem focus just posterior to the cervico-medullary junction, consistent with an intradural (subarachnoid) hemorrhage. Follow-up MRI five days later showed resolution of abnormality. MR imaging brain and cervical spine on third episode demonstrated a similar site of hemorrhage in the low posterior fossa adjacent to the craniectomy site. Cerebral angiograms and CTA were negative.

Conclusions
Spontaneous subarachnoid hemorrhage has been described in patients with sickle cell disease both with and without associated aneurysms. In some cases it follows blood transfusions and in others no etiology is found. What is unusual with respect to this patient, is the repeated focal and isolated hemorrhage near the occipital craniectomy. Review of the neurosurgical reports indicates that the dura was thickened and resected at surgery and after resection was closed with a bovine pericardium graft and the suture line coated with duraseal. There are reports in literature of repeated hemorrhage near occipital craniectomy repair sites though most were extradural hemorrhages and were adjacent to predominantly silastic grafts. The negative angiograms and the repeated hemorrhage at the postoperative site still favor the postoperative site (whether related to the dural graft or intrinsically) as a source possibly facilitated by her medical condition of Sickle Cell disease. We believe that radiologists and clinicians involved in the care of such children should be aware of this clinical and radiological conundrum.
Reversible diffusion-restriction lesion representing Cytotoxic Intramyelinic Edema in a patient with Traumatic Brain Injury

M Albayram¹, Y Al-Brashdi², S Haider¹
¹Calgary University, Calgary, Alberta, Canada, ²Alberta Children’s Hospital, Calgary, Alberta, Canada

Purpose
We report this case to increase the awareness of magnetic resonance imaging (MRI) features of cytotoxic intramyelinic edema visualized as reversible areas of restriction diffusion in diffusion-weighted imaging (DWI) and apparent diffusion coefficient (ADC) maps in a patient with traumatic brain injury (TBI).

Materials and Methods
An 8-year-old girl who was hit by a truck was brought by the emergency medical services (EMS) to the emergency department. The Glasgow-Coma-Scale (GCS) was 5/15 when EMS team
attended on the scene. She suffered polytrauma with TBI resulting in intubation and ventilation for the first two days.

Results
The computed tomography (CT) scan showed depressed right parietal bone fracture with subarachnoid hemorrhage requiring neurosurgical intervention. Her GCS improved dramatically up to 15/15 on the sixth day. Eleven days later, she experienced cognitive impairment rendering MRI scan necessary. The scan revealed the known depressed fracture and subarachnoid hemorrhage with contrecoup injury as T2 high signal intensity areas in the inferoposterior portion of the left front lobe and the left temporal lobe. Scattered punctate hemorrhagic areas were seen in both cerebral hemispheres in susceptibility-weighted images (SWI). Diffusion-weighted imaging and ADC maps showed diffusion restriction involving the corpus callosum, periatral white matter and in the right centrum semiovale with no significant hemorrhagic foci in these regions. On follow-up MRI scan 13 days later, there is complete resolution of the described abnormal DWI/ADC-restriction areas. The last neurological examination seven months after the trauma showed residual cognitive impairment with neuropsychological diagnosis of attention deficit disorder.

Conclusions
This reported case revealed complete radiological resolution of the cytotoxic intramyelinic edema. This is a rare entity should be kept in mind when diffusion restricted abnormalities are present in the clinical setting of traumatic brain injury especially if there is no white matter hemorrhagic foci. The underlying pathogenesis for such phenomena is uncertain. However, disruption of the cellular mechanism caused by trauma leads to diffuse cytotoxic injury which results in diffuse intramyelinic edema. The cellular protective pathway is not functioning at this stage but has not been damaged yet, which gives a reasonable explanation for the reversibility of these lesions in the follow-up imaging.

Salivary Gland Anlage Tumor – First Report of Fetal Imaging

R Radhakrishnan¹, M Calvo-Garcia¹, F Lim¹, R Jaekle², B Koch³
¹Cincinnati Children’s Hospital Medical Center, Cincinnati, OH, ²University of Cincinnati College of Medicine, Cincinnati, OH, ³Cincinnati Children’s Hospital, Cincinnati, OH

Purpose
We present a case of nasopharyngeal obstruction caused by a congenital salivary gland anlage tumor detected in utero. We will discuss the main differential diagnosis that should be applied in this scenario and the implications of this diagnosis in the management of the pregnancy.

Materials and Methods
The mother was a healthy 31-year-old gravida para 3 with late prenatal care. She was referred to our institution at 36 weeks for further evaluation of severe polyhydramnios. Fetal MR imaging (MRI) demonstrated a lobulated nasopharyngeal mass obstructing the airway. The patient was extensively counseled. At 37½ weeks, the baby was delivered by EXIT (ex utero intrapartum treatment) to airway procedure due to the concern for airway compromise at birth. Neonatal contrast-enhanced CT was obtained prior to resection of the mass at four days of life. A large,
pedunculated, midline nasopharyngeal mass tethered to the posterior septum with continuity with the adenoid pad was found at surgery (3 x 2 cm). Histopathology revealed salivary gland anlage tumor.

Results
Fetal MRI demonstrated a lobulated soft tissue mass (2.6 x 1.5 x 1.9 cm) occluding the nasopharynx and posterior left nasal cavity with intact skull base and normal intracranial structures. The lesion was isointense to hypointense on T2 and hyperintense on T1-weighted imaging relative to the brain parenchyma. There were no internal flow voids. There was significant polyhydramnios and a small stomach, supporting associated pharyngeal/airway obstruction. The main differential consideration was nasopharyngeal teratoma, dermoid and salivary gland anlage tumor. Postnatal contrast-enhanced CT imaging demonstrated a mildly enhancing lobulated lesion in the nasopharynx with mild expansion of the left posterior nasal cavity and stable size. The uploaded sagittal single shot fast spin echo fetal MR image demonstrates the mass occupying the nasopharynx between the nasal cavity and the oropharyngeal airway.

Conclusions
Congenital midline nasopharyngeal masses include teratoma, dermoid, encephalocele, craniopharyngioma, glial heterotopia and salivary gland anlage tumor. Salivary gland anlage tumor is a rare but characteristic lesion presenting in the early neonatal period with nasal or pharyngeal obstruction. It is a benign salivary gland lesion and surgical resection is curative.

Subcortical Diffusion Abnormalities Without Cortical Abnormalities After Prolonged Seizure in a Pediatric Case

M Albayram¹, K Myers¹, G Shiau¹
¹University of Calgary, Calgary, Alberta, Canada

Purpose
To illustrate the possible predictive value of acute changes in diffusion-weighted imaging in a case of prolonged seizure activity with extensive subcortical restricted diffusion.

Materials and Methods
This six-year-old girl with previous chronic sinovenous thrombosis and subsequent bilateral thalamic infarcts presented in status epilepticus and slow-to-resolve right-sided Todd's paralysis. The patient has congenital microophthalmos and congenital cataracts with a likely genetic carnitine transporter deficiency. Prior to the episode of status epilepticus, while the patient demonstrated global developmental delay, her development was advancing with no regression.

Results
On the immediate post-ictal MR imaging (MRI) images obtained, there was evidence of restricted diffusion with extensive cytotoxic edema involving the subcortical white matter including the U-fibers in the frontoparietal and temporo-occipital regions. No evidence of direct cortical involvement or central white matter abnormalities. Corresponding marked decreased signal in these same regions on MRI raise concern for permanent underlying parenchymal injury. Repeat MRI two months later demonstrated interval resolution of the cytotoxic edema with marked asymmetric left-sided widespread cerebral atrophy.

Conclusions
Subcortical diffusion abnormalities without cortical involvement is very rare after a prolonged seizure. Significant restricted diffusion with marked decreased signal intensity on the corresponding apparent diffusion coefficient (ADC) map may have predictive value in determining underlying permanent parenchymal subcortical injury. It has been postulated that the increased ratio of glutamine to glutamate creates an osmotic gradient causing astrocyte swelling or edema. This case supports the theory that prolonged seizures may cause deep subcortical white matter involvement.

Symptomatic Cervical Calcific Discitis with an Associated Schmorl’s Node and Abnormal Vertebral Body Signal in a Pediatric Patient

E Lindgren¹, V Lehman¹, C Rydberg¹
¹Mayo Clinic, Rochester, MN

Purpose
Demonstration of cervical calcific diskitis with an associated Schmorl's node in a pediatric patient with neck pain. Calcific diskitis is an uncommon condition which may be painful, particularly when it occurs in the cervical spine (1). Cervical disk calcification has been well described as a cause of pain in the past (2). However, reports of associated intravertebral migration (Schmorl's node) are rare (3, 4, 5) with few, if any, prior reports in the cervical spine.

Materials and Methods
We submit a case of a six-year-old female who presented with three weeks of neck pain without known injury. Physical exam revealed a degree of torticollis and marked diminished range of motion to the left. Given the initial imaging abnormalities of the C3-C4 disk space, including calcification, and a lucent lesion with abnormal signal throughout the C3 vertebral body (detailed below), she was treated with conservative management and close imaging follow up rather than a more aggressive treatment or biopsy. Follow-up imaging demonstrated resolution of the calcification, and the patient's symptoms resolved.

Results
Computed tomography (CT) of the cervical spine demonstrated calcification within the C3-4 space. MR imaging (MRI) with gadolinium revealed there was also a contiguous well circumscribed T2 hyperintense lesion in the inferior aspect of the C3 vertebral body suggestive of a Schmorl's node with edema and enhancement throughout the C3 vertebral body. Follow-up MRI at six weeks showed stability of the calcified extruded C3-4 disk, slight shrinkage of the
Schmorl's node within the inferior C3 vertebral body, and decreasing vertebral body edema and enhancement. Three-month follow up CT demonstrated near complete resorption of the calcification in the disk space with a persistent Schmorl's node consistent with calcific diskitis.

Conclusions
It is important to recognize calcific diskitis with an associated Schmorl's node to avoid misdiagnosis of another vertebral body lucent lesion or infection, and to prompt conservative treatment and imaging follow up (6). This case nicely demonstrates the follow-up imaging findings in calcific diskitis with an associated Schmorl's node and highlights the excellent prognosis.

KEYWORDS: Disk Herniation, Pediatric Spine, Spinal Imaging
Purpose
Atretic occipital cephalocele is an uncommon congenital anomaly, which usually presents as a nodular, small mass just above the external occipital protuberance. Patients with atretic occipital cephaloceles appear to have a low incidence of associated anomalies and a good prognosis for normal development. We herein present two cases of atretic occipital cephalocele with large posterior cyst and enlarged posterior fossa.

Materials and Methods
(Case 1) A male newborn baby of two days after birth was presented with a small cranial mass with bone defect. MPR and 3D images of computed tomography (CT) visualized the bone defect. Conventional and CISS image of MR imaging (MRI) visualized cephalocele of 2cm in diameter, fibrous tissue connecting cephalocele with bottom of the vermis, a large posterior cyst which communicated with the IVth ventricle, and enlarged posterior fossa and subependmal heterotopia. MR venography (MRV) visualized the highly located sinus confluence and cephalocele under the confluence. (Case 2) A one-year-old girl presented with small cranial nodular mass. Conventional and CISS image of MRI visualized small occipital mass suggested to be atretic cephalocele, sinus tract though the skull, a large posterior cyst which communicated with the IVth ventricle, and enlarged posterior fossa. The sinus confluence was highly located and nodule was under the confluence.

Results
High resolution heavy T2-weighted images visualized atretic occipital cephalocele with intracranial anomaly of large posterior cyst with enlarged posterior fossa in both cases.

Conclusions
Large posterior fossa cysts communing with the IVth ventricle in these two cases are suggested to be Blake's pouch cysts. Over distention of posterior fossa due to large Blake's pouch cyst might be the etiology of atretic occipital cephalocele in these two cases. High resolution heavy T2-weighted images of MRI is useful to visualize these anomalies.

Unusual Intracranial Metastasis from Prostatic Embryonal Rhabdomyosarcoma.

M Parekh¹, W Millar¹, K Amuluru², C Filippi³
¹New York Presbyterian Hospital-Columbia University Medical Center, New York, NY,
²Columbia University, New York, NY, ³Columbia University Medical Center, New York, NY

Purpose
Rhabdomyosarcoma (RMS) is a malignancy of children and young adults in which osseous and pulmonary metastases are common. Central nervous system (CNS) metastases from rhabdomyosarcoma are uncommon. When present, intracranial metastases are preceded almost always by pulmonary metastases, and intracranial metastases are predominantly seen to arise from the meninges. This is an unusual case of an infant diagnosed with prostatic rhabdomyosarcoma who subsequently developed a large, solitary extraaxial metastasis with pial
invasion without dural involvement nearly after a year of treatment with no osseous or pulmonary metastatic disease.

Materials and Methods
A 4-month-old male patient, presented to the ER with decreased appetite and three episodes of nonbilious vomiting. On physical examination, the pediatrician noted suprapubic fullness and recommended a pelvic ultrasound which revealed a 5 x 5 cm pelvic mass. On biopsy, the pelvic mass proved to be an embryonal rhabdomyosarcoma originating from the prostate. Metastatic work up was negative at that time. Following resection of the pelvic tumor, the patient underwent 14 cycles of chemotherapy and radiation. Subsequent chest CT exams and bone scans at regular intervals, did not reveal pulmonary or osseous metastasis. At 14 months of age, nearly after a month of completion of treatment, the patient presented with weakness of the left upper extremity and facial droop. Head CT and MRI brain examinations were ordered, both revealing a large right frontal region intracranial mass. After resection of this intracranial mass, the patient was treated with 20 additional cycles of chemotherapy and photon beam therapy. Interval brain MRIs revealed stable postoperative changes. A month after completion of treatment for CNS relapse, the patient developed a seizure. Repeat brain MRI revealed extensive T2 hyperintensity with associated enhancement in the midline and parafalcine regions, right more than left, predominantly leptomeningeal in location and to a lesser extent parenchymal.

Results
Head CT revealed a mixed hypo/isodense mass without hemorrhage. Follow-up brain MRI performed for further characterization of the mass demonstrated a large mixed T2 signal intensity extra-axial mass deforming the right frontal lobe. The mass, measuring approximately 7.6 x 6.0 cm, demonstrated T2/FLAIR hyperintensity, some regions of restricted diffusion, and heterogenous enhancement. Mass effect deformed the right frontal horn, and produced 7mm of right-to-left shift of the midline stuctures with subfalcine herniation. Effacement of the right sylvian fissure and perimesencephalic cistern was additionally present.

Conclusions
Embryonal rhabdomyosarcoma, metastatic to the leptomeninges from the prostate, without prior pulmonary or osseous metastatic disease is extremely rare in infants. Rhabdomyosarcoma (RMS) is a malignancy of mesenchymal cell origin that occurs primarily in children and young adults. The most common sites for this tumor, in order of frequency are: 1) head and neck; 2) genitourinary tract and 3) biliary tract. The different pathological subtypes include embryonal, alveolar and pleomorphic. Central nervous system (CNS) metastases from embryonal rhabdomyosarcoma are uncommon, being seen in only 2/85 cases in one series. Central nervous system (CNS) metastases in primary rhabdomyosarcoma tumors are typically meningeal rather than intraparenchymal (1). They are uncommon in infancy but carry a worse prognosis when present, as compared to adults. Patients who go on to develop intracranial metastases are almost always (>90% of cases) preceded by lung metastases (1, 2). In another series based on autopsy data, 6% of embryonal rhabdomyosarcomas developed cerebral metastases, but all of the patients had pulmonary metastases prior to development of CNS metastases (3).

Vigabatrin Induced Central Nervous System Toxicity in a Child with Aicardi Syndrome

P Naidu1, J Curran1, J Miller1
1Phoenix Childrens Hospital, Phoenix, AZ

Purpose
To demonstrate the MR imaging (MRI) findings of central nervous system (CNS) vigabatrin toxicity in an infant with Aicardi syndrome.

Materials and Methods
A 1-year-old female with pharmacologically refractory seizures and an established diagnosis of Aicardi syndrome underwent a noncontrast MRI of the brain prior to placement of a vagal nerve stimulator. Seizures had begun at one month of age, and were poorly controlled with anti-seizure...
therapy and a ketogenic diet. Introduction and gradual increase of Vigabatrin reduced seizure frequency.

Results
MR imaging demonstrated dysgenesis of the corpus callosum with colpocephaly and an interhemispheric cyst. A malformation of cortical development was present within the left frontal lobe, consisting of atypically located areas of thickened cortex with a microserrated contour, suggestive of polymicrogyria; a focus of gray matter heterotopia studded the margin of the left lateral ventricle. All of the aforementioned findings are consistent with the patient's history of Aicardi syndrome. New T2/FLAIR hyperintensity was noted within the anteromedial aspect of both thalami as well as portions of the dorsal pons and midbrain, with correlating diffusion restriction most impressive in the dorsal brainstem. These abnormalities of the thalami and brainstem resolved on follow-up examination.

Conclusions
The triad of callosal dysgenesis, infantile spasms, and chorioretinal lacunae is pathognomonic for Aicardi syndrome, a rare disorder likely resulting from an X-linked dominant mutation. Infantile spasms are a form of epilepsy that is unique to the developing brain, with a potential for poor neurodevelopmental outcome if the spasms are not controlled. ACTH and vigabatrin have been recognized as effective in the treatment of infantile spasms. Vigabatrin is associated with an irreversible retinopathy in adults, causing mild to moderate concentric peripheral visual field deficits. Infants are prone to developing vigabatrin CNS toxicity, manifesting as a reversible T2/FLAIR hyperintensity in the brainstem, thalami, and basal ganglia with concomitant diffusion restriction. These correlate to intramyelinic edema and microvacuolation seen on histopathological studies of animals. Infants are thought to be vulnerable on the basis of relative immaturity and ongoing myelination. The natural history of infantile spasms increases the likelihood that these patients will be treated with vigabatrin at a young age and consequently puts them at risk for the associated CNS toxicity. Here we share both the MRI features of vigabatrin toxicity as well as those of Aicardi syndrome in an effort to familiarize other radiologists with both conditions.

A Genitourinary Sign in the Neuraxis: Spinal Cord Endometrioma with “Shading”

H Wang1, L Hansen1, K Muller1, J Chen2
1University of California San Diego, San Diego, CA, 2San Diego VA/University of California San Diego Medical Center, La Jolla, CA
Purpose
To present a case of spinal cord endometrioma with diagnostic strategy and review possible etiologies for intramedullary endometrioma.

Materials and Methods
A 28-year-old female with a history of endometriosis and dyspareunia, treated with luprolide acetate, initially presented with urinary retention. Subsequently diagnosed with a compressive lumbar hematoma, she underwent decompression, but declined resection of a presumed hemorrhagic spinal tumor. Seventeen months later, she redeveloped urinary retention with leakage, new pain radiating from the buttocks to the thighs, a burning sensation in both feet and progressive lower extremity weakness. Symptoms were cyclical monthly and improved with chemically induced menopause. Neurosurgical exploration of the lumbar cord revealed an enlarged, hypervascular conus and a cystic lesion that previously had been disrupted leaving a dark greenish-brown wall. Frozen sections of the lesion showed gliotic spinal cord with hemosiderin staining and no neoplasm identified. Final pathology showed reactive, gliotic spinal cord with fragments of endometrial epithelium, stroma, and scattered hemosiderin laden macrophages, consistent with endometriosis. At follow up, patient reported improvement in all cord-related symptoms.

Results
Pre-operative MRI: solitary, ovoid, central 2.4 cm by 1.1 cm conus medullaris lesion, expanding the adjacent central canal of the cord. The mass was homogeneously T1-shortened and not convincingly enhancing. Central and peripheral T2-shortening suggested central blood products (so-called "shading" sign) with a hemosiderin/fibrous rim/wall. The adjacent cord was normal.

Conclusions
In endometriosis, endometrial tissue is found in extra-uterine locations, most commonly within the peritoneal cavity, but sometimes distant sites. Proposed etiologies include direct spread, hematogenous dissemination, or metaplasia of embryonic rests into endometrial tissue. When intraperitoneal, symptoms include pain, dysmenorrhea, and infertility; when extra-peritoneal, symptoms vary by affected area. Diagnosis usually entails direct visualization. Treatment is medical or surgical. Endometriomas involving the spinal cord are uncommon and usually present with symptoms related to local mass effect. These symptoms are not specific to endometriosis and can mimic other causes of spinal cord pathology. Location dependent symptoms include pain, weakness, and bladder or bowel dysfunction. Symptoms can be cyclical, due to hormonal response. Lesions may hemorrhage, resulting in additional mass effect. Proposed etiologies of spine endometriosis include dissemination of endometrial tissue via Batson's plexus, development or metaplasia of embryonic rests, or occurring hematogenously after surgical interventions involving the uterus. The classic imaging finding of endometriosis in the pelvis is described as the "shading sign." "Shading" refers to a T1-shortened structure with a variable pattern of T2-shortening: focal, diffuse, complete signal loss, or a layering dependent fluid level. The mechanism is complex and appearance depends on protein and iron concentrations accumulated during repeated hemorrhages. The presence of a T1-shortened spinal cord lesion may first raise the possibility of primary CNS hemorrhagic lesions including: cavernous malformation, ependymoma, hemangioblastoma, or melanoma. The "shading" sign, most commonly used in genitourinary imaging, in a lesion in a female patient may raise the possibility of a hemorrhagic lesion, such as an endometrioma, and should prompt search for additional history, specifically cyclic symptoms.
A Novel Approach: CT Guided Epidural Blood Patch Treatment in the Absence of a Myelographic-Evident CSF Leak

L Zou¹, S Roychowdhury²
¹Rutgers Robert Wood Johnson Medical School, New Brunswick, NJ, ²University Radiology Group, East Brunswick, NJ

Purpose
To demonstrate a novel approach of treating spontaneous intracranial hypotension without myelographic evidence of a cerebrospinal fluid (CSF) leak by using computed tomography (CT) to deliver a transfenoral blood patch adjacent to perineural root sleeve cysts.

Materials and Methods
A 56-year-old previously healthy man presented with daily positional headaches without a history of trauma or spinal intervention. MR imaging (MRI) brain with gadolinium showed diffuse pachymeningeal enhancement consistent with spontaneous intracranial hypotension. Computed tomography myelogram demonstrated no direct evidence of a CSF leak but multiple small bilateral perineural root sleeve cysts from T6-T9 were present. The patient did not respond to multiple traditional epidural blood patches. To avoid surgical exploration, the decision was made to use CT guidance to deliver a dorsal transfenoral epidural blood patch adjacent to the most prominent perineural root sleeve cyst. A 20-gauge needle was inserted into the epidural space adjacent to the right T8-9 prominent perineural root sleeve cyst using CT guidance. Fifteen cc of the patient's blood was injected into the epidural space. The patient tolerated the procedure well and there were no complications. After the procedure, patient's headache significantly improved. This improvement was sustained over subsequent months.

Results
MR imaging brain with gadolinium shows diffuse pachymeningeal enhancement consistent with spontaneous intracranial hypotension. Image from CT myelogram demonstrates needle insertion into the epidural space adjacent to the right T8-9 perineural root sleeve cyst for blood patch placement.

Conclusions
Computed tomography-guided epidural blood patching can be used for the treatment of spontaneous intracranial hypotension in the myelographic absence of a CSF leak by targeting perineural root sleeve cysts. Computed tomography-guided epidural blood patching is a new, safe and effective alternative compared to traditional surgical exploration.

Active Extravasation of Gadolinium-Based Contrast Agent On Lumbar Spine MRI Following Traumatic Lumbar Puncture

H Wang¹, J Pannell¹, N Farid¹

¹University of California San Diego, San Diego, CA

Purpose
Introduce a case of active extravasation of gadolinium-based contrast agent in the central nervous system (CNS).

Materials and Methods
A 39-year-old male with AIDS who presented with headache. Imaging revealed brain lesions concerning for toxoplasmosis versus CNS lymphoma, for which empiric toxoplasmosis treatment was initiated. As part of the work up, the patient also underwent lumbar puncture which was performed at bedside. Shortly after the procedure, the patient developed new bilateral leg weakness, diminished sensation below T10, decreased rectal tone, and urinary retention. MR imaging of the lumbar spine demonstrated a large subdural hematoma and active extravasation of gadolinium-based contrast. Patient underwent emergent surgical decompression. Intraoperative
findings included subdural hematoma compressing the cauda equina. During evacuation, an actively bleeding vessel was identified. Surgeons noted that dissection planes oozed significantly throughout the procedure. Evaluation for coagulopathy showed decreased fibrinogen.

Results
MR imaging demonstrated a 5.6 x 1.1 cm intradural extramedullary collection at the level of L3-5 which compressed the cauda equina. The collection was isointense to CSF on T2-weighted imaging and slightly T1 hyperintense. On T2-weighted imaging, there was a peripheral rim of T2 hypointensity. On the sagittal postcontrast images, there was a curvilinear area of apparent contrast enhancement extending from the central thecal sac anteroinferiorly and contacting the posterior aspect of the right L4 vertebral body. On the axial postcontrast images which were acquired several minutes after the sagittal postcontrast images, the areas of apparent contrast enhancement had significantly increased. Therefore, it was concluded that the areas of apparent contrast enhancement in fact represented active extravasation of gadolinium-based contrast agent.

Conclusions
While active extravasation of gadolinium-based contrast in the liver has been reported, a literature review does not reveal any reports of active extravasation of gadolinium-based contrast in the CNS. In this case, a patient underwent a common diagnostic procedure and suffered an uncommon complication of lumbar subdural hematoma resulting in cauda equina syndrome. Subdural hematoma following lumbar puncture is a rare but reported complication, as noted by Gaucher (1), Guthikonda (3), and Vos (5). Contrast-enhanced MRI not only demonstrated the subdural hematoma, but also showed areas of apparent contrast enhancement. A key finding in this case was the increase in the areas of apparent contrast enhancement on the sagittal postcontrast images which were acquired several minutes after the axial postcontrast images, thereby confirming a dynamic process and leading to the diagnosis of active extravasation.

KEYWORDS: Contrast, Contrast Enhancement, Contrast Extravasation
An Unusual Primary Osseous Tumor: Desmoplastic Fibroma of the Thoracic Spine

P Hill¹, D Pastel¹

Figure 1. Sagittal and axial post-contrast fat-saturated T1W image was obtained 7 minutes after the sagittal image. Apparent enhancement within the thecal sac (curvilinear on sagittal and markedly increased by the time axial image was obtained.)
**Dartmouth Hitchcock Medical Center, Lebanon, NH**

**Purpose**
To report the extraordinarily rare case of a thoracic spine desmoplastic fibroma causing myelopathic symptoms.

**Materials and Methods**
A 46-year-old male with a five-year history of lower back pain and prior L5-S1 diskectomy presented with new onset of parasthesias, myelopathic gait and hyperreflexia. A total spine MR revealed a homogenous T1 & T2 hypointense, expansile mass involving the T3 vertebral body, spinous process and articulating processes with epidural extension causing cord compression. Computed tomography (CT) examination detected a destructive lesion with a large lytic defect in the T3 vertebra with complete replacement of the osseous matrix in the majority of the vertebral body and posterior elements with a sclerotic inferior and anterior osseous remnant. To assess the histological diagnosis, a biopsy was attempted but due to the hard density of the mass was unsuccessful. A marginal tumor resection was performed and stabilization with T1-T6 laminar hook and posterior rods. Pathologic staining and immunoreactivity confirmed a diagnosis of desmoplastic fibroma.

**Results**
Axial CT image in a bone window, through the T3 vertebral body. A sclerotic sliver of the vertebral body remains, as the destructive lesion has replaced the osseous matrix. Scattered small fragments of the posterior elements are seen at the costo-vertebral joints and adjacent to the central canal. The spinous process is seen in the center of the image completely replaced by a soft tissue density. T1 sagittal image of the thoracic spine. A fairly homogenous, hypointense, expansile mass invades the majority of the T3 vertebral body and spinous process with obvious compression of the spinal cord at this level.

**Conclusions**
Desmoplastic fibromas represent an extremely rare primary osseous tumor and localization to the thoracic spine has been described only in a few case reports. Due to the paucity of cases, the radiologic characteristics have not been fully delineated. A combination of CT and MR imaging is recommended in the literature for full characterization of the osseous matrix and evaluation of intramedullary involvement for pre-operative planning. A wide margin of excision is recommended, as tumor recurrence has been reported to be between 37-72%. In cases where en bloc resection is not performed, follow up with contrast-enhanced MR is recommended for continued surveillance. Now, two years postresection, the patient has no radiologic evidence of recurrence and is pain-free, working and living an active life.

Case Report: Very Rare, High Risk HPV Oropharyngeal Squamous Cell Carcinoma Metastasis Arising in a Preexisting Cervical Spine Arthrodesis.

N Satovick¹, L Shah¹, R Wiggins¹

¹University of Utah, Salt Lake City, UT

Purpose
Osseous metastases from primary oropharyngeal cancer is the second most common site of metastases after lung, however cervical spine bony metastatic disease is uncommon. This is the first reported case of bony metastatic disease arising at the site of a pre-existing anterior cervical diskectomy and fusion (ACDF) from a primary high risk human papilloma virus (HPV) oropharyngeal squamous cell carcinoma (OPSCC).

Materials and Methods
A 53-year-old male presented with a slowly enlarging left neck mass. The patient had undergone an ACDF of C4-C7 four years prior to presentation and posterior decompression and fusion of C3-C7 three years prior to presentation. Biopsy of the tonsil returned nonkeratinizing squamous cell carcinoma (SCC) positive for high risk HPV by in situ hybridization. Staging PET-CT showed contralateral nodal disease without distant metastases. Final diagnosis was HPV positive
stage IVa (T3N2cM0) SCC of the palatine tonsil. Surveillance PET-CT three months following completion of radiation therapy found a new 7mm FDG avid nodule in the lingula and FDG uptake in the C4 vertebral body without fracture or osteolysis. Computed tomography-guided biopsy of the lung nodule confirmed metastatic SCC. Tissue sampling of the cervical disease was not obtained and metastatic disease was presumed based on imaging.

Results
Sagittal T2 and sagittal T1 postcontrast show an expansile T2 hypointense, enhancing C4 mass corresponding to the FDG avid lesion.

Conclusions
The imaging findings are consistent with a metastatic lesion and given the presence of pulmonary metastatic OPSCC the cervical vertebral lesion is very likely from the same primary. There are no findings to support differential considerations of bony fracture, arthrodesis failure, infection, or radiation induced osteonecrosis. There is a theoretical increased risk of metastatic disease at the site of arthrodesis given the altered micro environment with active cytokine and molecular interactions. Patients with bony spinal metastatic disease are at increased risk of pathologic fracture and neurologic compromise. Patients with metastatic disease at the site of prior spinal fusion and decompression have fewer treatment options and are at greater risk for complication than those with no prior spinal surgery. The potential for metastasis at the site of prior spinal fusion should be a consideration at the time of initial cancer diagnosis in order to anticipate potential future complications.

EE-110

Extramedullary Anaplastic Ependymoma: A Rare Cause of Spinal Cord Compression

B Griffith1, B Carter1, J Corrigan1, S Patel1, A Mahmood1
Purpose
Ependymomas are the most common intramedullary spinal neoplasm in adults, typically occurring in the cervical or thoracic spine. Intradural extramedullary ependymomas are quite rare, and when present, are often initially misdiagnosed as neuromas or meningiomas. This excerpt describes a rare case of an intradural extramedullary anaplastic ependymoma causing compression of the spinal cord.

Materials and Methods
We present the case of a 49-year-old female with a four-month history of left leg numbness and weakness, as well as a band-like burning sensation in her thoracic region. The patient also complains of increasing difficulty with urination. The patient underwent a T6-T12 laminectomy with microdissection at which time a large intradural extramedullary tumor was removed from the spinal canal. The tumor was noted to be separate from the cord with only a thin extension to the filum. Pathology demonstrated an ependymal neoplasm with hypercellularity, microvascular proliferation, tumor necrosis, and a Ki-67/ MIB-1 proliferation index of up to 15%. These findings are consistent with an intradural extramedullary anaplastic ependymoma. Despite achieving gross total surgical resection, the patient had persistent leg weakness and was to undergo radiation and chemotherapy.

Results
Thoracic spine MR demonstrates a large T2 hyperintense, T1 isointense solid enhancing mass in an intradural and extramedullary location. The mass causes severe mass effect along the anterior aspect of the thecal sac resulting in spinal cord compression and faint cord edema. There is no neuroforaminal remodeling or evidence of leptomeningeal or intramedullary enhancement. Upon imaging the remainder of the central nervous system, no additional enhancing lesions are identified.

Conclusions
Ependymomas are the most common intramedullary spinal neoplasm in adults. In contrast, intradural extramedullary ependymomas are quite rare, with less than 20 reported cases in the literature. Ependymomas typically arise from cells lining the ventricular system of the brain or central canal of the spinal cord. However, extramedullary ependymomas are postulated to arise from ectopic ependymal cells that are pinched off from the neural tube during its closure. Given the rarity and the potential for confusion with more common lesions such as neuroma or meningioma, it is important that neuroradiologists consider ependymomas in the differential diagnosis of intradural extramedullary spinal lesions.

KEYWORDS: Cord Compression, Ependymoma, Extramedullary
Isolated Hypoglossal Nerve Palsy Caused by an Atlantoaxial Synovial Cyst

R Goff¹, S Weindling¹, V Gupta¹
¹Mayo Clinic Florida, Jacksonville, FL

Purpose
Hypoglossal nerve palsy is an uncommonly encountered phenomenon with a wide variety of causes, often creating a difficult diagnostic dilemma for the clinician. Typical underlying pathologic processes include brainstem infarctions, demyelinating diseases, gliomas, infections, and hypoglossal nerve schwannomas. We report a rare case of isolated hypoglossal nerve palsy secondary to hypoglossal nerve impingement by an atlantoaxial synovial cyst. Distinguishing this entity from other more common lesions responsible for hypoglossal nerve palsy can have important treatment and prognostic implications, as emphasized by our case report.

Materials and Methods
A 69-year-old female presented with a two-year history of progressive tongue weakness, paresthesias, and right-sided tongue atrophy. Pertinent physical exam findings included isolated right 12th nerve palsy with ipsilateral tongue deviation and fasciculations. Outside MR imaging (MRI) described a small mass contiguous with the right hypoglossal canal, felt to be most consistent with a meningioma. Following radiation oncology consultation at our institution, a planning MRI was obtained prior to stereotactic radiation for presumed meningioma. MR imaging revealed a T2 hyperintense, marginally enhancing lesion adjacent to the right hypoglossal canal and approximating the hypoglossal nerve. The lesion had decreased in size when compared to an outside study performed 10 months earlier. Meningioma and schwannoma were excluded on the basis of predominant T2 hyperintensity, marginal enhancement, origin extrinsic to the hypoglossal nerve, and interval size decrease. Upon careful review of contiguous T1 postgadolinium images, a connection was established between this marginally enhancing lesion and the superior aspect of the right atlantodental joint. This constellation of findings was believed most suggestive of a superiorly projecting atlantoaxial synovial cyst compressing the cisternal segment of the hypoglossal nerve. In our brief literature search, cranial nerve XII palsy secondary to a craniocervical junction synovial cyst only has been described in four other case reports. The patient opted for conservative treatment as symptoms were not significantly limiting.

Results
MR imaging demonstrated a small skull base mass along the medial margin of the right hypoglossal canal adjacent to the cisternal segment of the hypoglossal nerve. The lesion is T1 hypointense, T2 hyperintense, and shows marginal enhancement postcontrast. Contiguous slices show a clear connection to the superior aspect of the atlantodental joint. Findings are most compatible with a atlantoaxial synovial cyst. Selected axial T2 space and T1 postcontrast MR images are shown below with yellow arrows identifying the lesion.

Conclusions
Hypoglossal nerve palsy rarely is seen in isolation, more common in the setting of multiple lower cranial nerve palsies. Imaging evaluation of hypoglossal nerve palsy requires high resolution imaging and detailed understanding of the nerve anatomy as it courses from the medulla to the intrinsic and extrinsic muscles of the tongue. A segmental approach has been proposed in the literature to organize hypoglossal nerve pathology based on the portion of the nerve affected. Craniocervical junction synovial cysts may clinically present with hypoglossal nerve palsy, and
have been previously reported. While uncommon, this entity should be remembered when a juxtaarticular, T2 hyperintense lesion lacking central enhancement is seen on MRI.

Leptomeningeal Carcinomatosis: Case Report of an Unusual Manifestation of Multiple Myeloma

O Banon\textsuperscript{1}, G Popradi\textsuperscript{2}, D Tampieri\textsuperscript{1}, D Melancon\textsuperscript{1}, M Cortes\textsuperscript{1}  
\textsuperscript{1}Montreal Neurological Institute and Hospital, McGill University, Montreal, Quebec, Canada,  
\textsuperscript{2}Royal Victoria Hospital, McGill University, Montreal, Quebec, Canada

Purpose  
Involvement of the central nervous system (CNS) in multiple myeloma (MM) has been described as a rare entity, with an incidence of only 1%.\textsuperscript{*} Among the various CNS manifestations, leptomeningeal myelomatosis (LM), with the characteristic presence of monoclonal plasma cells in the cerebrospinal fluid (CSF), is observed in less than 1% of all the MM cases.\textsuperscript{*} We would like to report a case of LM, which illustrates some common clinical and imaging findings of the disease.
Materials and Methods
A 57-year-old female presented to the emergency department with bilateral leg weakness, fecal incontinence and back discomfort. One year earlier, she had been diagnosed with a lambda light chain myeloma that was treated with radiation and chemotherapy. Her past medical history revealed partial resection of a cavernous meningioma, one year prior to the MM diagnosis. Magnetic resonance imaging (MRI) of the brain and spine were obtained and the findings are described below. Cerebrospinal fluid (CSF) analysis demonstrated the presence of plasmacytoid cells, and further correlation with CSF flow cytometry confirmed the diagnosis of LM. Pathology report at the time of MM diagnosis showed deletion of the p53 gene locus, a feature that has been associated with LM.*

Results
MR imaging of the spine revealed diffuse and extensive leptomeningeal enhancement along the spinal cord and cauda equina, consistent with leptomeningeal carcinomatosis. Brain MRI demonstrated intraventricular enhancing nodules. Of note, no bony lesions were present to suggest multiple myeloma. Figure 1 (attached image). Sagittal T1 view with gadolinium demonstrating diffuse leptomeningeal enhancement and thickening of the cauda equina roots. No bone lesions are noted.

Conclusions
We report an unusual case of leptomeningeal carcinomatosis in a patient with multiple myeloma. The patient presented with symptoms suggestive of cauda equina syndrome. Radiographic findings, as well as cerebrospinal fluid sampling and flow cytometry supported the diagnosis of leptomeningeal myelomatosis. With an incidence of less than 1%, LM is a rare manifestation of MM, and is associated with chromosomal abnormalities such as p53 gene alterations.*

MRI Guided Focused Ultrasound (MRgFUS) for the treatment of Fibroids complicated by Lumbosacral Plexopathy and Sciatic Nerve Injury

V Trinh1, M Ngo1
1Kaiser Permanente Los Angeles Medical Center, Los Angeles, CA
Purpose
To illustrate a rare case of lumbosacral plexopathy and sciatic nerve injury treatment-related complication of MRI-guided focused ultrasound (MRgFUS) for the treatment of fibroids. MRI-guided focused ultrasound for the treatment of fibroids is a relatively new FDA approved technique (approved in October 2004) in the treatment of symptomatic fibroids. Although determined relatively safe, possible neurologic complications include lumbosacral plexopathy and sciatic nerve injury. The case report will reveal the classic imaging features of these complications that, in our case, directly correlate with nonradiologic objective examinations and the patient's physical symptoms.

Materials and Methods
A 38-year-old female presents with worsening right leg weakness. The patient had no significant prior medical history other than symptomatic fibroids. She revealed she had undergone MRgFUS for the treatment of her fibroids a few weeks prior to her presentation but did not have any symptoms immediately after the procedure. The patient underwent nerve conduction testing which revealed an unrecordable right superficial peroneal (sensory) response. Additionally, electromyography showed abnormal spontaneous activity and decreased recruitment in the right L5-S1 anterior myotome. The constellation of findings was determined by the neurology service as consistent with subacute right lumbosacral plexopathy affecting the L5-S1 anterior myotome, with ongoing denervation consistent with Wallerian degeneration. An MR imaging (MRI) pelvis was ordered to further evaluate these findings. The MR pelvis exam corroborated the findings with evidence of abnormal asymmetric edema involving the right lumbosacral plexus and right sciatic nerve. Additionally, there was new anterior sacral bone marrow edema when compared to a preprocedural pelvic MRI, a key finding which adds specificity to the diagnosis of a MRgFUS treatment-related complication. The finding of sciatic nerve injury due to this procedure has been reported previously and the proposed mechanism of nerve damage is thought secondary to thermal injury and heating of the adjacent bone (sacrum).

Results
Axial sequential fat saturated T2 sequences are provided from cranial to caudal at the level of the pelvis. There is crescentic configuration of subperiosteal bone marrow edema along the ventral surfaces of S1 and S2. Additionally, there is increased edema involving the right lumbosacral plexus and extending peripherally to involve the right sciatic nerve. Preprocedure MRI of the pelvis prior to the MRgFUS exam (no attached given the limited character requirement) revealed a normal appearance to the sacrum, lumbosacral plexus, and sciatic nerve.

Conclusions
MRI-guided focused ultrasound is a relatively new noninvasive treatment for symptomatic fibroids (FDA approved in 2004). Our case report will illustrate the rare but reported possible neurologic complication of this procedure including lumbosacral and sciatic nerve injury. The proposed mechanism of injury is not related to direct burning of the nerve itself, but actually related to the heating of the sacrum and secondary thermal injury of the adjacent sciatic nerve.

Spontaneous Spinal Epidural Hematoma: Unusual Site of Bleeding in a Case of DIC.

B Chandrasekaran, K Sicard, M Ghadiali, B Midkiff

Saint Vincent Hospital, Worcester, MA

Purpose
Spontaneous spinal epidural hematoma (SSEH) is a rare entity characterized by nontraumatic bleeding into the epidural space. The dorsal aspect of the thoracic or lumbar region most commonly is involved. The source of hemorrhage is typically venous but also can be arterial. We present an interesting case of SSEH in the setting of fulminant disseminated intravascular coagulation (DIC) likely secondary to leukemia.

Materials and Methods
A 64-year-old female presented to the ED with acute nontraumatic low back pain. She denied a past history of trauma. Physical exam was positive for splenomegaly and subcutaneous
ecchymosis. Emergency abdomen/pelvis CT showed a left retroperitoneal hematoma, bleeding into the psoas and thoracolumbar paraspinal muscles, and high density material in the spinal canal consistent with blood products. Follow-up thoracolumbar spinal MR imaging (MRI) confirmed a large acute epidural hematoma causing severe spinal cord compression. Additionally, diffuse low signal intensity in the vertebral bodies on T1-weighted images suggested an underlying bone marrow infiltrative process. Subsequent blood work revealed pancytopenia, bandemia and features of DIC. Unfortunately, the patient's condition progressed to quadriparesis and she expired shortly after.

Results
Spontaneous spinal epidural hematoma is a rare neurological condition. Typical clinical presentation of SSEH is sudden back pain that can rapidly progress to paraparesis or quadriparesis, as with our patient. Spontaneous spinal epidural hematoma often is related to an underlying coagulopathy, infection, or underlying lesion such as a vascular malformation or neoplasm. MR imaging is considered the first choice diagnostic imaging method for SSEH. MR imaging typically shows a well circumscribed biconvex epidural hematoma. Acute to subacute hematomas show a characteristic high signal intensity on T1-weighted images. However, the appearance and signal characteristics of the SSEH depends on its age. A CT should be performed if MRI is unavailable, and typically shows a hyperdense epidural collection with features of cord compression. Early surgical intervention is the standard treatment; however multilevel acute hematomas may be difficult to treat operatively in patients with underlying coagulopathy, as in our patient. In such cases, conservative treatment has been documented.

Conclusions
Spontaneous spinal epidural hematoma is a rare but potentially fatal entity that needs to be recognized on early imaging. Computed tomography can help with early diagnosis by the presence of blood in the epidural space in the setting of coagulopathy, even before MRI can be obtained. Urgent decompression, in the absence of contraindications like severe coagulopathy can be lifesaving.

KEYWORDS: Hematoma
Vertebral body infarct and ventral cauda equina enhancement: two findings confirming an acute spinal cord infarct

F Diehn, L Eckel, C Hunt, D Black, V Lehman, C Wood, J Wald

Mayo Clinic, Rochester, MN

Purpose
To present a recently e-published case of an acute spinal cord infarct (SCI) in a young adult male, in which two confirmatory MR imaging (MRI) findings were present: a concomitant vertebral body infarct and the rare enhancement of the ventral nerve roots of the cauda equina.

Materials and Methods
A 24-year-old man experienced sudden onset of lower back pain and bilateral leg cramping while bending. On the subsequent day, acute leg weakness caused him to collapse. At a local hospital, bilateral lower extremity paralysis, areflexia, decreased pain/temperature sensation, and urinary retention were noted. Evaluation consisted of an entire spine MRI without/with intravenous gadolinium (findings described below). Intravenous steroids and immunoglobulin were initiated for suspected Guillain-Barré syndrome. After seven days of inpatient therapy he could once again self-transfer and was discharged to home in a wheelchair. Two days later he experience sudden sharp chest pain as well as loss of left leg sensation and strength. At the outside hospital, autonomic instability was documented. Neither head computed tomography (CT) nor CT of the chest/abdomen/pelvis with aortic dissection protocol revealed an etiology. An ECG and cerebrospinal fluid (CSF) analysis were normal. A repeat spine MRI was performed, 15 days after the initial MRIs (findings described below). Upon transfer to our institution, examination revealed areflexic paraplegia with pain/temperature discrimination absent below a
T11 sensory level, compatible with an anterior cord syndrome. Intravenous methylprednisolone was administered empirically to treat vasculitic or autoimmune etiologies. Extensive laboratory evaluation for infectious, rheumatologic and autoimmune causes of arterial thrombosis and for genetic/acquired hypercoagulability was unrevealing. Given this and the history of recent mild back injury, the presumed cause was fibrocartilaginous embolism. The patient was discharged to a rehabilitation facility, afebrile, hemodynamically stable, and with unchanged neurologic deficits.

Results
Sequential MRIs demonstrate progressive cord/conus signal abnormality/enhancement compatible with evolving anterior SCI, presumably from occlusion of the artery of Adamkiewicz. An osseous infarct develops in the posterior aspect of the T12 vertebral body, clinching the diagnosis of spinal cord infarct. Mild diffuse enhancement of the ventral cauda equina nerve roots develops, without enlargement or nodularity, and also confirms SCI.

Conclusions
Neuroradiologists should be aware that associated findings can definitively diagnose SCI. Ventral cauda equina nerve root enhancement is unusual, but probably an under-recognized confirmatory sign. A more commonly seen but still likely underappreciated finding is the concomitant presence of vertebral body infarct(s). These signs are likely most useful subacutely, especially when the clinical picture is not classic for SCI. This was true for the subject of this case report, as an inflammatory condition was being considered clinically given the stuttering symptoms; recognition of these two imaging signs led to accurate diagnosis.

320-Row Multidetector CT Angiography for Detection of Critical Cerebrovascular Anomalies: Comparison with Conventional Digital Subtraction Angiography

J Hebert¹, F Roncarolo¹, D Sarfati¹, D Tampieri², M Cortes²
¹Montreal Neurological Institute, Montreal, Quebec, ²Montreal Neurological Institute and Hospital, Montreal, Quebec

Purpose
The acquisition of a new 320-row multidetector CT scanner at the Montreal Neurological Institute and Hospital has provided higher quality imaging with less radiation exposure and shorter time of acquisition. However, its reliability has not been fully proven in critical vascular lesions, when it comes to replace a more invasive exam such as cerebral angiography. We wished to validate the accuracy of this equipment to investigate four common indications for patients to undergo conventional digital subtraction angiography (DSA): subarachnoid hemorrhage, vasospasm, unusual intracerebral hemorrhage, unruptured aneurysm.
Materials and Methods
Medical records and relevant imaging from 102 consecutive subjects who underwent a 320-row multidetector CTA and subsequently cerebral angiography from February 2010 to February 2013 were retrospectively analysed. Reports from both imaging modalities were compared to determine the diagnostic accuracy of CTA.

Results
The overall sensitivity and specificity of 320-row multidetector CTA for detecting cerebrovascular abnormalities were, respectively, 97.60 and 63.20%. Similar results were obtained for all four categories of clinical indications and a detailed breakdown per indication will be shown during the presentation.

Conclusions
Results obtained from CTA were consistent with those obtained on DSA regardless of the vascular pathology. To our knowledge, this study is the first validating the accuracy of 320-row CTA in diagnosing critical vascular lesions. This is the foundation for a prospective investigation aiming to reassure clinicians on the high reliability of a 320-row CTA thus limiting the need of cerebral angiography.

3D MRI in multiple sclerosis: A comparison of 3D DIR, 3D FLAIR, and 2D FLAIR

F Yu¹, C Bazan², B Tantiwongkosi³
¹University of Texas Health Science Center at San Antonio, SAN ANTONIO, TX, ²University of Texas Health Science Center San Antonio, San Antonio, TX, ³University of Texas Health Science Center at San Antonio, San Antonio, TX

Purpose
Many neurologists utilize the McDonalds criteria in the diagnosis of multiple sclerosis (MS), which relies heavily on the ability of MRI to detect white matter lesions (characterized as hyperintense on T2-weighted/FLAIR sequences). According to the criteria, patients must have 2 clinical attacks with dissemination in time (DIT) and space (DIS) (1). DIS requires lesions in 2 of the following locations: infratentorial, periventricular, or juxtacortical. For DIT, there must be a new lesion on a subsequent MRI. Therefore, accurate lesion detection in diagnosis and management of MS patients is essential. The purpose of our study is to compare the efficacy and clinical feasibility of 3D Double Inversion Recovery (DIR), 3D FLAIR, and conventional 2D FLAIR turbo spin echo sequences in the evaluation of multiple sclerosis lesions.

Materials and Methods
Internal review board approval was sought for this prospective analysis of adult multiple sclerosis patients (N = 30). All MRIs will be performed on a 3T MR scanner, to include 3D-FLAIR, 3D-DIR, and 2D FLAIR turbo spin echo sequences. The MR images will be reviewed by 2 neuroradiologists, with attention to white matter lesions.

Results
Preliminary findings from 6 patients demonstrated increased sensitivity of 3D FLAIR in the detection of white matter lesions when compared 2D FLAIR, particularly in the posterior fossa.
(174 supratentorial and 17 infratentorial lesions versus 115 and 7, respectively). The scan time for the 3D FLAIR sequence was marginally increased compared to the axial 2D FLAIR sequence (4:56 min versus 3:40 min), but significantly shorter than the combination of sagittal and axial 2D FLAIR sequences (9 minutes) which comprised our conventional multiple sclerosis protocol. In a subset of 2 patients, 3D DIR performed comparably with 3D FLAIR (56 supratentorial and 9 infratentorial lesions versus 66 and 8, respectively), although certain lesions were better characterized by one than the other (Figure 1).

Conclusions
Modern 3D MR sequences offer certain advantages over their 2D counterparts in light of increased signal-to-noise ratio as well as through-plane resolution, and within a reasonable scan time owing to fast spin echo and parallel imaging (2). Incorporating these features with DIR and FLAIR tissue contrasts should lead to clinically feasible improvements in MS lesion characterization and ultimately patient care (3) (4). Additionally, we will also attempt to illustrate the respective roles of 3D FLAIR and 3D DIR in this setting.

KEYWORDS: Inversion Recovery, Multiple Sclerosis, Multiple Sclerosis Plaques

Figure 1: 3D DIR versus 3D FLAIR axial MR images. The blue arrow (a) in the 3D DIR image indicates a left frontal white matter lesion not seen on the corresponding FLAIR image (b).

4D-Dynamic CTA

R Glikstein¹, S Chakraborty¹

¹The Ottawa Hospital, Civic Campus, University of Ottawa, Ottawa, ON

Purpose
To demonstrate the value of dynamic 4-D CTA in different intra and extracranial neurovascular pathologies

Materials and Methods
From July 2009 to June 2013, 1812 adult patients with acute neurological symptoms underwent dynamic CTA, on a 320 Toshiba CT scanner. The exam included non enhanced CT scan of the brain followed by dynamic CTA. IV bolus injection of 90 cc non ionic contrast was used to obtain perfusion studies and post-processing imaging including 4D time resolved images in coronal and sagittal planes. 3D reconstruction 4D imaging were obtained as well. Whole CTA from the aortic arch to the vertex was obtained. Dynamic CT angiogram (D-CTA) was performed in a 320-row volume CT scanner (Aquilion ONETM), which uses an ultra-high-resolution detector rows (0.5 mm in width) to image the entire brain in a single gantry rotation. D-CTA is a non-invasive technique to acquire a time series of bone subtracted or unsubtracted CT angiogram images of the whole brain, thus removing timing uncertainties found in typical static CT angiogram images. This approach also provides temporal flow information. The single volume acquisition takes 1 second resulting in a temporal resolution of 1/sec. By manipulating the raw data improved temporal resolution up to 5/sec is possible. The data acquisition of whole brain volumes at sequential time points starts at 7 sec from the time of contrast injection. This volume uses 300 mA 80 kV and is used as a mask for subtraction. The other volumes are acquired at 100 mA 80 kV. In the arterial phase (10 to 35 sec), whole brain volumes are acquired every 2 sec. In the venous phase (40 to 60 sec) volumes are acquired at 5 sec interval.

Results
955 patients with acute stroke, 529 patients with non traumatic subarachnoid hemorrhage, 328 patients with spontaneous intraparenchymal bleed. On ischemic stroke patients we were able to identify abnormal areas of perfusion, penumbra as well the site of arterial occlusion on intracranial vessels form large to small caliber, i.e., ICA or Vertebral artery to M3 branches. On patients with AVM or AVF we were able to identify dynamically the efferent and afferent vessels as well aneurysms associated to the vascular malformation. On patients with intraparenchymal bleeds related to hypertension or coagulopathies it was possible to identify the presence or absence of the spot sign, predicting value for possible hemorrhage progression. Other neurovascular pathologies were clearly identified such as traumatic or spontaneous vascular dissection, occluded stents, venous thrombosis, etc.

Conclusions
For a long period of time, DSA was considered as the gold standard method to diagnose neurovascular pathologies. With the new generation of multi slice helical CT scanners, post processing reconstruction, perfusion studies and dynamic evaluation of the vasculature from the arterial to the venous phase is very useful to determine precise site of the anomaly in cases of arterial occlusion, aneurysm, AVM or AVF. It helps to evaluate differences in timing between
vascular territories, allows guidance for neurovascular interventional procedures or neurosurgical treatment as well in the decision process on non-invasive treatments.

A Multi-Reader Assessment of MRI Diagnostic Accuracy in Sporadic and Variant Creutzfeldt-Jakob Disease

D Mollison¹, G Mackay², A Molesworth³, S Kealey⁴, R Will³, D Summers⁴
¹Western Clinical General Hospital, Edinburgh, UK, ²Southern General Hospital, Glasgow, UK, ³National Creutzfeldt-Jakob Disease Surveillance Unit, Edinburgh, UK, ⁴Division of Clinical Neurosciences, Edinburgh, UK

Purpose
A high incidence of pathognomic magnetic resonance imaging (MRI) findings previously have been described in both sporadic and variant Creutzfeldt-Jakob disease (sCJD/vCJD). We hypothesized that there may however be significant inter-rater variation in the identification of many of the described findings, particularly when presented with mixed cases of sCJD, vCJD and controls.

Materials and Methods
Anonymized MRI studies from 50 patients referred to the UK National CJD Surveillance Unit and for whom MRI was available were reviewed. These comprised 20 consecutive cases with final diagnosis of sCJD, 15 cases of vCJD and 15 control cases referred as suspected CJD in whom a final non-CJD diagnosis was made. Imaging acquisition protocols were variable - all available T2, FLAIR and diffusion-weighted imaging (DWI) sequences were reviewed. A consensus read by two neuroradiologists with a specialist interest in CJD was used as the imaging reference standard. A further 20 assessors recruited from international CJD surveillance networks reviewed all 50 studies, blinded to the final diagnosis. Images were reviewed via a browser-based portal, with all sequences for each case presented concurrently. A structured reporting system prompted each reviewer to grade the appearances of deep gray matter nuclei and cortical regions for each sequence. Assessors also offered a final diagnosis of sCJD, vCJD or non-CJD, and their degree of certainty. Reviewer demographics including experience and frequency of scan assessment were captured.

Results
The overall agreement of the imaging reference standard with the final diagnosis was 72%. There was high specificity for CJD, with all 15 noncases correctly identified. The positive predictive value for sCJD was 85% and vCJD 91%. The overall agreement of reviewers with the imaging reference standard was 79%; when adjusted for agreement expected by chance, this was moderate to good (kappa=0.64). No significant association could be demonstrated between diagnostic accuracy and length of interest, frequency of MRI assessment or clinical role. There was very good agreement between assessors and the imaging reference standard in assessment of the caudate head, anterior putamen and pulvinar. Assessment of the 'pulvinar sign', an important MRI finding in vCJD, also showed good agreement (k=0.78). There was only moderate agreement in assessing the presence of cortical high signal and poor agreement on specific
cortical regions involved. Correct scoring of abnormal signal in caudate, pulvinar nucleus relative to anterior putamen, and cortical regions were all associated with overall diagnostic accuracy. In sCJD the likelihood of an accurate diagnosis were significantly increased if DWI was the preferred sequence. Sequence preference was not associated with diagnostic accuracy for vCJD cases.

Conclusions
There is a range of inter-rater performance in the diagnostic accuracy for CJD based on MRI, even among reviewers with a specialist interest. Correct assessment of key gray matter and cortical signal change is associated with overall diagnostic accuracy. Our study highlights the importance of diffusion-weighted imaging, particularly for sCJD where cortical hyperintensity may be the only imaging finding.

EP-33

A Novel Observation of Hyperacute Ischemic Stroke in Rats: Using Prospective 3 T Diffusion MRI and 3 Dimensional Voxel-Based Analysis

K Yi¹, C Choi², S Cha¹, J Hwang³, H Lee⁴, S Lee⁵, Y Lee⁵
¹Chungbuk National University Hospital, Cheongju, Korea, ²National Medical Center, Seoul, Korea, ³Philips Healthcare, Seoul, Korea, ⁴Chung-Ang University College of Medicine, Seoul, Korea, ⁵National Primate Research Center, Cheongwon, Korea

Purpose
For the translational research of focal cerebral ischemia, rat middle cerebral artery occlusion (MCAO) models have been used most commonly. And yet previous reports revealed rat MCAO models were very diverse in their nature. This is to present our novel observation of experimental stroke in rats with similar lesion characteristics after MCAO.

Materials and Methods
Rats were subject to left MCAO using the suture technique. Immediately after occlusion, the animals were placed into an MRI scanner (3.0 T) and diffusion-weighted imaging (DWI) was repeated with a rat coil every 10 minutes. Every first MR imaging was started within 10 minutes after stroke onset. Immediately after each MR scan, DWI and apparent diffusion coefficient (ADC) maps were evaluated to determine whether successful MCA territorial infarction was obtained by two neuroradiologists. Five rats were followed with repeated DWI for 60 minutes and four rats for 120 minutes. Percentage of hemispheric lesion volume (%HLV), ADC value (ADC) were evaluated for quantitative analysis of ADC-derived lesion characteristics using voxel-based analysis. For voxel-based analysis, 3D volume analysis of lesion segmented by automatic method was performed using FSL software package (http://fsl.fmrib.ox.ac.uk/fsl/fslwiki/).

Results
Successful MCA territorial infarction was induced in nine rats (9/32, 28.1%) and they showed MCA territorial infarction at the first DWI 10 minutes after MCAO. Three dimensional voxel-based analyses showed that all ADC-derived lesion volumes did not change during the MRI follow-up period (%HLV at the first MRI: 52.1% (39.7~67.3%), Last 54.8% (39.7~66.4%)).
Apparent diffusion coefficient values of the ischemic lesions did not show the temporal changes during the DWI observation. At the first MR scan mean ADC value was 405 $\times 10^{-6}$ mm$^2$/sec (range 361~434$\times 10^{-6}$ mm$^2$/sec), the last was 390$\times 10^{-6}$ mm$^2$/sec (363~430$\times 10^{-6}$ mm$^2$/sec).

Conclusions

Applying prospective diffusion MRI and 3D voxel-based analysis, very early on after MCAO in rats, we observed experimental brain infarctions remaining unchanged with very similar lesion extent and the diffusion MR characteristics.

A Report of Twin Cases of Ruptured Epidermoid Cyst: A Rare Phenomenon

M Ghuman$^1$, S Vyas$^2$, N Khandelwal$^2$, V Gupta$^3$, S Kaur$^4$

$^1$Post-Graduate Institute of Medical Education & Research, Chandigarh, India, $^2$Dept of Radiodiagnosis, PGIMER, Chandigarh, India, $^3$PGIMER, Chandigarh, India, $^4$Indira Gandhi Medical College, Shimla, India

Purpose

Epidermoid cysts are congenital lesions of epidermal origin, representing 0.2% to 1.8% of all primary intracranial tumours. They usually present in the second to third decade of life. The most common symptoms are due to mass effect; headache, seizure, tinnitus, hearing loss, facial spasm, and trigeminal neuralgia and intracranial pressure etc. Epidermoids may rupture, although very rare, resulting in dissemination of the intracystic contents into the subarachnoid space and ventricles, and consequently, present with recurrent episodes of aseptic meningitis. In this case series, we report the rare complication of rupture of intracranial epidermoid cysts in two patients with emphasis on magnetic resonance imaging (MRI) characteristics and associated complications.

Materials and Methods

Patients presented to our hospital emergency room and subsequently underwent neuroimaging. Both the patients were subjected to MRI brain, which was performed on 3 Tesla MR units (Siemens and GE) with all the standard imaging sequences, which included diffusion weighted imaging and gadolinium enhanced study. On the basis of imaging diagnosis and clinical evaluation, surgical excision of the lesions was done. Histopathology was consistent with epidermoid cysts.

Results

Epidermoid cysts are congenital lesions of epidermal origin at the time of neural tube closure, between the third and fifth week of fetal development, hence they are also called 'inclusion tumours'. Their common sites are cerebellopontine angle and perimesencephalic cisterns. They are histologically benign and slow growing tumours. They usually tend to spread along normal cleavage planes and insinuate around vessels and nerves. However, in later stages of growth, they do behave as mass lesions, remaining clinically silent for many years. The presence of a fat component or cyst content within the ventricles or subarachnoid space is a rare finding; it may occur spontaneously or during the postoperative course. First patient's imaging revealed a large epidermoid cyst in quadrigeminal cistern with rupture of contents into bilateral
lateral ventricle while in second case with a cerebellopontine epidermoid, similar signal intensity contents were seen in temporal and parietal subarachnoid spaces.

Conclusions
Though extremely uncommon, rupture of intracranial epidermoid cysts can occur, leading to spillage of intracystic contents into subarachnoid spaces and ventricles. It is a potentially lethal complication that can result in repeated attacks of asptic meningitis, obstructive hydrocephalus, cranial nerve palsies, vasospasm and cerebral ischemia or infarction.7,9,10 Hence, in every case of epidermoid, evidence of intraventricular or subarachnoid contents or chemical meningitis should be diligently sought for early diagnosis and prevention of grave consequences of rupture.

A short acquisition time dynamic contrast-enhanced perfusion imaging for the diagnosis of brain tumors with fixed T1 method and full automatic detection of vascular input function

T_ Abe1, K Delgerdalai1, M Mungunkhuyag1, M Harada1
1The University of Tokushima Graduate School, Tokushima, Tokushima, Japan

Purpose
T1-weighted dynamic contrast-enhanced (DCE) MR imaging (MRI) is useful for the diagnosis of brain tumors. By using the pharmacokinetic model introduced by Tofts et al, volume transfer contrast Ktrans, extravascular extracellular volume Ve and fractional plasma volume fPV can be
calculated. Because imaging time over five minutes generally is recommended in this method, the use in clinical setting is difficult. Further, because the result varies depending on the position of the AIF, which generally is set manually, a standardization of the analysis was necessary. In this study, we examined a short acquisition time DCE sequence which is easy to use in clinical settings, using simple analytical methods (fixed T1 method and automatic vascular function detection).

Materials and Methods
MR examinations were performed by a 3 T MR scanner using a standard eight-channel head coil. Dynamic contrast-enhanced MRI was performed using the following parameters: TR/TE, 4.4/1.0ms; flip angle 12°; field of view, 300 × 210 mm; matrix, 128 × 90; slice thickness, 8 mm; number of slices, 16; consisting of 64 phases with a temporal spacing of 3.3 seconds. Total scan time was three minutes and 31 seconds. A gadolinium-DTPA (0.1 mmol/kg) was injected with power injector at a rate 2.5ml/s and 20ml saline subsequently was injected. This study included 24 patients and 28 lesions (four low grade glioma (LGG), 12 high grade glioma (HGG), seven metastasis, five lymphoma). The diagnosis was made histologically or radiologically. Pharmacokinetic model analysis was performed by using commercially available software (GenIQ, GE Medicalsystems, Milwaukee, WI). VOF and AIF were automatically detected. Analysis was performed by using fixed T1 method. Ktrans, Ve and fPV map were acquired. In each map, the round region of interest (ROI) was placed manually on the hot spot. The sizes of the ROIs were about 100mm2. The averaged signal intensity was measured. Another ROI was placed on the high intensity area on the T2-weighted image adjacent to an enhanced lesion in each tumor, if possible. To assess the differences between DCE parameters and tumor histology, Mann-Whitney-U test was performed. A P value of less than 0.05 was considered statistically significant. Receiver operating characteristics (ROC) curve analysis was performed to evaluate the diagnostic performance. Optimal cutoff value, sensitivity, and specificity also were calculated.

Results
Ve was the most useful parameter to differentiate LGG from other tumors (p=0.0031), lymphoma from other tumors (p=0.0020). But Ve showed no significant difference between HGG and metastasis (p=0.3980). In the T2-weighted image hyperintense area, Ktrans, Ve, and fPV were higher in HGG than metastasis. The area under the ROC curve for differentiating LGG or lymphoma was highest for Ve (LGG from other tumors: Ve cutoff: 0.176, sensitivity: 96%, specificity: 100%, lymphoma from other tumors: Ve cutoff: 0.95, sensitivity: 87% specificity: 100%). For differentiating HGG from metastasis, fPV value on the T2-weighted imaging hyperintense area showed the highest accuracy (fPV cutoff: 0.008, sensitivity: 75%, specificity: 71%, p=0.063)

Conclusions
A short acquisition time DCE sequence with simple pharmacokinetic model analysis (fixed T1 method and automatic VOF/AIF detection) is useful for the diagnosis of brain tumors.

A Systematic Review, Critical Appraisal and Analysis of the Quality of Economic Evaluations in Stroke Imaging
K Burton1, N Perlis1, M Krahn1, M Kapral1, A Moody1, A Laupacis1
1University of Toronto, Toronto, Ontario, Canada

Purpose
To review the quality of economic evaluations of acute stroke imaging to direct thrombolytic therapy and to identify areas for improvement in future economic evaluations.

Materials and Methods
We conducted searches of electronic databases including Medline, EMBASE, CINAHL, Econlit, the NHS Economic Evaluation Database and the Tufts Cost-Effectiveness Analysis (CEA) Registry from January 1950 through July 2012. Inclusion criteria were empirical studies published in any language that reported economic evaluation results of two or more imaging interventions for patients presenting with symptoms suggestive of acute stroke. Study quality was assessed by a 35-item checklist published by the British Medical Journal (BMJ).

Results
A total of 1,063 citations were identified, and five met the inclusion criteria. Four of five papers were explicit in their analysis perspectives, which included health care system payers, hospital and other stroke service providers. Two studies reported results for five-year time horizons and three reported lifetime results. All reported morbidity outcomes using the modified Rankin Scale score. The median quality score using the BMJ tool was 84.4% (range = 71.9-93.5%). Three studies evaluated perfusion computed tomography (CTP) as a comparator to unenhanced CT (UCT) but due to a paucity of data, assumed that CTP outcomes were equivalent to those of patients assessed by other imaging modalities. Most studies included post-thrombolysis intracranial hemorrhage states but most did not take into consideration the effects of AIS patients who could not tolerate contrast media or who incurred contrast-induced nephropathy (CIN).

Conclusions
Economic evaluations in acute stroke imaging are of high quality with respect to published methodological guidelines. Economic analyses of imaging in AIS patients may benefit from the inclusion of important clinical components of AIS imaging modeling including the incidence of CIN and recurrent stroke in addition to the incorporation of CTP-specific outcome data.

Abnormal Cells Discrimination Using the Different Shape Parameters

A Chaddad1, P Zinn2, R Colen2
1University of Texas MD Anderson Cancer Center, Houston, TX, 2MD Anderson Cancer Center, Houston, TX

Purpose
A time critical process in optical microscopy application such as cancer cells detection, is the determination of the cells position in the histopathological image. Aiming at short time and efficiency identification, we propose the shape features extracted from the three abnormal cells
detection, namely, Benign Hyperplasia (BH), Intraepithelial Neoplasia (IN), and Carcinoma (Ca) in order to discriminate between the grade of cancer cells.

Materials and Methods
Active contour method was developed using the progressive division of the image dimension to achieve faster segmentation. Three cell types were analyzed based on the morphological parameters computation and the Naive Bayes classifier. Bio-images were extracted from the optical microscopy using special filter, Liquid Crystal Tunable Filter (LCTF) and high resolution camera, Charge Coupled Device (CCD). Therefore, there are 16 sequential bands images for each type of abnormal cancer cells, BH, IN and Ca. We demonstrate the efficiency of the proposed method using the real data from optical microscopy. The performance indicator was evaluated by the classifier accuracy computation for each type of cancer cells.

Results
18 images from each cancer type were analyzed. Simulation results showed that the segmentation of microscopic images using this technique was of higher efficiency than the conventional snake method resides in its ability to segment Ca type cells that was difficult through other segmentation procedures. The time consumed during segmentation was decreased in a ratio of more than 50%. The classification accuracy result showed the perfect accuracy value in a particular the carcinoma type which was difficult previously.

Conclusions
The shape parameters (such us: area, Xor-convex and solidity) were found to be effective to discriminate between the three types of abnormal cell. In addition, classification of unknown cell was possible using this PNN classifier method. Our proposal proved to be a powerful method. It was able to identify multiple cancer types in optical microscope images. This method can also be used to detect objects with irregular shapes such as carcinoma cells. The classification accuracy increased significantly which is indicated to be highly promising in the discrimination between the grade of cancer cells.

Accounting for contrast bolus delay and dispersion in perfusion imaging of experimental stroke improves the predictive value for infarct growth rate

P Vakil, T Carroll, S Ansari, X Guo, G Christoforidis
1Northwestern University, Chicago, IL, 2Northwestern University Feinberg School, Chicago, IL, 3University of Chicago, Chicago, IL

Purpose
Singular value decomposition of the arterial input function (AIF) with tissue curves is commonly used in to measure cerebral blood flow (CBF), cerebral blood volume (CBV), mean transit time (MTT) and time to residue function maximum (Tmax) in ischemic stroke. Deconvolution analysis is known to be sensitive to delay and dispersion (DD) effects, which alter the true AIF to a vascular territory in a setting of collateral arterial supply. The DD results in overestimation of the volume of hypoperfusion in acute stroke. Paradoxically, this overestimation will be greatest in patients with robust collateral arterial supply, which slows infarct growth. We hypothesize that the degree of DD distortion of local AIFs, as measured by DSC perfusion reflect the presence of collateral supply, and can predict infarct growth rate in ischemic stroke.

Materials and Methods
Permanent middle cerebral artery occlusion (MCAO) was induced in six adult dogs. Leptomeningeal collateral recruitment was quantified on angiography. Serial MR diffusion and perfusion imaging was acquired every 30 minutes over the first four hours and at 24 hours. Infarct growth rate was modeled as the square root of imaging time (Figure 1) and compared to 24 hour infarct volume. Bolus delay and dispersion was determined from DSC images using a previously reported model: $R(t) = A/(ATD+1) e^{(-\beta t)/ATD}$ The predictive value of the existence of collateral flow at DSC (i.e. $\beta/ATD$) was determined using Pearson correlation and was compared to more standard indicators of hypoperfusion (MTT, Tmax, CBV, and CBF) to determine the added value of DSC perfusion kinetics in predicting infarct growth.

Results
Bolus kinetics from DSC images predicted infarct growth rate. Table 1 reports Pearson correlation coefficients and statistical significance between MR and angiographic imaging markers to infarct growth rate. Perfusion parameters showed expected linear trends with infarct growth rates. Although not statistically significant, the strength of these linear trends improves...
with DD correction. Collateralization recruitment score and the DD coefficient showed the strongest correlation with infarct growth (Pearson Correlation>0.9 and P<0.01) (Figure 1). Furthermore DD-coefficient was strongly linear with collateralization score (Pearson=0.9, P-value=0.01). In Figure 1 we have confirmed prior finding that the rate of growth of a infarct is slower in the presence of leptomeningeal flow (left, red curve) than when collateral flow is poor (left, blue curve). Local AIFs in DD modeling account for collateral arterial supply enabling prediction of infarct growth rate.  

Conclusions  
The degree of DD, correlates with collateralization score and is predictive of infarct growth rate in permanent MCAO occlusion.

**Acute Basilar Artery Occlusion: Do MRI and CTA-Source Images Agree?**

D Boulter¹, A Yoo¹, T Leslie-Mazwi¹, R Gonzalez¹, P Schaefer¹
Purpose
The natural history of acute basilar artery occlusion (BAO) is dismal. Several papers report prognostic imaging findings for BAO treated with intra-arterial therapy (IAT). Three scoring tools have been described for use with CTA source images (CTA-SI). None have evaluated prognostic MRI features prior to IAT. The purpose of this study was to assess the agreement between MRI and CTA-SI for early ischemic change by parenchymal region, and to determine the effect on existing scoring tools.

Materials and Methods
17 patients with acute BAO were treated with IAT and also received pre-treatment MRI. 14 of these patients also received CTA. Neuroradiologists who were blinded to clinical information reviewed CTA-SI and MRI images during separate sessions. MRI diffusion-weighted images (DWI) and CTA-SI were scored using criteria from the previously described 32-point global score, the 8-point pons-midbrain index (PMI), and the 10-point pc-ASPECTS score. A separate scoring of the DWI data was obtained with more stringent criteria that excluded isolated small infarcts measuring less than 15 mm in the cerebrum or cerebellum, although small thalamic and brainstem infarcts were still included. Agreement between the modalities was assessed by region and correlated with patient outcomes and reperfusion status. Functional outcome was dichotomized into good (mRS 0-3) or poor (mRS 4-6). Mortality (mRS 6) was also independently assessed. Reperfusion status was dichotomized into reperfusers (TICI 2B-3) versus non-reperfusers (TICI 0-2A).

Results
Overall correlation between DWI and CTA-SI for the global score was moderate (Spearman rho: 0.73). When small cerebral and cerebellar infarcts were excluded from the DWI analysis, correlation with CTA-SI improved (Spearman rho: 0.77). The correlation was similar for pc-ASPECTS (Spearman rho: 0.69). Agreement between CTA-SI and DWI differed by anatomic region (Table). The medulla and parietal regions were excluded from this analysis as they were involved in fewer than 2 patients based on MRI. Overall, the best agreement was seen in the thalamus and cerebellum with moderate kappa scores. There was minimal to weak agreement in the remainder of the regions, with the worst agreement in the brainstem (weighted kappa: 0.15 for pons and 0.02 for midbrain). As a result, there was minimal agreement between CTA-SI and DWI for scoring the PMI (weighted kappa: 0.16). Outcomes were good in 4 patients and poor in 13 patients, 9 of whom died. There were 10 patients who reperfused, 4 of whom died. None of the existing scoring scales predicted dichotomized outcomes with statistical significance. Only the degree of pons involvement on CTA-SI predicted mortality (p=0.02).

Conclusions
Existing scoring metrics for CTA-SI can be applied to DWI, with overall moderate correlation between these modalities for global measures of early ischemic change following basilar artery occlusion. However, agreement varies markedly by region, with virtually no agreement in the brainstem where lesion morbidity has been reported to be the highest. These findings have important clinical implications for the application of existing prognostic scores.

**Advanced Multimodal Imaging in Epilepsy: The Abnormal Human Connectome**

S Stufflebeam¹, J Polimeni¹, T Witzel¹, C Catana¹, N Tanaka¹, R Zanzonico¹, A Cole², E Eskandar², O Rapalino², B Buchbinder²

¹Massachusetts General Hospital, Charlestown, MA, ²Massachusetts General Hospital, Boston, MA

**Purpose**

Here we illustrate an approach to combine advanced multimodal neuroimaging datasets in a patient with medically refractory epilepsy who is undergoing pre-surgical evaluation. Structural MRI, MR diffusion-derived connectivity, hemodynamic & electromagnetic functional connectivity, and glucose metabolism were acquired. This includes some unique imaging technology and protocols: The Connectom MRI with high-performance gradients for advanced diffusion MRI, and the BrainPET for simultaneous resting-state fMRI and FDG PET.

**Materials and Methods**

Subject: A 52-year-old left-handed woman with medically refractory epilepsy undergoing pre-surgical mapping. Image Acquisition: 3T Connectom MRI (300 mT/m gradient strength): Multi-shell Q-ball diffusion (b = 0, 1k, 3k, 5k, 10k); Diffusion toolkit used for reconstruction and whole-head tractography (http://www.tractvis.com). 3T Siemens Skyra MRI: Pre- and Post-Gad 1mm isotropic multi-echo MPRAGE. 7T MRI: 32-channel head coil: T2* 2D FLASH and TSE @ 330x330micron, 1mm thick slice; axial slab of 200 micron time-of-flight MR angiogram through the hippocampi. fMRI: 1.2mm isotropic resting-state BOLD. MEG: 306 Channel Elekta-Neuromag MEG with 70-channel EEG cap; Minimum norm estimate (MNE) was performed on the inter-ictal discharges using a boundary element model. The dipolar currents were fused to the meMPRAGE. MR-PET: 3T TIM MAGNETOM Trio MR scanner (Siemens Healthcare Inc.) modified to support the BrainPET (Siemens), a MR-compatible brain-dedicated PET scanner prototype. ~5 mCi of FDG was administered to the subject and the emission data were recorded. PET images were reconstructed with a 3D OP-OSEM algorithm. The head attenuation map was derived from the MPRAGE data acquired simultaneously. Simultaneously, 3mm isotropic resting-state BOLD fMRI images were also acquired. Image Analysis: Resting-state functional...
connectivity analysis: After typical pre-processing, the Pearson correlation was calculated between a seed voxel and at every other voxel's time course, within a 12 mm radius. The degree of local coupling was calculated by summing the number of voxels above a correlation threshold of 0.25 (Stufflebeam, et al., 2009). After the initial analysis of the imaging modalities as outlined above, we used FreeSurfer tools to combine the images.

Results
A non-enhancing, 1cm oval lesion impinged on the left hippocampus, that had a significant intraventricular component. The 7T MRI T2* images demonstrated 'popcorn' hemosiderin deposition, and surrounding serpiginous tubular structures (see Figure). 7T MRA did not show any significant flow-related enhancement. The FDG MR-PET showed hypometabolism in the left hippocampus, extending into the posterior medial temporal lobe. MEG show rare interictal discharges in the lateral and medial temporal lobe. The language fMRI suggested right-hemisphere dominance (overall LI = 0.2). Functional connectivity analysis showed increased local connectivity in the medial temporal lobe consistent with a posterior medial temporal lobe ictal onset zone. Tractography of the Connectom diffusion images showed displacement of the fornix by the lesion, and possible invasion. Preoperative diagnosis was thought to be most likely a cavernous malformation or an arteriovenous malformation (AVM). Pathology was AVM.

Conclusions
A common challenge facing imaging centers is how to best combine imaging data to maximize it's usefulness for pre-surgical planning. We used a FreeSurfer-based solution to combine the diffusion, structural, and functional data. Each imaging technology played a critical role in the management of this patient's surgical plan. The structural and functional connectivity analysis identified an abnormal connectome with a seizure onset zone in the left hippocampus, yet showed abnormalities well beyond the medial temporal structures.

L Lopez Porras¹, J León², L Garcia-Ferrer³, S Campos Hervas¹
¹ERESA Grupo Médico, Valencia, Spain, ²Hospital Universitario de Valencia, Valencia, Spain, ³Hospital Provincial de Castellón, Castellón, Spain

Purpose
Retrospective review of MR Imaging characteristics of three cases of histologically proven extraventricular neurocytomas (EVN) and its clinical outcome.

Materials and Methods
The three patients underwent pretreatment MR examination. The MR imaging (MRI) examinations were performed on a 1.5 T scanner using our tumor protocol which includes: coronal T1-weighted spin-echo imaging, axial and coronal T2-weighted imaging, axial GRE T2* imaging, axial FLAIR T2 imaging, diffusion-weighted B-1000 imaging and postcontrast volumetric 3D T1-weighted imaging, MR spectroscopy (MRS) and MR perfusion (MRP). The diagnosis was based on histological evidence after surgery.

Results
Three male patients of 21, 31 and 34 years of age presented with headache and dizziness, all showing large cerebral tumors in frontal or parietal lobes with cystic-necrotic changes, perilesional edema, marked contrast enhancement and partly with hemorrhagic foci or calcificactions in MR Imaging. MR spectroscopy revealed an increased Cho/NAA ratio and a glycine peak at 3.60 ppm. Histology demonstrated EVN with tumor angiogenesis, increased mitotic activity and nuclear atypia. All three patients underwent surgery and received radiotherapy, suffering relapses, the survival rate being 12, 16 and 48 months.

Conclusions
Despite both central and extraventricular neurocytomas being considered as a WHO grade II central nervous system tumors with a relatively low aggressive behavior, the three EVN cases we present showed high grade tumor malignancy characteristics with an aggressive behavior and a considerably shortened survival rate compared to that of central neurocytomas. MR spectroscopy and MRP can indicate an atypical behavior when showing high grade malignancy features and peritumoral infiltration as presented. The average survival rate is shortened especially when Ki:67 marker is increased.

Purpose
To study potential changes in volume of cerebral gray matter in patients with a first episode of psychosis (FEP), and if these changes differ from those of schizophrenics. To evaluate if changes in volume in schizophrenics depend on the presence of auditory hallucinations.

Materials and Methods
The following groups of subjects were included: 1) FEP patients (n=22, 14 males, aged (in years) 25.591 ± 5.234. 2) Schizophrenics (n=77). This group included patients with auditory hallucinations (n=42, 26 males, aged 37.952 ± 8.551) and without (n=35, 21 males, aged 34.857 ± 9.481). 3) Healthy controls (n=62, 35 males, aged 34.113 ± 9.570). A subgroup of 22 age/sex-matched controls was defined for additional comparison to FEP patients, in view of the differences in mean ages. High field brain, volumetric T13D-MPRAGE MRI was obtained (3 T Philips Achieva, software version 2.6.3). The voxel-based morphometry (VBM, SPM 8) methodology was applied searching for voxel-wise differences in gray matter volume among groups (corrected p<0.05, family wise error, FWE).

Results
First episode of psychosis patients compared to controls showed volume loss in the lateral temporal, medial parietal (precuneus, posterior cingulate), occipital and insular regions bilaterally. This same pattern was observed when compared to schizophrenics. Additionally, FEP patients had, compared to controls, volume gain in the anterior, medial and inferior temporal, occipital, medial-inferior frontal regions, and cerebellum. This same pattern was observed when compared to schizophrenics. On the contrary, schizophrenics compared to controls and to FEP patients showed a different pattern of volume loss, including the anterior, medial and inferior temporal, medial parietal and medial-inferior frontal regions. This same pattern was observed when PEP patients were compared to matched controls, and to schizophrenics having/not having hallucinations. There was no volume gain in schizophrenics compared to controls. No differences were seen between hallucinating and nonhallucinating schizophrenics.

Conclusions
There are volume changes - gain and loss -, having different patterns of involvement, already seen in FEP patients. These changes differ from those observed in schizophrenics, being indepedendent from the presence of auditory hallucinations. Our results suggest
plasticity/cortical reorganization and neuronal loss in schizophrenia along the temporal spectrum, independently from the phenotype. This work has been partly supported by grant 091230/091231 (La Marató de TV3), and by grants FIS 08/0705, 08/0475 and ETES 09/91030 (Instituto de Salud Carlos III, Ministerio de Economía y Competitividad, Spain).

Anti-NMDA Receptor Encephalitis: A Case Series from a Radiological Perspective

M Zhang¹, D Tampieri²
¹McGill University Health Centre, Montreal, Quebec, Canada, ²Montreal Neurological Hospital and Institute, Montreal, Quebec, Canada

Purpose
Anti-N-methyl-D-aspartate (NMDA) receptor encephalitis is a relatively novel diagnosis. It was first reported in the literature in 2005. The purpose of this poster is to present the radiological findings of a series of six proven cases of anti-NMDA receptor encephalitis and to review the current literature from clinical and neuroimaging perspectives.

Materials and Methods
Imaging and chart review of six clinically proven cases of anti-NMDA receptor encephalitis treated at the Montreal Neurological Institute from 2005 to 2013 was performed. The current published literature concerning the topic also was reviewed.

Results
Anti-NMDA receptor encephalitis is one of the top causes of autoimmune encephalitis, surpassing any viral-induced encephalitis in young individuals, with an increasing number of
cases reported from around the world yearly. It commonly is associated with ovarian teratoma and mostly it affects women of child-bearing age. Clinically, it is a challenging clinical diagnosis, as there are different phases with variable onset and a wide range of symptoms. The clinical picture is supplemented with laboratory testings, EEG recordings and MRIs. MR imaging is reported as normal in approximately 50% of cases, in literature and in our experience. When positive, the MRI findings demonstrate T2 and FLAIR hyperintensities involving the medial temporal lobes, the cerebellar and cerebral cortex, the basal ganglia, the brainstem, and rarely the spinal cord. The imaging pattern of this condition is not homogenous or typical. Furthermore, imaging plays a vital role for the search of associated tumors and ovarian teratomas.

Conclusions
We present the imaging findings of a rare but not uncommon condition: anti-NMDA receptor encephalitis. This is a relatively novel diagnosis most often affecting young women of child-bearing age associated with ovarian teratomas. This condition has to be known in order to provide adequate diagnosis and plan for more extensive imaging in this group of patients since often they require abdominal imaging and surgery for the primary teratoma. We illustrate some specific clinical and radiological aspects of this condition that need to be kept in mind for the diagnosis.

KEYWORDS: Encephalitis, Teratoma
Application of SWI for Scolex Demonstration in Calcified Neurocysticercosis Lesions

G Porto\textsuperscript{1}, L Lucato\textsuperscript{1}, C Leite\textsuperscript{2}, H Gomes\textsuperscript{3}
\textsuperscript{1}Hospital das Clínicas/Universidade de São Paulo, São Paulo, Brazil, \textsuperscript{2}University of São Paulo, São Paulo, São Paulo, \textsuperscript{3}Hospital Das Cilnicas (FMUSP), Sao Paulo, Brazil

Purpose
Neurocysticercosis (NCC) is an infectious disease caused by the larvae of the pork tapeworm Taenia Solium and is considered the most common parasitic disease of the CNS. Calcified brain lesions are a common finding. Identification of the scolex is pathognomonic, but sometimes it is difficult to differentiate a calcified neurocysticercosis cyst from other calcified lesions. This study was performed to describe SWI (susceptibility-weighted imaging) findings in calcified NCC lesions, focusing on scolex detection.

Materials and Methods
Subjects with the diagnosis of NCC, presenting single or multiple calcified lesions were studied with computed tomography (CT) and SWI sequence obtained on a 3T magnet. The study was IRB-approved and all subjects provided written informed consent.

Results
Twenty-six patients were included in this analysis. Scolex could be detected in a single calcified lesion in only one patient by CT. However SWI was able to identify the scolex in 15 patients. A total of 365 calcified lesions were identified by CT, in 46 of which scolices could be depicted by SWI, instead of only one identified by CT.

Conclusions
Susceptibility-weighted imaging sequence allows a better identification of the scolex in calcified lesions, allowing diagnosis of NCC. These findings indicate that SWI sequence is extremely useful in clinical practice, especially in the scenarios of single calcified lesions or in non-endemic regions, where the presumptive diagnosis of NCC can be challenging.

Association between carotid artery plaque inflammation and brain MRI

L Saba¹, M Anzidei², C Catalano³, F Zaccagna³, M Piga², E Genovese²
¹University of Cagliari, Monserrato, Italy, ²University of Cagliari, Cagliari, Italy, ³University la Sapienza, Rome, Italy

Purpose
There are several evidences that carotid plaque composition is independent risk factor in ischemic stroke. The purpose of this work was to explore the association between the entity of inflammatory cells present in the carotid plaques and brain MR imaging (MRI) findings.

Materials and Methods
Forty consecutive (males 33; median age 64±7 years) patients were analyzed prospectively.
Brain MRI was performed using a 1.5 T system and lesions pertinence of the anterior circulation was recorded. All patients underwent carotid endarterectomy "en bloc"; histological sections were prepared and immuno-cytochemical study was used to characterize and quantify the inflammatory cells present in plaques, using the CD68, CD3 and CD45 monoclonal antibodies. Cell counting was performed at a magnification of X400 using a test grid with an area of 0.25 square mm and graded according do the degree from one to five. Receiver operating characteristic (ROC) curve analysis, Pearson Rho correlation and Mann-Whitney test were applied.

Results
The immuno-cytochemical study demonstrated that the cap of ruptured plaques in patients affected by stroke\TIA (n=25) was characterized by many inflammatory cells, principally macrophages (CD68) compared with those caps observed in ruptured plaques from patients without symptoms (Mann-Whitney = p < 0.001, ROC curve area = 0.901). Correlation analysis showed a statistically significant association between the number of brain nonlacunar infarct and the entity of macrophages (p < 0.001); no association was found with lacunar infarct (p = 0.1934).

Conclusions
Results of this preliminary study suggest that the entity of inflammatory cells in the carotid artery plaque is associated with the presence of cerebrovascular events and with the number of MRI brain detectable infarct.

**Atypical developmental venous anomaly associated with contrast enhancement and hyperperfusion in the surrounding basal ganglia**

N Sahin¹, A Solak¹, B Genc¹, N Bilgic¹

¹Sifa University School of Medicine, Izmir, Turkey

Purpose
Developmental venous anomalies (DVAs) are the most common type of cerebral vascular malformations. They generally are accepted as variants of venous development and frequently identified incidentally, particularly on contrast-enhanced MR imaging. Most of the DVAs do not affect the integrity of the surrounding parenchyma. The purpose of this article is to illustrate DVA with atypical hemodynamic pattern and discuss the role of imaging for diagnostic workup of DVA.

Materials and Methods
A 55-year-old woman presented with dizziness, vertigo, and disequilibrium. No abnormalities were reported on unenhanced cranial MR imaging performed at another facility three days previously. Therefore, MR imaging was repeated with contrast enhancement at our institution.

Results
Postcontrast MR images showed DVA with classical caput medusa appearance in the right basal ganglia draining to the deep venous system. In addition, there was contrast enhancement in the basal ganglia around DVA. However, there was no associated parenchymal signal intensity
abnormality on MR images. On perfusion MR imaging, there was increase in cerebral blood flow (CBF), cerebral blood volume (CBV), mean transit time (MTT), and time-to-peak (TTP) of both DVA and surrounding basal ganglia. DVA, which could not be seen on conventional MR imaging, was easily distinguished on SWI. The symptoms of the patient resolved completely within a few days. The MR imaging findings were stable at her 6- and 12-month follow-up.

Conclusions
Developmental venous anomalies may present with atypical imaging findings, such as contrast enhancement and increased perfusion in the surrounding parenchyma, probably due to anomalous venous drainage. These unusual perfusion patterns of the DVAs should be differentiated from other entities such as hypervascular brain tumors or ischemia with hemodynamic changes, which have different clinical management.

KEYWORDS: Basal Ganglia, Developmental Venous Anomalies, MR Perfusion-Weighted Imaging
Atypical manifestation of CNS tuberculosis

A Alazzaz, S Alzubaidi

Purpose
Our objective was to evaluate the uncommon CT and MR features of CNS TB in order to make a definite diagnosis. Discuss their pathogenesis, diagnosis, and treatment. Highlight the awareness to know the atypical TB pattern that help in early diagnosis and management & prevent fatal complication.

Materials and Methods
Abstract Still tuberculosis is significant public health concern & its prevalence is markedly increased in recent years, approximately 5 to 10% of cases of TB have CNS involvement. This article presents the range of atypical manifestations of tuberculosis (TB) of the craniospinal axis which is including rare location, unusual pattern with some rare complication as well as concurrence of two or more rare finding in same patient. We provide group of cases with rare location like pineal gland, suprasellar cistern & pituitary stalk involvement, an abscess formation is uncommon complication as a solely lesion in 3 of our patient & one case is with concurrent with all different tuberculomas stages. big pachymeningeal masses are illustrated in four cases as well as two cases mimicking intra axial tumor. we also illustrated a rare TB complication on brain vasculature e.g ruptured cerebral mycotic aneurysm. Involvement of vertebral column is common in tuberculosis but intra & extramedullary tuberculoma are rare as well as tuberculous myelitis. Generally all these atypical manifestation can mimic other disease like malignency or demyelinating disease. its complication on brain vascular is fatal & increase the mortality & the delay in the diagnosis of intra axial & intra/extra medullary involvement will also increase the morbidity. So awareness of the atypical TB pattern help in early diagnosis and management.

Abstract Still tuberculosis is significant public health concern & its prevalence is markedly increased in recent years, approximately 5 to 10% of cases of TB have CNS involvement. This article presents the range of atypical manifestations of tuberculosis (TB) of the craniospinal axis which is including rare location, unusual pattern with some rare complication as well as concurrence of two or more rare finding in same patient. We provide group of cases with rare location like pineal gland, suprasellar cistern & pituitary stalk involvement, An abscess formation is uncommon complication as a solely lesion in 3 of our patient & one case is with concurrent with all different tuberculomas stages. big pachymeningeal masses are illustrated in four cases as well as two cases mimiking intra axial tumor. we also illustrated a rare TB complication on brain vasculatur e.g ruptured cerebral mycotic aneurysm. Involvement of vertebral column is common in tuberculosis but intra & extramedullary tuberculoma are rare as well as tuberculous myelitis. Generally all these atypical manifestation can mimic other disease like malignency or demylinating disease. its complication on brain vascular is fatal & increase the mortality & the delay in the diagnosis of inta axial & intra/extra medullary involvement will also increase the morbidity. So awareness of the atypical TB pattern help in early diagnosis and management.

Brain Herniations into the Dural Venous Sinuses or Calvarium: MRI of a Recently Recognized Entity

B Battal\textsuperscript{1}, M Castillo\textsuperscript{1}
\textsuperscript{1}University of North Carolina Chapel Hill, Chapel Hill, NC

Purpose
Brain herniations into the dural venous sinuses (DVS) are rare findings that recently have been described and their etiology and clinical significance are controversial. In this exhibition, we present five patients with brain herniations into the DVS or calvarium that were identified on MR imaging (MRI) and discuss their imaging findings, possible causes, and relationship to patient's symptoms.

Materials and Methods
Recently, we observed five patients showing brain herniation into the DVS or calvarium containing various amounts of cerebral or cerebellar parenchyma surrounded by CSF. All patients were examined with MRI including high resolution pre and postcontrast T1- and T2-weighted sequences. With respect to brain herniations we documented their locations, signal intensities in different sequences, and size. We then reviewed clinical records in an attempt to establish if any symptoms were related to the presence of these herniations.

Results
Three males and two females were examined (age range, 11-68 years). Three patients had unilateral temporal lobe herniations into the transverse sinuses, one had a cerebellar herniation
into the skull, and one had bilateral temporal lobe herniations into the transverse sinuses as well as a cerebellar herniation into the sigmoid sinus. In all, the herniated brain and surrounding cerebrospinal fluid (CSF) had normal signal intensity on all MRI sequences. When correlated with clinical symptoms, brain herniations were thought to be incidental and asymptomatic in three patients and two patients had histories of headaches.

Conclusions
Brain herniations with surrounding CSF into the DVS/skull should be considered as potential sources of filling defects in the DVS. We believe that they are probably incidental findings that may be more common than previously recognized and should not be confused with the more common arachnoid granulations, clots, or tumors. Two patients had headaches, but their relation to the presence of herniated brain was uncertain.

Brain metabolic response to ketogenic diet in patients with primary brain tumors: 1H-MRS study

O Aizenstein1, M Artzi2, D Ben Bashat2, F Bokstein1, G Liberman1, N Vaisman1, F Vitinshtein1
1Tel Aviv Sourasky Medical Center, Tel Aviv, Israel, 2Tel Aviv Sourasky Medical Center/Tel Aviv University, Tel Aviv, Israel

Purpose
Normal cells depend on glucose metabolism as their sole energy source, but can switch to the usage of fat products (ketone bodies) during caloric restriction. In contrast, tumor cells lack metabolic flexibility and are largely dependent on glucose. Thus, high-fat and low carbohydrate ketogenic diet (KD) was suggested as a therapeutic option for malignant brain cancer. This study aimed to detect and characterize longitudinal brain structural and metabolic changes in patients with malignant brain gliomas under KD.

Materials and Methods
Proton magnetic resonance spectroscopy (1H-MRS) was performed in five patients with high grade gliomas, treated with KD and bevacizumab. MR scans were performed before and every two months following KD initiation, including conventional imaging and 1H-MRS obtained at the normal appearing white matter.

Results
Substantial reductions in tumor volumes were detected two months following KD, in three of five patients (Figure 1A), attributed to the effect of bevacizumab, initiated alongside KD. After two months of therapy, an increase in tumor volumes was detected in these patients. During KD, a single peak of Aceton (Acn) was identified at a chemical shift of 2.22 ppm in two patients (Figure 1B). In addition, an increase in Glutamate and/or Glutamine (Glu+Gln) was detected in four of five patients, which may indicate Acn accumulation rather than an actual Glu+Gln increase due to misdetection of Acn in this chemical shift range. All other detected metabolites showed nonspecific and varied longitudinal patterns.

Conclusions
1H-MRS can provide biomarkers for accumulation of cerebral acetone, and can be a useful tool.

(Filename: TCT_EP-11_KDfig1.jpg)

EP-54
Purpose
In treating dural arteriovenous fistulas (dAVFs), the goal of embolization is occlusion of the dural vein close to the shunt point; We have recently reported the efficacy of superselective shunt occlusion (SSSO) in which coiling only the small venous pouch or compartment just downstream of the shunt point. Thus, detection of the shunt point is crucial in performing this method. The purpose of this study is to establish a more intelligible technique to detect shunt point compared with conventional DSA images and 3-dimension rotational angiography (3-D RA) images.

Materials and Methods
We have developed a new technique named circular color coding (CCC): in which arrival time of contrast media was determined by time-density curve obtained from conventional DSA pixel by pixel, followed by converting the arrival time to circular color phases. By this technique, blood flow is demonstrated as sequential "rainbow-colored" imaging(figure 1). CCC was applied to 18 dAVFs, and neuroradiologists/neurosurgeons assessed the shunt points with CCC, conventional DSA, and 3-D RA images separately.

Results
SSSO were available in 6 of 18 cases, and CCC showed more accuracy and required shorter time in determining shunt points in all 6 cases than either conventional DSA or 3-D RA images alone.

Conclusions
CCC achieved easier and better understanding of the shunts by coloring blood flow compared with conventional DSA in which difference of contrast density should be strictly discriminated. By complementary use of 3-D RA which has better spatial solution, CCC would be a very useful technique in therapeutic process for dAVFs.

Cerebellar white matter degeneration in patients with spinocerebellar ataxia type 6 measured with diffusion kurtosis imaging

K Sato\textsuperscript{1}, K Kamagata\textsuperscript{1}, H Terada\textsuperscript{2}, S Aoki\textsuperscript{1}

\textsuperscript{1}Juntendo University School of Medicine, Bunkyo-ku, Tokyo, \textsuperscript{2}Toho University Sakura Medical Center, Sakura, Chiba

Purpose
Diffusional kurtosis imaging (DKI) is a novel method based on non-Gaussian water diffusion model. We performed analyses of DKI in patients with spinocerebellar ataxia type 6 (SCA6), which is a rare, autosomal dominant neurodegenerative disease. The purpose was to investigate microstructural changes of the cerebellar substructures including the cerebellar peduncle tracts based on DKI-derived metrics to better understand the specific involvement of SCA6.

Materials and Methods
Diffusional kurtosis imaging data were obtained in three patients with SCA6 and five age and sex-matched controls with 3T MRI (Skyra, Siemens) with b-values of 0, 1000, 2000s/mm\textsuperscript{2} along 30 different motion probing gradient directions. The data with b-value of 1000s/mm\textsuperscript{2} were used for diffusion tensor analysis, while the data with 3 b-values were used for mean kurtosis.
computation. Tract-specific analysis was performed for the superior cerebellar peduncle (SCP), middle cerebellar peduncle (MCP), and inferior cerebellar peduncle (ICP). Region of interest (ROI) analysis was performed for the cerebellar white matter. Regions of interest were set at the vermis, medial and lateral part of the cerebellum. Fractional anisotropy (FA), apparent diffusion coefficient (ADC), and mean kurtosis (MK) were compared between two groups.

Results
Significant increase of ADC (MCP: \( p = 0.003 \), ICP: \( p = 0.015 \)) and decrease of MK (MCP: \( p = 0.022 \), ICP: \( p = 0.002 \)) were found in patients as compared to controls. There was no significant changes in SCP. Fractional anisotropy did not show changes in the cerebellar peduncles. Region of interest analyses showed significant decrease of FA (\( p = 0.03 \)) and MK (\( p = 0.001 \)) only in mid part of the cerebellum.

Conclusions
Despite the small number of subjects, our results of significant decrease of ADC and MK suggested that they are more sensitive than FA in detecting degenerative changes in cerebellar subregions in patients with SCA6. The microstructural changes were mainly seen in ICP, MCP, and mid parts of the cerebellum. These imply degeneration of afferent fibers of the cerebellum and the paleocerebellum is prominent and characteristic, but further investigation with larger number of subjects is warranted.

Cerebral White Matter Changes in Patients with Obstructive Sleep Apnea

M Henry\(^1\), A Baril\(^2\), K Gagnon\(^2\), A Desautels\(^2\), C Lafond\(^2\), M Jaques\(^2\), D Gilbert\(^2\), N Gosselin\(^2\)
\(^1\)Université de Montréal, Montréal, Quebec, Canada, \(^2\)Hôpital du Sacré-Coeur de Montréal, Montréal, Quebec, Canada

Purpose
Obstructive sleep apnea (OSA) is a frequent sleep disorder characterized by respiratory pauses during sleep, which provoke hypoxemia and sleep fragmentation (1). A recent study showed that OSA is an independent risk factor for white matter changes (WMC) (2). However, how theses WMC are distributed across brain regions in OSA patients remains unclear. The aim of the present study was to compare white matter changes distribution by the observation of white matter hyperintensities (WMH) between OSA patients and healthy control subjects. Moreover, this study aimed at exploring variables associated with increased WMH in OSA patients.

Materials and Methods
Fifteen male patients with moderate to severe OSA (age: 64.7 ± 4.8, body mass index (BMI): 28.4 ± 3.6, Apnea-Hypopnea Index (AHI): 31.5 ± 13.9) were compared to 15 control subjects (5 women, 10 men, age: 62.8 ± 4.9, BMI: 26.4 ± 3.0, AHI: 2.6 ± 2.0) matched for vascular risk factors (Vascular burden scale) (3). All subjects underwent an overnight polysomnography and a 3 T magnetic resonance imaging (MRI) scan with T2-weighted images and FLAIR. White matter hyperintensities were evaluated with the complex version of the Scheltens Visual Rating Scale (SVRS) (4,5) and analyses were performed on total scores and on the regions scores. Student t-tests were used to compare group differences on WMH and Pearson's correlations were used to
assess the relationship between SVRS scores and other variables including age, BMI, AHI, sleep time with an oxygen saturation < 90% and vascular burden scale score. Results were considered significant at p < 0.05.

Results
Ninety-three percent of subjects showed WMH in the OSA group as well as in the control group. No significant group difference was observed for the SVRS total score. When WMH for each region were compared between groups, OSA patients showed less WMH than control subjects in the occipital lobe (p < 0.05), but no other group differences were observed. A negative correlation was found between the minimal oxygen saturation during sleep and the SVRS total score in OSA patients (r=-0.56, p < 0.05), where lower oxygen saturation was associated with more WMH. No other significant correlations were observed in the OSA or the control group.

Conclusions
In this preliminary study, no increase in WMH was found in OSA patients compared to control subjects. Moreover, no major group difference was observed in the distribution of WMH, except for a lower occipital WMH among the OSA group. Interestingly, OSA patients with lower oxygen saturation during sleep showed higher WMH. Further studies should investigate whether the presence of white matter changes is associated with anomalies on diffusion tensor imaging and/or with greater cognitive deficits among the OSA population.

Characterization, Demographic and Casuistic Assessment of Superficial Brain Hemorrhages.

D Dodig, 1, S HADI1, W Bartynski1, M Matheus1
1Medical University of South Carolina, Charleston, SC

Purpose
Hemorrhages that happen near surface of the brain, confined to subpial space or trapped focally in one segment of the subarachnoid space, may have distinct prognostic implications. It has been speculated that this distribution may be associated with development of laminar infarcts, arguably as a result of vasoconstriction of the most distal superficial vessels within the subpial space. However, epidemiology and detailed imaging characteristics of this possible distribution are undefined. Our study proposes to characterize imaging findings and assess epidemiologic information for hemorrhages located along the surface of the brain.

Materials and Methods
Three radiologists retrospectively assessed head CTs and clinical history in 361 patients with intracranial hemorrhage, aiming for classification of the hemorrhage, cause, and demographics. The hemorrhages were classified as intraparenchymal, epidural, subdural, subarachnoid and superficial. Superficial hemorrhage was considered when focal widening of the sulci or fissure and displacement of the adjacent cortex were present.

Results
In our group of patients with intracranial hemorrhage 35 (9.7%) had "superficial" characteristics. From those, 16 (45.7%) were associated with trauma, 12 (34.3%) with aneurysm rupture, 3
(8.6%) were related to other causes such as coagulopathy, post-surgical or endovascular treatment, pseudo aneurism and hypertension, and in 4 (11.4%) cases we were not able to determine the cause. Two most frequent locations were frontal lobes (n=18) and Sylvian fissures (n=8). Median age was 58 years (mean 58.3; range 3 months to 84 years) and there was a slight female prevalence (female 60%, male 40%). 3 month old female with superficial and subdural hemorrhage in right temporoparietal lobe was a term, C section infant suffering from cardiomyopathy, awaiting heart transplantation. Traumatic injury caused right frontal superficial and overlaying subdural hemorrhage in a 3 year old female. Almost all (n=34) patients had other hemorrhage present, mostly subarachnoid (n=31). All the superficial hemorrhages showed hypodensity of the surrounding/displaced cortex.

Conclusions
A small percent of intracranial hemorrhages may show a distribution that does not fit the usual classification. The distribution could be the result of subpial location or a confined clot in a localized segment of the subarachnoid space. The subpial distribution has been previously described in term neonates after what was considered to be a birth trauma and in a small case series of 10 adult patients. Based solely on acute imaging modality, separation between subpial hematoma and a localized clot in a focal segment of the subarachnoid space is not possible. However, the possible consequences of both these superficial hemorrhage patterns to the adjacent displaced cortex are similar, leading to laminar edema with subsequent infarction. Our study shows that this distribution is not infrequent, happens in adults and kids, usually after trauma and aneurysm rupture. In all cases the displaced parenchyma shows evidence of edema, which may progress to infarct. Attention to superficially located intracranial hemorrhage should be made and further investigation and better understanding of imaging characteristics are necessary considering the possible impact on the adjacent brain parenchyma, patient treatment and clinical outcome.

CLINICAL VALUE OF 7T IMAGING IN MEDICALLY REFRACTORY EPILEPSY: COMPARISON TO 1.5 AND 3T MR IMAGING

B Vachha¹, S Stufflebeam², N Tanaka², P Caruso¹, O Rapalino³
¹Massachusetts General Hospital, Boston, MA, ²Massachusetts General Hospital, Charlestown, MA, ³Massachusetts General Hosp., Boston, MA

Purpose
Ultra-high field magnetic resonance imaging (MRI) offers significant gains in signal- and contrast-to-noise ratio but is affected by increasing susceptibility artifacts and magnetic field inhomogeneity. The FDA has approved 7T MRI for research, but currently there are no 7T MRI scanners that have been approved for clinical use. While several studies have shown the utility of 7T MRI for anatomical imaging, there is a paucity of reports evaluating its use in identifying intracranial pathologies. With the success that surgical approaches can provide for localization-related epilepsy, identification of potential causes of seizure is critical. This study evaluates the
potential clinical value of 7T MRI in medically refractory epilepsy cases comparing findings at 7T to those at 1.5T/3T MRI.

Materials and Methods
34 patients with medically refractory epilepsy (age: 15-52 years; 21 females) underwent 1.5 and/or 3T MRI performed as part of routine clinical presurgical evaluation and an IRB-approved 7T MRI examination. 1.5/3T imaging studies were retrospectively reviewed and compared with 7T MRI studies by two neuroradiologists by consensus. Additional clinical information (including EEG/MEG) as well as pathological sampling was used for retrospective analysis of the datasets.

Results
Compared to 1.5/3T MRI, findings on 7T MRI improved conspicuity of pathology and impacted clinical management in 13 of 34 cases (38.2%). 7T MRI demonstrated pathology in 4 cases that were interpreted as negative on 1.5/3T. 7T MRI resulted in a change in imaging interpretation of the pathology in 3 cases where the initial finding was detected on 1.5/3T MRI. 19 patients with refractory epilepsy cases had focal EEG findings; 11 of these 19 patients had focal abnormalities at 1.5/3T, while 14 of 19 patients had focal abnormalities on 7T imaging.

Conclusions
With improvements in signal-to-noise ratio, 7T MRI may provide additional clinical information in patients with refractory epilepsy, particularly with respect to better visualization and definition of intraparenchymal vascular and focal cortical dysplastic lesions. This modality has the potential to alter clinical management in patients with medically refractory epilepsy.

Comparison of Vessel Occlusions Shown by CT Angiography to Conventional Catheter Angiography in the Evaluation of Patients in the Acute Stroke Setting

T Miller¹, S Kohn², D Pasquale³, J Farinhas¹, J Burns¹, A Brook¹
¹Albert Einstein College of Medicine, Bronx, NY, ²North Shore-LIJ Health System, Manhasset, NY, ³Loyola University, Maywood, IL

Purpose
Purpose is to determine the inter-reader reliability within CTA as well as any inter-modality discordance between CT angiography and the gold standard conventional catheter angiography of the head and neck for detection of different levels of vessel occlusion in the acute stroke setting.

Materials and Methods
This study retrospectively compared CT angiography studies to catheter angiography in the evaluation of head and neck arteries in patients with suspected acute stroke. Using the Radiology Information System, a list of all head and neck CT angiography followed by cerebral angiogram studies performed for acute stroke from April 1, 2004 to December 31, 2009 was obtained. All studies were performed on 64-slice GE LightSpeed Scanners (GE, Milwaukee Wisconsin) and Philips Biplane Angiography Suite (Philips Medical Systems, Bothell, Wash). The pair of studies was read in a blinded fashion independently and prospectively using PACS. The ages of the
patients undergoing these studies ranged from 22 to 92 with an average 66.7 (S.D. 14.2 yrs). 15 females and 8 males comprised the study population. Cases were presented in a random order. Readers were permitted to use their own reconstructions, including TeraRecon (TerRecon, San Mateo, CA) 3D reformations as well as Volume Viewer 2 (AW suite 2.0 6.5.1.w). For each case, the reader was asked to evaluate major arteries of the anterior and/or posterior circulation including the carotid, middle cerebral, anterior cerebral, posterior cerebral, basilar, and vertebral arteries as dictated by the areas of documented lesions. The readers would designate a vessel as 1) severely stenotic, 2) nearly occluded, or 3) occluded or 4) Open. The readers true impression of the physiologic status of nearly occluded and occluded vessel on the CT were then labeled as most likely to be true occlusions or most likely to be patent on conventional catheter angiography. Catheter Angiography studies were analyzed in a similar manner to their CTA counterparts. Each study was read by a blinded reader and in random order. Criteria used to define severe stenosis were as per WASID trial 1) severely stenotic, 2) nearly occluded, or 3) occluded or 4) open.

Results
812 vessel segments (Common carotid, Extracranial ICA, Intracranial ICA, M1, M2, A1, AComm, A2, P1, P2, Vert, Basilar, PICA, AICA, SCA) were analyzed. 29/812 (3.5%) stenotic, occluded, or nearly occluded vessels were identified and analyzed by 3 independent readers in a blinded fashion. On CTA there was complete agreement on 21/29 vessels (72.4%). There was partial agreement (2 out of 3 readers) between severe and near occlusion on 3 vessels (9.7%) and between near occlusion and complete occlusion in 5 vessels (16.7%). On catheter angiography, there was complete agreement between readers on 26/29 vessels (89%). To compare CTA with catheter angiography, vessels in which disagreement was present were reviewed as a group and consensus decision was made. When comparing the reader results for CT angiography to the gold standard there was 24/29 (83%) vessel agreement. In 3 of the cases of disagreement there was visualization of an occlusion on CTA, while a severely stenotic, but patent, vessel was noted on conventional angiography. The converse occurred in the other two cases, where a severely stenotic lesion was present on CTA and was found to be completely occluded on conventional angiography. Among the pairs of studies where disagreement existed, 3 cases had reader discordance within one or both of the individual imaging modalities.

Conclusions
CT angiography in the acute stroke setting is rapidly becoming the triage modality of choice. As it becomes increasingly relied upon for crucial decisions in urgent settings, the validity of the results are all that more important to demonstrate. Although evaluated previously, prior reports did not take into account collaborative reading, analysis of nearly occluded vessels, or extracranial vascular disease. It is impractical to provide gold standard imaging for all patients in the acute stroke setting. The current study demonstrated lower sensitivity and specificity for vessel occlusion on CTA than has been shown previously. This discrepancy was seen in specific situations. Imaging was degraded by poor cardiac function, patient motion, and metal from teeth and surgical clips which limits all CTA exams. Some stenosis or occlusions in patients with unique collateral anatomy, adjacent veins, plaque architecture, or thrombus pathology may be intrinsically difficult to characterize on CTA. In these unusual situations group analysis may increase the accuracy of CTA in characterizing nearly occluded vessels when making these critical triage decisions in an acute stroke setting.

KEYWORDS: Angiogram, CTA, Diagnostic Accuracy
Compartmentation of Brain Water in the acute phase of Ischemic Stroke

P Brugieres¹, P Thomas¹, A Gaston¹
¹Henri Mondor, Creteil, IDF

Purpose
To characterize brain water motion during an acute ischemic stroke.

Materials and Methods
Ten patients with an acute ischemic stroke < 48 hours have been explored on a 1.5 T Siemens Avanto System with diffusion Imaging using multiple b factor-values from 0 to 5000 s/mm² by steps of 500 s/mm² and with T2-SE weighted Imaging using multiple TE values from 8.8 ms to 265.6 ms by steps of 8.8 ms. The compartments with fast and slow diffusion (ffast and fslow) and the respective apparent diffusion coefficient (ADC) values of the two compartments could be calculated by using the relation: S= S0.(ffast.exp(-b.ADCfast)+fslow .exp(-b.ADCslow). By using the relation: S(t)= S0.(fT2long.exp(- TE/T2long) +fT2short.exp(-TE/T2short) , it is possible to extract the fractions of water with short (fT2short) and long (fT2long) TE and the respective TE values (TEshort and T2long) of the two compartments. Measurements were localized on the ischemic and the contralateral normal brain.

Results
By comparison with the normal parenchyma, ischemic brain is characterized by a lower ffast (0.52 versus 0.67, p =0.0035) with no modification of ADCfast and ADCslow and by an increase of fT2long (0.69 versus 0.59, p=0.047) associated with an increase of the T2long(157.9 ms versus 124.3 ms, p=0.021).

Conclusions
These observations disagree with the concept of a "volumic" compartmentation of brain water because the both increased fT2long and T2 long should be associated with an increased ffast. These observations could agree with a "dynamic" compartmentation (decreased trans-membrane diffusivity related to aquaporine-4 under-expression) or with a microperfuive explanation (astrocytic end-foot edema responsible for a decreased microcirculation).

Computer Aided Diagnosis of Acute Brain Ischemic Stroke of CT Imaging

M Wu¹, C Chin², C Shen³, Y Tyan³, H Wong⁴
¹Chung Shan Medical University Hospital and Institute of Medicine of Chung Shan Medical University, Taichung, Taiwan, Province of China, ²Chung Shan Medical University, Taichung, Taiwan, Province of China, ³Chung Shan Medical University Hospital, Taichung, Taiwan, Province of China, ⁴Chang Gung Memorial Hospital, Taichung, Taiwan, Province of China
Purpose
The purpose of this study is to improve sensitivity of diagnosis of acute infarction using computer-aided diagnosis system with unsupervised feature perception enhancement method.

Materials and Methods
This system mainly uses unsupervised region growing algorithm to segment the CT imaging into eight important areas. And, it uses coinciding regional location method to highlight the infarction areas. Two neuroradiologists blinded to all patient identifiers and clinical data, first evaluated only the standard noncontrast CT imagings for the area of infarction. Readers then were asked to rediagnosis of infarction area after reviewing the computer aided diagnosis imagings.

Results
After reviewing the computer-aided diagnosis imagings, the sensitivity of acute infarction detection revealed a significant increase from 39% to 90%.

Conclusions
We proposed an unsupervised feature perception enhancement method to detect the acute infarction area in brain CT images. This computer-aided diagnosis system has the potential to assist radiologists in diagnosis of acute brain infarction.

Contrast-enhanced MR Venography in Patients with Multiple Sclerosis to Assess Stenoses of the Internal Jugular Veins. Is There Correlation with CCSVI Criteria?

C Torres¹, M Hogan², C Lum³, T Nguyen⁴, S Chakraborty⁵, B Schwarz², S Belanger², L Legault-Kingstone², M Bussiere⁶, M Freedman², H Dabirzadeh², M Schweitzer⁷, R Thornhill²

¹The Ottawa Hospital, Ottawa, Ontario, ²University of Ottawa, Ottawa, ON, ³University of Ottawa, Ottawa, Ontario, ⁴The Ottawa Hospital, University of Ottawa, Ottawa, Ontario, ⁵The Ottawa Hospital, University of Ottawa, Ottawa, Ontario, ⁶Grey Nuns Community Hospital, Edmonton, AB, ⁷SUNY Stony brook University Medical Center, Stony Brook, NY

Purpose
Zamboni et al suggest that multiple sclerosis (MS) may develop secondarily to impaired central nervous system venous outflow and describes this as Chronic Cerebrospinal Venous Insufficiency (CCSVI). Internal jugular vein (IJV) stenosis is suggested as a cause. This study assesses the prevalence of IJV stenosis in patients with multiple sclerosis and age matched controls using contrast enhanced MR venography (CE-MRV). Potential correlation of IJV stenosis with CCSVI defined by Doppler ultrasound (US) is evaluated.

Materials and Methods
This was a single-center, prospective, observational study of 50 subjects with a confirmed diagnosis of multiple sclerosis with age-matched controls. Research ethics approval and informed consent were obtained. Subjects were randomly selected from 6 MS categories. CE-MRV was performed on a 3T magnet. US evaluation of the intra and extracranial circulation was used to define CCSVI criteria. Imaging results were reviewed independently by pairs of neuroradiologists blind to subject assignment. From MRV images the degree of stenosis was
graded within the lower, mid and upper 1/3 segments of the IJV. US evaluation was considered positive if 2 or more CCSVI criteria were present.

Results

100 studies were undertaken. 13 could not be evaluated due to poor MRV quality (6 patients, 7 controls). Median ages (range) were 50 (27-67) for patients and 54 (25-73) for controls. The female to male ratio was 1.9 for patients and 0.6 for controls. Inter-observer variability for IJV stenosis was fair for lower 1/3 (ICC 0.45 (0.24-0.61)), poor for mid 1/3 (ICC 0.18 (-0.03-0.38)) and good for upper 1/3 (ICC 0.71 (0.58-0.80)) IJV segments. IJV stenosis was identified in 85 (98%) of subjects. Stenosis >= 50% was identified in 31 (70%) of patients and 32 (74%) of controls and was more probable in both groups in the upper 1/3 IJV segment. Stenosis of the lower 1/3 IJV segment was more frequently observed in patients (p=0.01, RANOVA). A positive CCSVI score was identified in 12 patients and no controls (p < 0.001, Fisher's exact test). For positive CCSVI there was a greater proportion of IJV stenosis >= 50 but only in the lower 1/3 IJV segment (p < 0.001) where a weak correlation (Spearman-Rank – 0.4, p <0.001) exists between CCSVI score and stenosis.

Conclusions

IJV stenosis is highly prevalent on MRV and does not distinguish between MS and control subjects. A weak correlation exists between lower 1/3 segment IJV stenosis and CCSVI criteria.

Correlation between voxel based morphometry and resting state functional connectivity in Alzheimer Disease

A Santos1, C Rondinoni1, J Rolo1, M Foss1, T Nunes1, J Moriguti1, C Salmon1

1University of Sao Paulo, Ribeirao Preto, Brazil

Purpose

Multimodal imaging aims to seize the best of the worlds offered by each modality employed. Previous reports indicate feasibility of applying voxel-based morphometry (VBM) in parallel with functional images. Results disentangle the relationships between cortical atrophy and decreased metabolic signals in the anterior and posterior cingulate regions of the Default-mode Network (DMN) in older participants. Although these are core areas in the maintenance of brain connectivity, basal areas like the hippocampus and lateral temporal cortex play a role in the default network (Greicius et al., 2004). Here, we sought to correlate differences in functional connectivity and cortical variations as shown by VBM. Resultant volumes-of-interest from the comparison between AD patients and normal control T1-weighted image volumes were used to identify disease-related deviations of brain functional connectivity. Our aim was to verify the relationship between structural variability and functional compromise depending on each resting state network.

Materials and Methods

A group of 17 elderly were recruited for this study. Mean age for experimental group was 74 years old (s.d. 4.5). Data gathered from a control group was used as age-paired controls for comparison of T1-weighted morphometry and functional connectivity (n=17, mean age 71, s.d.
Patients were diagnosed as Alzheimer patients as confirmed by a specialist examination (mean CDR=1, mean MMSE=16). The research protocol was approved by the local Ethical Committee and all participants signed an informed consent. Resting state functional images were acquired in an Achieva 3 T MR scanner (Philips, The Netherlands) using a noise-attenuated EPI. Tridimensional T1-weighted images were acquired for functional co-registration and morphometry in SMP8. Volumes were matched to the MNI template, segmented, normalized with volume preserving modulation, smoothed (8 mm FWHM) and submitted to statistical test. Functional data were submitted to preprocessing and independent component analysis (ICA) in BrainVoyager QX (Brain Innovations, The Netherlands). After group ICA calculations, (Esposito et al., 2005), functional connectivity values were acquired using resulting VOIs from VBM as binary masks.

Results

Voxel-based morphometry analysis showed differences in medial posterior cingulate cortex, left amygdala, parahippocampal gyrus, medial frontal cortex, and fusiform gyrus. The areas are mainly related to DMN, Salience network and Visual network. Group-wise comparison between standardized ICA values of each VBM resulting VOIs showed differences in zICA of areas coincident with the DMN. Posterior cingulate (Brodmann Area 31) and precuneus (BA 7) showed lower values for patients. Values in posterior cingulate reached 3.50 zICA for patients (1.55 SD) and 4.85 (1.18 SD) controls. Precuneus VOIs showed 2.16 (1.18 SD) for patients and 3.09 (1.40 SD) for controls. Pearson r coefficient for gray matter content and ICA values in posterior cingulate reached 0.45 (d.f= 32, p<<0.05) when all 34 participants are considered.

Conclusions

We identified differences between controls and Alzheimer disease patients by analyzing T1-weighted morphometry and functional resting state data. Results point to an association between cortical thinning and differences in functional connectivity related to AD. Findings may be useful to point out the prodromal phase of Alzheimer disease, shedding light on possible anatomical markers for the progress of the disease.

Cortico-spinal Tract Signal Abnormality on MRI in Glioblastoma Multiforme: Is it Wallerian Degeneration or Tumor Infiltration?

C Hsu¹, S Bhuta¹, G Kwan¹, R Jones²
¹Gold Coast University Hospital, Gold Coast, Australia, ²James Cook University, Townsville, Australia

Purpose
Wallerian degeneration (WD) is an inflammatory response of the nervous system to various forms of axonal or neuronal insult. Glioblastoma multiforme (GBM) is an aggressive WHO grade IV tumor known for tumoral infiltration well beyond the enhancing margins. The aim of the study is to characterize the MR imaging (MRI) signal alteration of the cortical spinal tract (CST) in GBM patients and to determine if imaging model best represent Wallerian degeneration or tumoral infiltration.

Materials and Methods
Retrospective review of 63 consecutive patients (mean age 58; 52 males: 11 females) with histologic confirmation of GBM was performed. MR imaging tumor protocol was done on Siemens 1.5 T Symphony and Siemens 3.0 T Skyra MR systems. The location of GBM and
extent of white matter infiltration [centrum semi ovale, (CST)] was documented on T2 and FLAIR images. Two independent authors (CC-TH and SB) reviewed the studies and zonal classification was used to define extent of abnormality. Zones were defined as I) Centrum semiovale to posterior limb of internal capsule, II) Posterior limb of internal capsule to cerebral peduncle of midbrain, III) Midbrain to pons, IV) Pons to pyramids of medulla. In addition DWI/ADC was used to determine restricted diffusion and postcontrast T1 axial and coronal to assess extent of enhancement. Follow-up examinations (mean duration of 15 months) also were reviewed to document zonal progression of disease and or atrophy. Statistical analysis was performed using Fisher's exact test, Binomial regression and Spearman's rank correlation.

Results
On initial MRI examination 54% (34/63) of GBMs in the frontal, temporal or parietal lobes with involvement of the centrum semi ovale had T2 and FLAIR high signal intensity in the CST. There was no CST involvement in patients with occipital lobe primary. Initial zonal distributions were as follows: 17 in zone I, 10 in zone II and 7 in zone III. Only 6% (2/34) of patients with signal alternation of CST demonstrated enhancement and none showed restricted diffusion. On follow-up examination 39% (24/62) of patients showed new high signal intensity in the CST (46%; 11/24) or progression of zonal stages (46%; 11/24). Only 8% (2/24) had no interval progression. Follow-up zonal distributions were as follows: five in zone I, nine in zone II, five in zone III and five in zone IV. Atrophy of the middle cerebral peduncle was observed in 60% (14/24) of follow-up patients.

Conclusions
Signal abnormality in the CST in patients with GBM is not uncommon. Progressive signal change with associated atrophy of the middle cerebral peduncles best is likely to follow the Wallerian degeneration model over white matter tract infiltration. It is further supported by lack of enhancement even on follow-up studies. The progression of zonal stages on follow-up examination and presence of atrophy in half of the patients is a supporting evidence that Wallerian degeneration of CST is a feature seen in GBMs.

Cynomolgus MRI label atlas and map for fully automated morphometric analyses

J Maldjian¹, C Whitlow², M Nader³
¹Wake Forest University, School of Medicine, Winston Salem, NC, ²Wake Forest University School of Medicine, Winston-Salem, NC, ³Wake Forest University School of Medicine, Winston Salem, NC

Purpose
Currently available non-human primate templates typically require input of a skull-stripped brain for structural processing. This can be a manually intensive procedure, and considerably limits their utility. The purpose of this study was to create a cynomolgus MRI population template, associated tissue probability maps (TPM), and a label atlas to facilitate true fully automated MRI structural analyses for morphometric analyses.
Materials and Methods
Structural T1-weighted 1.5T MRI scans of 16 experimentally naive cynomolgus monkeys (Macaca fascicularis) were used in this study. An unbiased population average template was created using a symmetric diffeomorphic registration (SyN) procedure. Skull stripping, segmentation, and label map generation were performed using the publically available rhesus INIA19 MRI template and NeuroMap label atlas (1). A 6-class TPM and a 6-layer 2-class normalization template was created from the cynomolgus segmentation for use within the SPM framework. Fully automated morphologic processing of all of the cynomolgus MRI scans was then performed using the cynomolgus TPM and cynomolgus normalization template including skull-stripping, segmentation and normalization.

Results
The cynomolgus template creation procedure resulted in excellent skull stripping, segmentation, and NeuroMap atlas labeling with 720 structures successfully registered. Fully automated processing was accomplished for all cynomolgus scans, demonstrating excellent skull-stripping, segmentation, and normalization performance.

Conclusions
We describe creation of an unbiased cynomolgus structural MRI population template and atlas. The template includes an associated 6-class TPM and DARTEL 6-layer 2-class normalization template for true fully automated skull-stripping, segmentation, and normalization of cynomolgus structural T1-weighted MRI scans. We describe the most detailed cynomolgus label atlas currently available based on the NeuroMaps atlas with 720 labels successfully registered. We additionally describe a novel method for atlas label generation that capitalizes on previous work in this area using high-dimensional highly accurate image matching procedures for inter-species morphologic normalization.

EP-63
Diagnostic Accuracy of MRI vs. FDG-PET in the Evaluation of Temporal Lobe Epilepsy

A Mashayekh1, C Intenzo1, P Barker2, D Lin2
1Thomas Jefferson University, Philadelphia, PA, 2Johns Hopkins University School of Medicine, Baltimore, MD

Purpose
Approximately 30% of patients with EEG or pathological evidence of temporal lobe epilepsy (TLE) have normal MRI scans [1,2] (so-called non-lesional TLE). The purpose of this study was to compare the diagnostic accuracy of MRI vs. PET in pathologically confirmed TLE, and identify the type of pathology in negative cases for each modality.

Materials and Methods
Fifty five adult patients (mean age 41 ± 13 years; 31 female) who had both FDG-PET/CT and MRI for presurgical evaluation of temporal lobe epilepsy between 2010 and 2012 were identified from a query of clinical radiology database. All these patients subsequently underwent unilateral temporal lobectomy and/or amygdalohippocampectomy, or laser ablation of the mesial temporal lobe. Clinical data, EEG pathology and surgical outcome results were compiled, and the final
overall clinical diagnosis in patients with successful outcome (Engel class I) was used to assess the diagnostic accuracy of MRI and FDG-PET/CT.

Results
Forty one (75%) patients had successful outcome during mean follow up period of 16.5 ± 10 months; fifteen patients had <12 months follow up. Among all patients who had successful outcome, 30 were PET+/MRI+, 9 were PET+/MRI-, and 2 were PET-/MRI-. The 9 PET+/MRI-subjects included 4 with neocortical epilepsy, 3 with both reactive changes of the neocortex consistent with chronic epilepsy and mesial temporal sclerosis (MTS) (3/9), and 2 with neocortical epilepsy and undetermined hippocampal pathology due to fragmentation of the samples (2/9). The pathology of 2 PET-/MRI- group was reactive changes of the neocortex consistent with chronic epilepsy.

Conclusions
Even with optimized imaging protocols, MRI fails to identify 27% of TLE cases in the current study, similar to rates reported in the literature. The false negative rate is lower with PET (5%), confirming PET as the more sensitive modality for guiding surgical decisions. The negative imaging cases involving the neocortex are likely subtle focal cortical dysplasias that remain a major challenge for structural, and to a less extent, metabolic imaging techniques.

EP-16
Differences Between the Findings of Ultrasonography and Magnetic Resonance Imaging for Evaluation of Carotid Artery Stenosis

Y Kakehi¹, S Ishihara¹, H Ishihara¹, S Kohyama¹, J Niimi¹, N Uemiya¹, F Yamane¹
¹Saitama Medical University International Medical Center, Saitama, Japan

Purpose
Ultrasonography and MR imaging (MRI) are indispensable study for screening of carotid artery stenosis. Each study can evaluate a stenosis degree of carotid artery. But there may be a difference in the results of stenosis degree with each studies, and so we sometimes need cerebral angiography to determine a stenosis degree of carotid artery. Furthermore, the cases of carotid artery stenting gradually increase, and it became apparent that a vulnerable plaque makes carotid artery stenting difficult for high risk of ischemic stroke. Vulnerable plaque is detected by ultrasonography with hypoechoic lesion, and by MRI in a black blood sequence with hypersignal lesion. But there is the case which have different findings of a vulnerable plaque between ultrasonography and MRI in a black blood sequence. We compared a result of ultrasonography and MRI with cerebral angiography, those were performed to the cases of carotid artery stenting or percutaneous transluminal angioplasty, and evaluated superiority of ultrasonography and MRI with consideration from literatures.

Materials and Methods
The cases of carotid artery stenosis performed CAS or PTA from April 2007 through May 2013 were evaluated (CAS 196 cases, PTA 30 cases). We measured a stenosis degree of carotid artery in the North American Symptomatic Carotid Endarterectomy Trial (NASCET) in MRA, echo, DSA each. It was classify in the following four groups. (1) 0〜49%, (2) 50%〜69%, (3) 70%〜
99%, (4) 100%. In addition, we evaluated a vulnerable plaque by ultrasonography and MRI in a black blood sequence, and checked the difference between each test result.

Results
The ratio that a stenosis degree of carotid artery in MRA accorded with cerebral angiography was 78% (63 of 81 cases). The number of overestimated cases was 11, underestimated cases were seven. MR angiography (MRA) had a tendency to overestimate a stenosis degree of carotid artery. The ratio in ultrasonography accorded with cerebral angiography was 47% (38 of 81 cases). The number of overestimated cases was eight, underestimate cases were 35.

Ultrasoundography had a tendency to overestimate a stenosis degree of carotid artery. In the measurement of a stenosis degree, MRA was higher in accuracy than ultrasonography. In the evaluation of a vulnerable plaque, the result of ultrasonography tended to depend on the subjectivity of the ultrasonographer, but it was useful for a mobile plaque evaluation.

Conclusions
In the evaluation of carotid artery stenosis lesion, MRI and ultrasonography are effective methods, and they are minimally invasive. But there are good and bad points with both modalities. It is necessary to use MRI and ultrasonography properly by evaluation points for understanding well the pathophysiology of carotid artery stenosis.

Differentiating melanoma and lung cancer brain metastases using dynamic contrast-enhanced T1-weighted MR perfusion imaging

V Hatzoglou¹, A Mehta¹, J Tisnado¹, C Linares¹, M Folkert¹, K Peck¹
¹Memorial Sloan-Kettering Cancer Center, New York, NY

Purpose
It is difficult to predict the primary origin site of brain metastases based on conventional MR imaging. Dynamic contrast-enhanced T1-weighted MR imaging (DCE-MR) can provide physiologic information about tumor vascularity. We hypothesize that DCE-MR imaging can help differentiate melanoma brain metastases from non-small cell lung cancer brain metastases based on the quantitative analysis of their hemodynamic imaging properties.

Materials and Methods
A total of 50 brain metastases for which the primary tumor origin was either melanoma (23 patients) or non-small cell lung cancer (27 patients) were included. The kinetic enhancement of tissue during and after injection of Gd-DTPA was obtained using a 3D T1-weighted fast spoiled-gradient (SPGR) echo sequence. Preprocessing included background noise removal, spatial and temporal smoothing, and detection of the arterial input function (AIF) from the aorta. All regions of interests (ROIs) around the lesions were placed by a neuroradiologist. Anatomical images that matched the DCE-MRI images were used to guide ROI placements. Voxel-by-voxel estimates of perfusion parameters, including vascular permeability (Ktrans), plasma volume (Vp), slope and peak-enhancement were calculated. A Mann-Whitney U test, at a significance level of p≤0.05, was performed to compare differences of the DCE-perfusion parameters between the two groups.
Results
Of the four perfusion parameters, Vp was observed to have the largest difference in mean (µ) between melanoma (mean=4.1/sec) and lung cancer brain metastases (mean=2.2/sec). A Mann-Whitney U test showed a significant difference between the observed Vp values for the two groups (p≤0.04). However, other parameters were not significantly different between two groups.

Conclusions
Our data demonstrate brain metastases from non-small cell lung cancer brain metastases based on quantification of hemodynamic properties derived from dynamic contrast-enhanced T1-weighted MR perfusion imaging. Identifying the primary tumor site can be especially important in patients with coexisting malignancies. Additional studies are warranted to assess and compare the perfusion characteristics of other types of brain metastases.

KEYWORDS: Brain, Melanoma, Metastases

Top Row: Right frontal lobe NSCL metastasis with Vp of 1.52 on perfusion color map.
Bottom Row: Right frontal melanoma metastasis with Vp of 8.46 on perfusion.

Differentiation between vasogenic edema versus tumor-infiltrative area in patients with glioblastoma during bevacizumab therapy: a longitudinal MRI study

O Aizenstein¹, D Blumenthal¹, B Corn¹, M Artzi², F Bokstein¹, G Liberman¹, D Ben Bashat²
¹Tel Aviv Sourasky Medical Center, Tel Aviv, Israel, ²Tel Aviv Sourasky Medical Center/Tel Aviv University, Tel Aviv, Israel

Purpose
Bevacizumab generally brings about an initial substantial radiologic response in most patients with glioblastoma (GB). Yet, several studies have shown that following bevacizumab, GB is more likely to progress to an infiltrative pattern, associated with an increased MR imaging (MRI) T2-weighted signal. This work seeks to differentiate between vasogenic edema versus tumor-infiltrative area in GB patients.

Materials and Methods
Fourteen patients with GB were scanned longitudinally, before and during bevacizumab therapy (40 MR scans). MR imaging included conventional imaging, diffusion, dynamic susceptibility contrast, dynamic contrast enhancement imaging, and MR spectroscopy (MRS). Classification of the non-enhancing fluid attenuation inversion recovery (FLAIR) area was performed based on mean diffusivity, cerebral blood volume and flow maps. The components obtained were characterized further using multiple MRI parameters. Validation of classification results was obtained using MRS. Longitudinal changes of the different components were studied.

Results
The non-enhancing FLAIR lesion area was classified based on its MRI fingerprint into vasogenic edema and tumor-infiltrative area (Figure 1A). The tumor-infiltrative area demonstrated a higher malignant pattern compared to the vasogenic edema, supported by MRS. Substantial reductions of the enhanced T1-weighted and hyperintense FLAIR lesion areas were detected. However, these reductions were accompanied by a reduction of the vasogenic edema yet with an increase/no change of the tumor infiltrative area, in most patients (Figure 1B).

Conclusions
Quantifying the infiltrative tissue in patients with GB following bevacizumab therapy provides a more accurate assessment of the response to therapy in these patients.

Diffusion Tensor Tractography in Mild & Moderate Traumatic Brain Injury

M D’Souza¹, H Grover², r trivedi¹, k singh¹, A Choudhry³, p kaur⁴, p kumar¹, s khushu¹, R tripathi¹
¹Institute of nuclear medicine and allied sciences, New Delhi, Delhi, ²Institute of nuclear medicine and allied sciences, New Delhi, Delhi, ³Ram Manohar Lohia Hospital, New Delhi, Delhi, ⁴Institute of nuclear medicine and allied sciences, New Delhi, Delhi

Purpose
Diffuse axonal injury (DAI), the neuropathology in mild & moderate traumatic brain injury (TBI), produces microscopic brain changes, challenging to assess with conventional neuroimaging. Diffusion tensor tractography (DTT) may have advantages over other methods as it allows 3D quantification of entire length of white matter (WM) tracts of interest. Present study aims to evaluate WM tracts integrity with DTT in acute mild & moderate TBI using: fractional anisotropy (FA), that represents degree of alignment of fibers in a voxel & mean diffusivity (MD), that represents restrictions to water diffusion.

Materials and Methods
18 patients (age group 19-48 yrs) were recruited within 7 days of TBI. Inclusion criteria: mild or moderate TBI, injury mechanism consistent with DAI; at least 8th grade education level; age above 16 yrs. Exclusion criteria: prior history of TBI & history of any neuropsychiatric illness or
Drug abuse.17 age-matched healthy controls with no neurocognitive disorders were recruited (age group 16-46yrs). Imaging was performed on a 3.0T imager (Skyra, Siemens) using a 32-channel head coil. Protocol: T1 & T2W, FLAIR, SWI & DTI sequences. Fiber assignment by continuous tracking (FACT) algorithm was used for fibre reconstruction. Corpus callosum (with parcellation into 7 subregions), superior & inferior longitudinal fasciculus, corticospinal tracts, cingulum, superior cerebellar peduncle, middle cerebellar peduncle, inferior cerebellar peduncle; anterior, superior, posterior thalamic radiations were generated and quantified using JAVA-based software. Independent t-test was performed to see the difference in FA (fractional anisotropy) and MD (mean diffusivity) values between controls and patients. p value ≤ 0.05 was considered significant.

Results
Conventional MRI scans revealed changes of DAI and small focal hemorrhagic contusions, more on the left side, in 11 patients. Patients displayed significant reduction in FA (p<0.05) in several tracts: the fornix, corpus callosum, left uncinate fasciculus, left inferior fronto-occipital fasciculus, left superior thalamic radiation, left superior and right inferior cerebellar peduncle. MD was not significantly increased in most tracts, except the fornix, right and left superior cerebellar peduncle.

Conclusions
Diffusion Tensor Tractography in acute mild and moderate TBI can identify axonal injury neuropathology, over and above that visualized on conventional MRI.

**Distinction of neuromyelitis optica lesions from multiple sclerosis in brain MRI**

G Simao1, R Seragioli1, D Brum2, A Santos1
1University of Sao Paulo, Ribeirao Preto, Brazil, 2UNESP - Universidade Estadual de Sao Paulo, Ribeirao Preto, Brazil

**Purpose**

Neuromyelitis optica (NMO) and multiple sclerosis (MS) are two demyelinating diseases sometimes showing similar central nervous system (SNC) injury pattern at brain MR imaging (MRI). Brain lesions in NMO patients are more common than what one might expect. There are cases when both the clinician and the radiologist have difficulties in differentiating them. We investigated if brain MRI can help to differentiate NMO patients from MS patients by analyzing the morphology of the brain lesions.

**Materials and Methods**

We retrospectively analyzed the brain MRI of 25 aquaporin-4 antibodies (NMO-IgG) seropositive patients with proved NMO spectrum. Then, the brain MRI was compared with 25 MS patients. The brain lesions were classified as 1) NMO suggestive or 2) MS suggestive, based on morphology and localization. Neuromyelitis optica suggestive was extensive corticospinal tract lesion, extensive hemispheric, extensive lateral periventricular, cervicomedullary, or periependymal lesions surrounding the third and fourth ventricles. Multiple sclerosis suggestive
was lesions ovoid and perpendicular to the lateral ventricle, juxtacortical lesions in the U-fiber, the callosal-septal interface and the peripheral brainstem involvement.

Results
Eight (32%) patients with NMO have lesions that fulfilled the 2010 revised McDonald criteria for MS. Six (24%) patients have only NMO characteristic lesions. Six (24%) have both NMO and MS suggestive lesions. Six (24%) patients have both NMO and MS suggestive lesions. Only one (4%) NMO patient had only MS suggestive lesions. Six (24%) NMO patients had normal brain MRI.

Conclusions
Although NMO and MS share similar cerebral parenchymal lesions with perivenular distribution, there are some characteristics of a parenchymal lesion that allow differentiation. Neuromyelitis optica are more extensive supratentorial, central in the brainstem, and more common in the cervicomedullary junction.

KEYWORDS: MR Imaging Brain, Multiple Sclerosis, Neuromyelitis Optica

**EP-07**

**DWI in Adult Medulloblastoma**

A Bhatt¹, L Eckel¹, F Diehn¹, K Schwartz¹, C Hunt¹, D Kallmes¹, K Koeller¹, K Krecke¹

¹Mayo Clinic, Rochester, MN

Purpose
To describe diffusion-weighted imaging (DWI) findings in patients with adult medulloblastoma. Cerebellar medulloblastoma is a common tumor in the pediatric population, often demonstrating restricted diffusion, but is uncommon in adults. In this review, we evaluated MR imaging (MRI) of adult medulloblastomas, with a particular interest in DWI characteristics.

Materials and Methods
After IRB approval, we screened our pathology database for all pathology proven medulloblastomas in patients 18 years of age or older at the time of diagnosis with available preoperative MRI images. We evaluated the following features: age at presentation, gender, pathologic diagnosis, location, enhancement characteristics, cystic component, T2 appearance, DWI appearance, and margin characteristics. Images were reviewed by two neuroradiologists.

Results
Our database yielded 18 patients (11 men, 7 women, ranging in age from 28 to 77 years) who had pre-operative MRIs available for review. Twelve of the 18 tumors (66%) were centered in the cerebellar hemispheres, while the other six were primarily vermian in location. Fourteen out of 18 (78%) demonstrated some degree of enhancement. Fifty percent of the tumors were partially cystic. Diffusion-weighted imaging was performed in 13 out of the 18 patients, all of which demonstrated some component of restricted diffusion.

Conclusions
Adult medulloblastomas demonstrate some degree of restricted diffusion. Based on this retrospective review, a mass which does not demonstrate restricted diffusion is unlikely to be a medulloblastoma. Other characteristics such as the presence of enhancement or a cystic component are encountered less frequently.
Dynamic contrast-enhanced perfusion imaging analysis for diagnosis of brain tumors using different measurement method

T Abe¹, M Harada², M Mungunkhuyag¹, K Delgerdalai¹

¹The University of Tokushima Graduate School, Tokushima, Japan, ²Tokushima University, Tokushima, Japan

Purpose
T1-weighted dynamic contrast-enhanced (DCE) MR imaging (MRI) is useful in the diagnosis of brain tumors. By using the pharmacokinetic model introduced by Tofts et al, the transfer contrast Ktrans, extravascular extracellular volume Ve and fractional plasma volume fPV can be calculated. Most of brain tumors are heterogeneous; the result can be changed by setting of region of interest (ROI). In this study, we compare the maximum method and peak method to assess the usefulness in the diagnosis of brain tumor.

Materials and Methods
MR examinations were performed by a 3 T MR scanner using a standard eight-channel head coil. Routine pre and postcontrast clinical imaging was performed according to local protocol. Dynamic contrast-enhanced MRI was performed using the following parameters: TR/TE, 4.4/1.0ms; flip angle 12°; field of view, 300 × 210 mm; matrix, 128 × 90; slice thickness, 8mm; number of slices, 16; consisting of 64 phases with a temporal spacing of 3.3 seconds. Total scan time was three minutes and 31 seconds. A gadolinium-DTPA (0.1 mmol/kg) was injected with power injector at a rate 2.5 ml/s and 20ml saline subsequently was injected. This study included 24 patients and 28 lesions (four low grade glioma (LGG), 12 high grade glioma (HGG), seven metastasis, five lymphoma). The diagnosis was made histologically or radiologically. Pharmacokinetic model analysis was performed by using commercially available software (GenIQ, GE Medicalsystems, Milwaukee, WI). In each map, the round region of interest (ROI) was placed manually on the hot spot. The sizes of the ROIs were about 100mm². The averaged signal intensity (peak method) and maximum signal intensity (maximum method) were measured. To assess the differences between DCE parameters and tumor histology, Mann-Whitney-U test was performed. A P value of less than 0.05 was considered statistically significant. Receiver operating characteristics (ROC) curve analysis was performed to evaluate the diagnostic performance. Optimal cutoff value, sensitivity, and specificity also were calculated.

Results
Ve-peak was the most useful parameter to differentiate LGG from other tumors (p=0.0031), lymphoma from other tumors (p=0.0020), but showed no significant difference between HGG and metastasis. The diagnostic performance of the other parameters (Ve-max, Ktrans-peak and Ktrans-max) was lower than Ve-peak. The area under the ROC curve for differentiating LGG or lymphoma was highest for Ve-peak (LGG from other tumors: Ve-peak cutoff: 0.176, sensitivity: 96%, specificity: 100%, lymphoma from other tumors: Ve-peak cutoff: 0.95, sensitivity: 87% specificity: 100%).
Conclusions
In the diagnosis of brain tumors using DCE perfusion technique, accuracy was different depending on the measurement method. In this study, Ve-peak has the best diagnostic performance, and it was useful for the diagnosis of LGG and lymphoma in particular.

EP-47

Dynamic Education: Teaching Carotid and Vertebral Artery Dissection Evaluation to Residents

S Cambron¹, R Khan², D Pastel³
¹Dartmouth Hitchcock Medical Center, Lebanon, NH, ²University of Arizona, Department of Medical Imaging, Tucson, AZ, ³Dartmouth-Hitchcock Medical Center, Lebanon, NH

Purpose
In our experience carotid and vertebral dissections are often missed by residents on-call. This directly impacts patient care as delayed diagnosis may result in stroke. We demonstrate a method to improve resident accuracy in detecting extra-cranial carotid and vertebral artery dissections through evaluation, educational intervention, and finally re-evaluation

Materials and Methods
In this IRB-approved study, we will evaluate the use of the flipped classroom educational technique to improve resident accuracy in the diagnosis of extra-cranial carotid and vertebral artery dissections. Residents from Dartmouth-Hitchcock Medical Center and University of Arizona Medical Center will participate in this study. First, the baseline diagnostic accuracy of residents will be determined by administering 20 anonymized neck CTAs that will contain normal and abnormal cases. The residents will be instructed to provide free text "on-call" interpretations. Their performance will be scored by an attending neuroradiologist. Next, residents will watch an educational video using a flipped classroom online lecture discussing the evaluation, diagnosis, and treatment of dissections. Residents will then participate in a case based workshop with faculty guidance in diagnosis. Finally, we will determine the accuracy of resident interpretation after participation using the same testing method.

Results
We will report resident diagnostic accuracy pre and post-intervention at 2 separate institutions.

Conclusions
We hypothesize that the flipped classroom model of classroom education can improve resident diagnostic accuracy when interpreting extra-cranial carotid and vertebral artery dissections.

Emergent, Off-Hours MR Imaging of the Head and Soft Tissue Neck: an Institutional Review
Purpose
Over the past decade after hours emergent MR imaging anecdotally appeared to be increasing at our tertiary care referral center. A review was performed of emergent Head and Soft Tissue Neck MRI utilization including the types of exams requested, the specialties of the ordering clinicians, and how these MR results did or did not impact patient care and clinical management.

Materials and Methods
Following approval by an Institutional Review Board, MR imaging (MRI) reports were obtained from 37 emergent head MRIs performed over the last 13 years. The corresponding relevant medical records were reviewed to categorize the type of imaging findings, if any therapy was administered and if so, determine the interval between completion of the MRI exam and delivery of the therapy.

Results
Emergent after hours head and soft tissue neck MRI utilization remained relatively stable while adult emergency department visits increased by 24% over the last 13 years. Sixty-two percent (23/37) of MRIs demonstrated significant findings and 57% (13/23) of these patients received a definitive therapy based on the MRI finding. Only 22% (8/37) of patients received a definitive therapy within six hours of MRI completion. Sixty-five percent (24/37) of head MRs included either MRA or MRV. The neurology department ordered the majority (46%) of scans.

Conclusions
Despite increases in overall patient volumes, emergent head and soft tissue neck MRI utilization has not changed over 13 years at our institution. Over 60% of emergent head and soft tissue neck MRIs demonstrated significant findings, but only a minority of patients received a definitive therapy within six hours.

Evaluation of cerebrovascular reserve by acetazolamide-challenge ASL perfusion MRI: Comparison with acetazolamide-challenge SPECT using I-123 iodoamphetamine

N Tomura¹, M Fujishima¹, M Kokubun¹, Z Watanabe¹

¹Southern Tohoku Research Institute for Neuroscience, Southern Tohoku General Hospital, Koriyama, Japan

Purpose
The purpose of this study was to determine the relation between change in cerebral blood flow (dCBF) evaluated using acetazolamide (ACZ)-challenge SPECT (ACZ-SPECT) with I-123 iodoamphetamine and dCBF evaluated using ACZ-challenge arterial spin labeling perfusion MRI (ACZ-ASL) in patients with major cerebral artery steno-occlusive disease.

Materials and Methods
The study was performed in 10 patients with stenosis of the unilateral internal carotid artery (n = 4), bilateral occlusion of the internal carotid artery (n = 1), stenosis of the unilateral middle cerebral artery (n = 1), and cerebrovascular moyamoya disease (n = 4). MR imaging (MRI) was performed with a 3T MRI unit. Fast spoiled gradient-recalled acquisition in the steady state (FSPGR) images were obtained before ASL sequences. After the skull structures were stripped using VBM8 (http://dbm.neuro.uni-jena.de/vbm8/), ASL images were aligned to FSPGR images using affine registration. The standardized normal structures of the computerized brain atlas (SRI24 atlas, http://www.nitrc.org/projects/sri24/) were fitted to FSPGR images by nonlinear registration. Pulsed continuous ASL MRI were acquired before and 5, 10 and 15 min after administration of ACZ with the following parameters: field of view = 24 cm, slice thickness = 4
mm, repetition time = 5216 ms, echo time = 9.8 ms, points × arms = 512 × 8, post-labeling delay = 2525 ms, number of excitations = 2, acquisition time = 3 min 39 s. ACZ-SPECT was performed using the quantitative SPECT dual-table autoradiographic method (Iida H, J Nucl Med 2010:51:1624). The first scan was acquired from 0 to 28 min and the second scan was acquired from 30 to 58 min. I-123 iodoamphetamine was administered at 0 and 30 min. ACZ was administered 20 min after the first I-123 iodoamphetamine injection. The whole-blood count for the input function was taken at 10 min. kACZ-induced dCBF was evaluated in the anterior cerebral arterial, middle cerebral arterial, and posterior cerebral arterial territories of the brain. Those three data points per subject were included in the analysis. The LBPA40/SRI24 atlas (http://www.nitrc.org/projects/sri24/) was used to define the major arterial territories of the brain. The relation between dCBF evaluated using the two techniques was evaluated using simple linear regression.

Results
The dCBF of ACZ-SPECT ranged from -19.3 to 66.9%. The dCBF of ACZ-ASL ranged from 3.1 to 72.6% at 5 min post-ACZ administration, -29.7 to 65.6% at 10 min post-ACZ administration, and -36.5 to 67.4% at 15 min post-ACZ administration. dCBF of ACZ-SPECT correlated with dCBF of ACZ-ASL at 5 min post-ACZ administration (r = 0.63, p < 0.01), but not with dCBF of ACZ-ASL at 10- (p = 0.73) or 15- (p = 0.95) min post-ACZ administration. Conclusions
dCBF determined using ACZ-ASL 5 min after ACZ administration correlates with dCBF determined using ACZ-SPECT, and can be used to evaluate cerebrovascular reserve in patients with cerebrovascular disease. ACZ-ASL is an alternative to ACZ-SPECT.

Evaluation of the Vessel Wall in Patients with Untreated Intracranial Aneurysms

D Saloner¹, S Ahn², H Haraldsson¹, C Hess³, G Laub²
¹UCSF, San Francisco, CA, ²Siemens Medical Systems, San Francisco, CA, ³UCSF, San Francisco, CO

Purpose
To develop and implement high resolution methods for evaluating the vessel wall in individuals with untreated intracranial aneurysms

Materials and Methods
Subjects with untreated intracranial aneurysms who are part of an ongoing longitudinal study to evaluate aneurysm progression were recruited for evaluation of their intracranial vessel walls. High resolution three dimensional vessel wall imaging was performed pre and post injection of Gadolinium. The following sequences were implemented on a Siemens 3T Skyra: A T1-weighted 3D SPACE sequence (0.5mm x 0.5mm x 0.5mm); a 3D balanced steady state sequence (TrueFISP) (0.7mm x 0.7 mm x 0.7 mm); and a 3D contrast-enhanced MRA sequence (0.7mm x 0.7 mm x 0.7 mm)

Results
Five subjects were studied. Three subjects had aneurysms of the internal carotid artery, one of the basilar tip, and one had a giant fusiform basilar artery aneurysm with substantial intralumenal thrombus. In all cases, the SPACE sequence provided excellent black blood images both pre and post contrast injection without any apparent intralumenal flow artifact. CE-MRA sequences (30 sec acquisition) provided high quality images which were demonstrated to have an error of reproducibility of less than 3%. Visualization of the vessel wall could be obtained with good contrast (see Figure 1 which is a single slice image of the basilar artery selected from a 3D volume.) Visualization of the aneurysmal wall was variable. In some cases, the wall appeared thickened and clearly apparent. In other cases it was thinned and difficult to visualize. Contrast enhancement could be seen in different vessel segments, particularly at regions of vascular stenosis.

Conclusions
The 3D T1-SPACE sequence provides excellent visualization of the vessel wall that can be useful in assessing the thickness of the wall in aneurysmal disease. The sequence produces robust black blood images. Isotropic image resolution permits reformattting in planes that best display the vessel wall. Even though the sequence is long – 10 minutes – images did not appear to be degraded by motion artifact and it provides more consistent imaging of the wall than the 2min 30sec TrueFISP sequence. In general, contrast enhancement appears to be diffuse and non-specific. In the case with intralumenal thrombus, substantial enhancement of different elements of the thrombosed volume was apparent.

Filtered Back Projection (FBP) vs. Iterative Reconstruction (AIDR 3D): comparison of dose and image quality in CT scans of the head and spine.

C Therrien\textsuperscript{1}, D Tampieri\textsuperscript{1}
\textsuperscript{1}Montreal Neurological Institute and Hospital, Montreal, Quebec, Canada

Purpose
Compare dose and image quality between unenhanced computed tomography (CT) exams of head and spine obtained using two different techniques: conventional filtered back projection (FBP) and iterative reconstruction (AIDR 3D).

Materials and Methods
We retrospectively reviewed 30 consecutive CT scans of the brain, cervical spine and lumbar spine without injection of contrast media. The scans were performed with the AquilionOne (Toshiba) with the regular helical acquisition protocols: 1) fixed mA for brain CT and 2) modulated mA for the cervical and lumbar spine studies. The CT dose given by the CTDI values and image quality, assessed by SNR and CNR measures, were evaluated. The reconstructions techniques used were filtered back projection (FBP) and iterative Reconstruction (AIDR 3D).

Results
The iterative reconstruction allows a reduction of patient dose for CT scans of the head and spine. Dose, noise and contrast are reduced for brain CT scans. A significant dose reduction is noted for examinations of the cervical spine with a slight increase in image quality. And for exams of the lumbar spine, a dose reduction is observed with a major increase in image quality. It is possible to adjust the acquisition parameters that affect the dose to increase the image quality if necessary for CT of the cervical spine. For the scans of the lumbar spine, it is possible to reduce the dose while reducing the image quality which is greatly higher with AIDR 3D. The image quality of CT exams acquired with modulated mA is increased greatly with the iterative reconstruction while reducing dose to the patient. However, the brain still represents challenge to image with this modality due to its composition of soft tissue surrounded by the skull. A significant minimal dose is required to penetrate the bone structure and enable a diagnostic image of the brain anatomy.

Conclusions
Overall, the iterative reconstruction reduces patient dose for CT scans of the neurological system while maintaining diagnostic image quality. This reduction is even more important on exams with protocols allowing the use of modulation of the mA.

Flebographic Study Does Not Show Differences Between MS Patients and Controls

S Fabiano\textsuperscript{1}, S Marziali\textsuperscript{1}, M Stefanini\textsuperscript{2}, F di Giuliano\textsuperscript{1}, R Floris\textsuperscript{1}, G Simonetti\textsuperscript{1}
Purpose
Hypothetical correlation between chronic cerebrospinal venous insufficiency and multiple sclerosis (MS) has gained the attention of patients and the scientific community. Studies performed by eco-color-Doppler have shown different results and it's necessary to use more objective diagnostic techniques. The aim of our study was to evaluate the presence of stenoses affecting azygos veins and internal jugular veins using venography in patients with MS.

Materials and Methods
We recruited two groups of subjects who underwent venography: "study group" included 29 MS patients and "control group" included 15 healthy volunteers. The ileo-lumbar plexus, the azygos and the internal jugular veins were catheterized selectively. We considered to be a significant stenosis any cross-sectional area reduction of the venous lumen greater than 50%. Furthermore, blood pressure was measured in the studied vessels at the stenotic internal jugular veins.

Results
Selective venography showed at least one significant venous stenosis in 84% of subjects examined, without significant difference between the "study group" and the "control group". Positive venography was found in 50% of all subjects examined, without any significant difference between the two groups. The multivariate logistic regression analysis failed to assess any significant association between the presence of a positive venography and MS condition. The difference between the median blood pressure of stenotic and nonstenotic internal jugular veins was not statistically significant (p=0.46).

Conclusions
Our data exclude any direct correlation between chronic cerebrospinal venous insufficiency and MS, because venous abnormalities were equally present in both groups.

Functional and Morphological Patterns of Involvement in Neurodegenerative Brain Disorders: A Combined Approach Using FDG-PET, ASL-MR Imaging, and Structural MR Imaging

B Gomez Anson¹, H Marquez Masquiaran¹, V Camacho Marti¹, A Fernandez Leon¹, F Nuñez Marin¹, E Granell Moreno¹, M De Juan Delago¹, A Lozano Martinez¹, A Lleo Bisa¹
¹Hospital de la Santa Creu i Sant Pau, Barcelona, Spain

Purpose
A combined approach using metabolicfunctional and morphological information in neurodegenerative brain disorders has been advocated (1). However, the added value of this approach in current practice and the potential discrepancies between techniqueinformation has not been assessed yet in detail. The aim has been to present our preliminary experience in this regard.

Materials and Methods
Among 60 patients referred from a tertiary referral memory clinic, who underwent both FDG-
PET and structural MRI (3D-MPRAGE) at our institution during the last two years, 20 had additional 3 T single phase ASL. The most common indication for imaging was to support the clinical suspicion, adding in differential diagnosis between frontotemporal lobar degeneration – FTLD- and Alzheimer disease –AD-. Metabolic/functional patterns of involvement as provided by FDG-PET and ASL, and morphological (volume loss) on structural MRI were evaluated by visual, expert assessments on a blinded fashion. Table 1 summarizes final diagnosis as made by a dedicated neurologist after follow up, and evaluation results. Most characteristic functional and morphological patterns of involvement in FTLD (frontal and semantic variants), AD, corticobasal degeneration, Creutzfeldt-Jakob, and Huntington disease are shown. Examples of agreement/discrepancies between functional and morphological information are demonstrated.

Results
As shown in Table 1, there was agreement between functional (PET) and structural patterns in the four AD cases, with ASL and PET also being concordant. On the contrary, out of nine cases with FTLD, there was agreement between functional (PET) and structural MRI only in one. Additionally, five patients with FTLD had ASL/PET concordance. There were cases with more marked functional information, others with more profound loss of volume, and others with discrepancies between patterns at regional level.

Conclusions
Although characteristic patterns of involvement are seen on functional (PET, ASL) and structural (MRI) imaging, there may be disagreement between them. This is more frequent within the FTLD group, as has been reported recently (2). Recognition of the discrepancies between functional and morphological information may be an additional, useful diagnostic tool for the radiologist in clinical practice.

Generalized versus Patient-specific Inflow Boundary Conditions in Computational Fluid dynamic Simulations of Cerebral Aneurysms

C Majoie¹, I Jansen¹, H Marquering¹, W Potters¹, E van Bavel¹, R van den Berg¹, J Schneiders¹

¹Academic Medical Center, Amsterdam, Noord-Holland
Purpose
Intracranial aneurysmal hemodynamics have been associated with aneurysm growth and rupture. Hemodynamics in aneurysms commonly are determined using computational fluid dynamics (CFD) using generalized inflow boundary conditions in a parent artery. Recently, patient-specific inflow boundary conditions are being implemented more frequently. Our purpose was to compare intracranial aneurysm hemodynamics based on generalized versus patient-specific inflow boundary conditions.

Materials and Methods
For 36 patients, geometric models of aneurysms were determined using 3D rotational angiography (3DRA). 2D phase contrast magnetic resonance imaging (PC-MRI) velocity measurements of the parent artery were done. Computational fluid dynamics simulations were performed twice: once using patient-specific PC-MRI velocity profiles and once using generalized Womersley profiles as inflow boundary conditions. Resulting mean and maximum WSS values were analyzed and hemodynamic characteristics were qualitatively compared.

Results
Quantitative analysis showed statistically significant differences for mean and maximum WSS values between the two inflow boundary conditions (p<0.001). Qualitative assessment of hemodynamic characteristics showed differences in 21 of the 36 cases. These consisted of differences in high WSS location (N=8), deflection location (N=3), lobulation WSS (N=12) or in vortex and inflow jet stability (N=9). The latter showed more instability for the generalized inflow boundary conditions in seven out of nine cases.

Conclusions
Using generalized and patient-specific inflow boundary conditions for CFD results in different WSS magnitudes and hemodynamic characteristics. Generalized inflow boundary conditions result in more vortices and inflow jet instabilities. This study emphasizes the necessity of patient-specific inflow boundary conditions for calculation of hemodynamics in cerebral aneurysms using CFD techniques.

Gradient of Perilesional Abnormalities is Associated with Degree of Lesion Abnormality in Quantitative MRI Parameters

S Siemonsen¹, W Schmidt², C Heesen¹, J Fiehler¹
¹University Medical Center Hamburg-Eppendorf, Hamburg, Hamburg, ²University Medical Center Hamburg-Eppendorf, Hamburg, Germany

Purpose
In Multiple Sclerosis (MS) changes can be found in normal appearing white matter (NAWM) in comparison to healthy individuals using MRI. Changes of apparent diffusion coefficient (ADC) and magnetization transfer ratio (MTR) in are thought to reflect tissue destruction, i.e. in terms of demyelination and axonal loss. We hypothesized that changes of ADC and MTR in NAWM are
more pronounced in the vicinity of MS lesions indicating local tissue destruction invisible in conventional MRI.

Materials and Methods
19 untreated relapsing-remitting MS patients with an MRI examination including diffusion-imaging, magnetization-transfer-imaging and T2-weighted images were included. 395 lesions were marked on T2 weighted images and regions of interest(ROIS) in terms of lesion-surrounding concentric shells were defined for each lesion. NAWM was defined as white matter brain tissue voxels at least 10 shells distant of any lesion. Relative T2 values (rel.T2), ADC and MTR were measured within each lesion and each corresponding shell as well as in NAWM for each patient.

Results
Increased ADC and decreased MTR values in comparison to NAWM were detectable within lesion shells: increased ADC values within the shells closest to the lesion were measurable in 276 of the first shells and decreased MTR in 210. Values of ADC, MTR and rel.T2 within shells were independent of lesion size but significantly (p<0.001, R=0.68 for ADC and R=0.60 for MTR) correlated with values measured within the corresponding lesions.

Conclusions
Changes in the vicinity of visible MS lesions are measurable and seem to be dependent on the severity of tissue destruction within the lesion but not dependent on primary lesion size. Therefore in a number of cases MS lesions extend well beyond visible lesion boundaries on conventional MRI and pronounced tissue destruction is measurable within the NAWM in the vicinity of single MS lesions.

High Rate of Spontaneous Recanalization in Untreated Acute Ischemic Stroke Patients: A Natural History Study

A Vagal1, M Reddy2, H Sucharew3, S Yeramaneni3, P Khatri2, Q Hou4, P Michel5, T Jovin6, M Wintermark7, R Aviv8
1University Hospital/University Cincinnati College of Medicine, Cincinnati, OH, 2University of Cincinnati Medical Center, Cincinnati, OH, 3Cincinnati Childrens Hospital Medical Center, Cincinnati, OH, 4University of Virginia, Charlottesville, VA, 5Centre Hospitalier Universitaire Vaudois, Lausanne, AS, 6University of Pittsburgh, Pittsburgh, PA, 7University of Virginia, Charlottesville, VA, 8Sunnybrook and Women’s College HSC, Toronto, ON

Purpose
The majority of the evidence of arterial recanalization in acute ischemic stroke comes from either intravenous thrombolytic or endovascular device data sets. Very limited information about spontaneous recanalization exists regarding stroke patients who have not received any reperfusion treatment. Our objective was to study the rate and predictive factors of spontaneous recanalization in untreated acute stroke patients.

Materials and Methods
From a large, prospectively collected acute stroke database (CHUV, UPMC and Sunnybrook
hospital), all untreated patients with baseline CT angiogram (CTA) within 24 hours and subsequent follow-up vascular imaging (CTA or MR angiogram) within 24-48 hours were compiled for analysis. Respectively, institutional review boards approved collection and analysis of data from the repository. Baseline CTA images were reviewed for the site and severity of arterial occlusion, clot burden score and degree of collateral circulation. The severity of arterial occlusion or stenosis was graded using the modified Thrombolysis in Myocardial Ischemia (TIMI) and Interventional Management of Stroke (IMS) III trial CTA scoring systems. Follow-up CTA/MRA imaging was reviewed to determine recanalization status. Multivariate regression models were used to assess variables predicting recanalization.

Results
Among 128 untreated patients (mean age 65 years, median NIHSS 12, baseline CTA mean 4.9 hours from stroke onset) with follow-up vascular imaging (mean 26 hours), 90 (70%) had proximal arterial occlusion. Of these 90 patients, 43 (48%) had spontaneous full recanalization, 43 (48%) had no evidence of recanalization, and 4 (4%) with unidentifiable recanalization status. Rates of recanalization by occlusion location subtype were: extracranial ICA 10 of 27 (37%); intracranial ICA 14 of 30 (47%); M1 29 of 51 (57%); M2 19 of 30 (63%). No differences in demographic and baseline characteristics between recanalization status groups were observed. There was no statistical difference between favorable outcomes (defined as 3 month mRS 0-2) between those who had spontaneous recanalization and those who did not (45% versus 34%, p-value=0.30). In the multivariable logistic regression model, spontaneous recanalization was associated significantly with higher collateral score (aOR=1.26, p-value=0.004) and lower clot burden score (greater thrombus length) (aOR=0.76, p-value=0.03) (Table 1). Adjusting for key variables, the multivariable model for clinical outcomes demonstrated that stroke severity (NIHSS) was the only significant predictor of good outcome and that spontaneous recanalization was not associated with favorable outcomes.

Conclusions
There is a high rate of spontaneous recanalization in 24-48 hours in untreated acute stroke patients, especially distal occlusion. Spontaneous recanalization is associated significantly with higher collateral score and lower clot burden score and is not a predictor of favorable outcome.

EP-79

High-resolution 3T MRI Characterization of cavernous and juxta-cavernous internal carotid aneurysms: preliminary experience.
A Drofa¹, E Obusez², S Jones², M Bain², S Hussain², F Hui²
¹Cleveland Clinic, Lakewood, OH, ²Cleveland Clinic, Cleveland, OH

Purpose
Cavernous aneurysms are generally considered to be extradural lesions that, when ruptured, may result in cavernous carotid fistulae and, when sufficiently large, have been thought to be able to erode dura and enter the subarachnoid space. Accurate characterization of cavernous segment aneurysms and the relationship to the cavernous sinus may be useful in assessing the relationship with adjacent dura, and may eventually provide some insight into morphology and risks associated with untreated cavernous aneurysms. We describe high-resolution MR protocol (HRMRP) for detection and localization of intracavernous aneurysms.

Materials and Methods
The high resolution MR database at the institution was reviewed according to local IRB.8 patients with unruptured cavernous and paraclinoid aneurysms were identified, further selecting purely cavernous aneurysms. Coronal T1 post contrast "blackblood" TSE FS images were analyzed. In 1 of these patients the results were compared with the digital subtraction angiography data and in 1 with the results of CTA using previously described landmarks of extra- intradural localization.

Results
A total of 3 intracavernous aneurysms were reliably visualized using new protocol. MR imaging was concordant with CTA data in 1 patient and with digital subtraction angiography data in another. In the third patient our protocol allowed reliable intracavernous localization of the aneurysm and no further imaging was thought to be necessary.

Conclusions
HRMR is an innovative technique that may be used as an adjunct to conventional imaging of cavernous aneurysms, allowing visualization of the relationship of the aneurysm, the cavernous sinus and the nearby dura overlying the cavernous sinus. Early experience suggests utility but greater experience will be necessary to assess predictive value.

Hippocampal Malrotation: Epilepsy in disguise. What to look for.

L Lopez Porras\textsuperscript{1}, J León\textsuperscript{2}, L Garcia-Ferrer\textsuperscript{3}, S Campos Hervas\textsuperscript{4}
\textsuperscript{1}ERESA Grupo Médico, Hospital General de Castellón, Castellon, Spain, \textsuperscript{2}ERESA Grupo Médico, Hospital Clínico Universitario de Valencia, Valencia, Spain, \textsuperscript{3}ERESA Grupo Médico, Hospital Provincial de Castellón, Castellon, Spain, \textsuperscript{4}ERESA Grupo Médico, Valencia, Spain

Purpose
Demonstrate the common characteristics of MR Imaging findings of patients with hippocampal malrotation and epilepsy using volumetric and high resolution imaging.

Materials and Methods
We reviewed MR Imaging of 12 patients with hippocampal malrotation diagnosed at our institution between 2009 and 2011 (4 female and 8 male patients) with a mean age of 28 years.
The MR imaging (MRI) examinations were performed on a 3.0 T scanner (GE Signa) using our epilepsy protocol which includes: sagittal T1-weighted spin-echo imaging, axial T2-weighted FRSE-XL imaging, axial proton-weighted FRSE imaging, axial GRE T2* imaging, axial and coronal FLAIR T2 imaging, coronal T2 FSE-XL high resolution imaging, volumetric 3D FSPGR imaging and diffusion-weighted B-1000 imaging.

Results
We evaluated the following morphological characteristics: incomplete inversion of the hippocampus with abnormally rounded shape, unilateral abnormality, normal signal intensity, unsharp internal structure, abnormal angulation of the collateral sulcus, abnormal size and localization of fornix, normal temporal lobe size and temporal horn enlargement. The most prevalent radiological signs were a round shape of the hippocampus with normal size and signal intensity, a more vertical collateral sulcus and an empty choroid fissure. The less prevalent radiological findings were a displaced fimbria, a reduced horizontal portion of the parahippocampal gyrus and a thick subiculum.

Conclusions
The hippocampal malrotation is a malformation to be considered in the differential diagnosis of patients with seizures.

Histogram Analysis of Apparent Diffusion Coefficient Map in Distinguishing between Typical and Atypical Primary Central Nervous System Lymphomas and Tumefactive Demyelinating Lesions

S Kim¹, C Choi¹, H Kim¹, N Kim¹, S Lu²
¹Asan Medical Center, Seoul, Korea, ²The First Affiliated Hospital of Nanjing Medical University, Nanjing, Jiangsu Province, Korea

Purpose
This study aimed to investigate the usefulness of histogram analysis of apparent diffusion coefficient (ADC) maps for discriminating primary central nervous system lymphomas (PCNSLs), especially PCNSLs with atypical MR features from tumefactive demyelinating lesions (TDLs).

Materials and Methods
Forty-seven patients (33 men, 14 women, 29-82 years old) with PCNSLs and 18 (10 men, 8 women, 22-66 years old) with TDLs were enrolled in this study. Hyperintense lesions on T2-weighted images (T2WIs) were defined as regions of interest (ROIs) after T2WIs were registered to the corresponding apparent diffusion coefficient (ADC) maps (T2WI-ADC) using a dedicated software package (Nordic ICE; NordicNeuroLab, Bergen, Norway). Apparent diffusion coefficient histograms were calculated from the ROIs containing the entire lesions on every section on a voxel-by-voxel basis using in-house developed software. Apparent diffusion coefficient histogram parameters were compared in all of the PCNSLs and TDLs, and in the subgroup of atypical PCNSLs and TDLs. Receiver operating characteristic (ROC) curves were constructed to evaluate the diagnostic performance of histogram parameters and to determine the optimum thresholds.

Results
Discrepancies between the PCNSLs and TDLs were found in the minimum ADC values (ADCmin), the 5th and 10th percentiles (ADC5% and ADC10%) of cumulative ADC histograms. However, no statistical significance was found in the mean ADC value, the ADC value at mode, kurtosis and skewness. Lower ADCmin, ADC5% and ADC10% also were found in PCNSLs with atypical MR features when compared with those of the TDLs. ADCmin was the best indicator for this discrimination with the threshold of 599 × 10⁻⁶ mm²/sec (sensitivity 68.1%, specificity 77.8%).

Conclusions
Histogram analysis of ADC maps based on the entire lesion may help for the discrimination of PCNSLs from TDLs.

EP-02

Imaging Findings of Central Nervous System Involvement in Multiple Myeloma

EP-02
Purpose

Central nervous system (CNS) involvement in multiple myeloma is rare, occurring in approximately 1% of all cases. It has a poor prognosis, which has somewhat improved with the most recent treatment protocols. Both the brain and the spine can be involved. MR imaging (MRI) is the best imaging test, and the diagnosis is generally made in combination with cerebrospinal fluid (CSF) cytology/flow cytometry. The aim of this project is to investigate different imaging manifestations of CNS involvement in multiple myeloma, estimate their prevalence and correlate them with CSF cytology/flow cytometry and biopsy results. A variety of images from brain and spine MRIs and CTs of multiple myeloma patients with CNS involvement will be included in this electronic poster.

Materials and Methods

After obtaining IRB approval, we carried out a retrospective review of imaging studies performed on multiple myeloma patients with confirmed or strongly suspected CNS involvement between 2002 and 2013. In collaboration with the departments of pathology and oncology, a list of 32 multiple myeloma patients with potential CNS involvement was compiled. Imaging studies of their brains and spines were reviewed and, if positive, were classified into different patterns of involvement: leptomeningeal enhancement in the brain or spine, parenchymal lesions in the brain or spinal cord, cranial nerve infiltration, intracranial dural-based involvement or epidural lesions in the spinal canal. The patients' electronic medical records were searched for CSF cytology/flow cytometry and biopsy results. Patients with negative or unavailable CSF results whose only abnormality on imaging were masses extending from adjacent osseous lesions were excluded. Twenty-three patients met the inclusion criteria for this study. Prevalence of different imaging manifestations of CNS involvement in these multiple myeloma patients was calculated.

Results

Eight of 23 (34.8%) multiple myeloma patients with suspected CNS involvement had positive CSF cytology/flow cytometry results. Four of the 8 (50%) patients had parenchymal brain involvement, 2 (25%) had leptomeningeal enhancement in the brain, 2 had intracranial dural-based lesions, 1 (12.5%) had cranial nerve infiltration, 1 had leptomeningeal spinal involvement, 1 had intramedullary spinal involvement and 1 had no imaging evidence of CNS involvement. Of these 8 patients, 4 (50%) had two sites of CNS involvement on imaging, which was most commonly seen with brain parenchymal (3/8 or 37.5%) and leptomeningeal brain lesions (2/8 or 25%). Fourteen of 23 (60.9%) patients had biopsy proven CNS involvement with multiple myeloma. Twelve of the 14 (85.7%) patients had epidural lesions in the spinal canal, 3 (21.4%) had evidence of cranial nerve infiltration, 3 had intracranial dural-based involvement and 1 (7.1%) had leptomeningeal enhancement in the brain. None of the 14 patients had CSF results available in our electronic medical records. Of the 14 patients, 3 (21.4%) had two sites of CNS involvement on imaging, which was seen most commonly with spinal epidural (3/14 or 21.4%) and intracranial dural-based lesions (2/14 or 14.3%). One of the 14 patients (7.1%) had three sites of CNS involvement on imaging. One of the 23 patients had dural-based intracranial and epidural spinal lesions on imaging with nonspecific CSF cytology, nondiagnostic flow-cytometry and no available biopsy results. Overall, the most common imaging manifestations were spinal epidural (13/23 or 56.5%), intracranial dural-based (6/23 or 26%), parenchymal brain (4/23 or 17.4%), cranial nerve (17.4%) and leptomeningeal brain lesions (3/23 or 13%). Nine of the 23
patients (39.1%) had two or more sites of CNS involvement on imaging, which was most commonly seen with spinal epidural (5/23 or 21.7%), intracranial dural-based (5/23), parenchymal brain (3/23 or 13%) and leptomeningeal brain lesions (3/23).

Conclusions
Imaging findings of CNS involvement in multiple myeloma are diverse. Epidural spinal lesions are the most common and intracranial dural-based lesions are the second most common manifestation. Parenchymal brain involvement and cranial nerve infiltration are the other relatively prevalent findings. Leptomeningeal enhancement in the brain and, less commonly, the spine also can be seen. Rarely, the spinal cord itself may be involved. Frequently, there are two or more sites of CNS involvement with multiple myeloma, which most commonly occurs when spinal epidural and intracranial dural lesions are present. Central nervous system involvement in multiple myeloma can infrequently be occult on imaging and be evidenced only by positive CSF cytology/flow cytometry results. It is important to identify CNS involvement in multiple myeloma since it affects treatment by determining the need for intrathecal chemotherapy and cranial irradiation as well as for prognostic purposes.

Imaging Genomic Biomarker Signature for MGMT Promoter Methylation Identification in Glioblastoma

G Thomas¹, J Wang², Z Mahmood¹, M ElBanan¹, P Zinn¹, R Colen¹
¹MD Anderson Cancer Center, Houston, TX, ²The University of Texas M. D. Anderson Cancer Center, Houston, TX

Purpose
To create an imaging biomarker signature in order to identify those Glioblastoma (GBM) patients with MGMT promoter methylation.

Materials and Methods
We identified 99 treatment-naïve patients from The Cancer Genome Atlas (TCGA) who had both gene and microRNA expression profiles (MGMT methylation status) and pretreatment MRI from The Cancer Imaging Archive (TCIA). Qualitative VASARI imaging features for these 99 patients were assessed by 3 independent neuroradiologists and consensus was reached. Quantitative volumetric analysis was done in the 3D Slicer software 3.6(http://www.slicer.org) using segmentation module. Fluid Attenuated Inversion Recovery (FLAIR) was used for segmentation of the edema and post-contrast T1 weighted imaging (T1W1) for segmentation of enhancement (defined as tumor) and necrosis. Each qualitative and quantitative feature was correlated to MGMT methylation status both independently and as groups and subgroups. Survival analysis was done in all cases. Biomarker signature based on profiling and survival were created.

Results
An imaging biomarker signature was created that predicted MGMT promoter methylation status. Multiple qualitative and quantitative MRI features correlate with MGMT methylation status. Multiple parameters were associated with survival.
Conclusions
MGMT methylation status plays an important role in patient predictive and prognostic stratification of patients with GBM. The identification of a non-invasive biomarker signature as a surrogate for MGMT methylation can help stratify patients in specific therapy and predict response versus non response to therapy. An imaging genomic signature can be expected to promote a more robust personalized approach to patient care and accelerate drug development and clinical trials.

Imaging Genomic Texture Analysis Based on Haralick Features

S Loupot¹, J Stafford¹, P Zinn¹, R Colen¹
¹MD Anderson Cancer Center, Houston, TX

Purpose
In this study, we investigated the feasibility of using the Haralick Texture Features as a map from MRI images to genomic markers. We applied 19 features descriptors from literature to MRI of GBM and found that these features are dependent on the size of the image being analyzed, as well as the values used to calculate the grey level co-occurrence matrix that is used in the determination of Haralick's Features. Work has been done to classify GBM based on texture, but this is the first to our knowledge that uses the features defined by Haralick et. al.

Materials and Methods
Eighteen features were investigated as per Haralick feature set to include measurements of homogeneity, entropy, energy, dissimilarity, etc. Texture analysis was performed on our expert-segmented MR images that included segmentation of three individual components (contrast enhancement, necrosis, and edema/invasion). Each was calculated based on a grey level co-occurrence matrix. This matrix was a representation of the spatial distribution of the grey levels in the image. The texture features were statistical descriptions of this co-occurrence matrix. Our results were then applied to our validation set.

Results
Texture analysis on the expert segmented images demonstrated areas of GBM that were homogeneous and areas of that were heterogeneous. Using the texture analysis feature set, we were able to create an accurate landscape of "geneity" of GBM. These were also reproducible in our validation set.

Conclusions
We successfully applied several texture features to our previously expert-segmented MRIs of GBM. We were able to correlate the texture features of the tumor to the different regions (contrast enhancement, necrosis, and edema/invasion) and develop a base line on which to make predictions of genomic expression.

Infiltrating Gliomas Involving the Cranial Nerves: Case Series and Review of the Literature

M Mabray1, M Mamlouk1, G Punch1, C Glastonbury2, S Cha1
1University of California San Francisco, San Francisco, CA, 2University Of California San Francisco, San Francisco, CA

Purpose
Infiltrating glial neoplasms involving the cranial nerves are a rare but important entity to recognize. These tumors may simulate nerve sheath tumors, intracranial perineural spread of head and neck tumors, or leptomeningeal spread of disease. The purpose of our study is to characterize the imaging features of this rare manifestation of gliomas and to review the previously described cases in the literature.

Materials and Methods
Individual cases of gliomas infiltrating into or involving a cranial nerve were retrospectively identified through a search of our teaching file database and radiology reporting system. A retrospective review of the literature was performed using PubMed to identify original cases of glioma infiltrating within or along cranial nerves. Cranial nerve involvement as leptomeningeal spread or involvement of the olfactory or optic nerves were specifically excluded, as anatomically and histologically CN1 and CN2 are white matter tracts and not true cranial nerves.

Results
Eight original cases of gliomas involving a cranial nerve from our institution are presented. Six of the cases involved the trigeminal nerve, one case the oculomotor nerve, and one case the trigeminal and facial nerve. The mean age of patients was 41 years old (range of 9-67) old; four were women and four were men. Three cases were unifocal tumors and five cases were in the setting of multifocal glioma. In all three of the unifocal tumors and in one of the multifocal tumors the presenting symptom was cranial neuropathy. On histopathology, six cases were grade IV (glioblastoma), one case was grade II, and one case was grade III. In none of the cases was a gross total resection attempted or achieved, treatment consisted of radiation and chemotherapy.

On imaging, all eight cases showed tumors involving cranial nerves with typical features of infiltrating glioma. This comprised of expansion, irregular or rim enhancement, infiltrative T2 FLAIR signal hyperintensity, variable degree of reduced diffusion, increased cerebral blood volume on perfusion, and elevated choline/NAA on spectroscopy. These imaging features were key in distinguishing these tumors from other lesions that may occur in the same location such as nerve sheath tumors, perineural spread of head and neck malignancies, leptomeningeal spread of cancer, or meningiomas. Review of the literature revealed a total of eleven reported cases of glioma with cranial nerve involvement excluding leptomeningeal spread ranging in date from 1904 to 2011. The age is available for seven of the patients with a mean age of 36 years old (range of 8-70). Eight cases were reported to involve the vestibulocochlear nerve, one case to involve the oculomotor nerve, one case to involve the trigeminal nerve, and one case to involve the vestibulocochlear, facial, and trigeminal nerves. On histopathology nine of the cases are reported as low-grade gliomas (WHO grade I-II) and two cases are reported as glioblastomas (WHO grade IV).

Conclusions
We present imaging characteristics of infiltrating gliomas involving the cranial nerves, a rare but
important entity to recognize preoperatively. This presentation will improve the attendee's awareness of this process and the imaging features on standard and advanced imaging sequences.

Inhospital Survival Following Conservative Therapy in Severe Acute Stroke Patients Within 3 Hours of Onset Due To Severe Hypoperfusion in the Middle Cerebral Artery Territory Displayed by MR Perfusion Study

Y Tanno¹, Y Aoyagi¹, T Iwata¹, S Kasakura¹, Y Miayazaki¹, T Mori¹, K Yoshioka¹
¹Shonan Kamakura General Hospital Stroke Center, Kamakura, Japan

Purpose
The purpose of our study was to investigate inhospital survival following conservative therapy in
severe acute stroke patients within three hours of onset due to severe hypoperfusion in the middle cerebral artery territory displayed by MR perfusion study.

Materials and Methods
Included in our retrospective analysis were acute stroke patients 1) who were admitted to our institution within three hours of onset from 2005 to 2013, 2) who had severe hypoperfusion in the affected MCA territory displayed by MRI/PWI study and 3) who undergo no revascularization therapy. Time intensity curves (TICs) of PWI were generated on region of interests set at symmetrical positions of the bilateral MCA territories. The time to peak (TTP) and the peak signal (PS) was compared between the affected side (a) with the contralateral side (c). Severe hypoperfusion was defined as TTPa minus TTPc of one second or more and PVa divided by PVc of less than 0.5. Evaluated were patient's baseline characteristics, NIHSS score on admission, emergency CT-ASPECTS and MRI DWI-ASPECTS, length of hospitalization stay. We investigated inhospital survival rate at 10 days and factors for survival.

Results
Forty-two patients were analyzed. Their average age was 81.7 years, median NIHSS on admission was 21.5 (18.7-25.5: interquartile range), median DWI-ASPECTS was two (0-3), median CT-ASPECTS was three (1.7-6), average length of hospital stay was nine days, 21 patients (50%) died during hospitalization. Among them, 20 patients (95%:20/21, 48%:20/42) died within 10 days. CT ASPECTS on admission was significantly correlated with inhospital survival. However, age, DWI-ASPECTS and NIHSS on admission were not related to survival. Indeed, DWI-ASPECTS and NIHSS on admission were very severe in all patients. Logistic regression analysis demonstrated that CT ASPECTS was the independent factor for survival (OR= 20.52, 95% CI=1.19 to 581, P<0.05). Receiver operating characteristic (ROC) curve (AUC 0.693) showed that cut-off-point for survival was three in ASPECTS.

Conclusions
When acute ischemic stroke patients within three hours of onset presenting severe hypoperfusion of the MCA territory, severe NIHSS and low DWI-ASPECTS were treated conservatively, inhospital survival rate was only 52% at 10 days. We must rescue patients with CT ASPECTS of two or less and improve clinical outcome of patients with CT ASPECTS of three or more.

Insights from the Ventral Premotor Cortex (BA 44): Glial Tumor Spread Pattern Important for Survival and Functional Outcomes.

J Hamilton¹, S Guillory¹, L Chavali¹, V Kumar¹, C Ison¹, K Shah¹, D Schellingerhout¹, S Prabhu¹, L Chi¹, R Colen¹, J Wefel¹, L Hayman², A Kumar¹
¹UT MD Anderson Cancer Center, Houston, TX, ²Anatom-e Information systems, Ltd, Houston, TX

Purpose
To describe the spread and functional outcomes of gliomas arising from or involving the ventral premotor cortex, also called "the motor of Broca's", Brodmann Area 44 (BA44) or pars frontalis.

Materials and Methods
Twenty-eight cases of diffuse glioma involving BA 44 were retrospectively reviewed. Pre-and postoperative deficits imaging and neurologic testing, pathology and survival were assessed. The volume representing BA44 was defined as the Brodmann defined cortex with the underlying superficial white matter ending at the crossing fibers of the corona radiata. Representative and difficult cases were rendered in volume for confocal viewing.

Results
Gliomas restricted solely to BA 44 (n=12) had a characteristic "C" or "lotus flower" shape, with a rounded deep border straddling the pre-central sulcus of the inferior frontal gyrus. Spread to adjacent operculum or insula was common (n=12), while 6 patients had deeper spread/multifocal disease. BA 44 is involved in fine motor hand coordination, verbal fluency, attention and executive functions. The glioma was left sided in 19 patients in close proximity to language function. Gross total resection of at least the enhancing component was obtained in 12 patients, with incomplete resection often due to sparing of the face motor cortex posteriorly, arcuate tract deep or Broca's area anteriorly. Available neurological exams 1-2 weeks after surgery showed significant decline in 3 patients, mild decline in 11 and a mixture of improvement / decline in 6. Patient often improved until time of recurrence. At last follow-up (40+/27 months), patients with gliomas restricted to BA 44 were more likely to be alive (83% versus 38%, p=0.02 by Fisher exact test) and less likely to have GBMs (17% versus 56%; p=0.05), than those spreading beyond.

Conclusions
BA 44 is an important area for integrating attention and proprioceptive information to voluntarily coordinate complex movements. The gliomas characteristic shape has important functional and survival implications for spread beyond BA44. BA44 has been deemed eloquent because it cannot be removed without deficit (ref. 1), however, in the majority of these patients the deficits were minor and some patients experienced partial improvement. Clinical relevance:
Understanding the characteristic shapes of BA 44 diffuse gliomas allow for detection of spread beyond this area, with important implications for functional outcomes, neurosurgical risk, and survival.

KEYWORDS: Broca'S, Functional Brain Mapping, Glioma
25 year old female with anaplastic astrocytoma involving the left ventral premotor cortex (BA44). The tumor is C-shaped, straddles the pre-central sulcus (arrowhead). Note that Broca’s area (BA 45) and the motor strip are spared (BA4; arrows). The smooth deep border is attributed to the underlying arcuate fasciculus (blue) and corticobulbar tract (yellow)
Intracranial Arterial Vascular Wall Imaging Using Volumetric Cube T1 MRI sequence at 3 Tesla - Initial Experience

A Mello¹, G Simão¹, R Althoff¹, E Figueiredo²
¹CEDIRP Ribeirão Preto, Ribeirão Preto, Brazil, ²GE Healthcare Sao Paulo, Sao Paulo, Brazil

Purpose
Analyze the utility of volumetric sequence Cube T1, in a 3 T unit, for the characterization of intracranial arterial wall and their different pathologies.

Materials and Methods
We retrospectively analyzed brain of 741 patients who underwent magnetic resonance angiography (MRA) with TOF (time of flight) technique and volumetric Cube T1 in unit 3 T, in our department from June 2012 to December 2013, with different indications such as headache, suspected stroke/TIA, suspected dissection, for evaluation of atherosclerotic disease, dizziness, amnesia and suspected. Examinations performed on the equipment Discovery MR750 (GE Healthcare, WI, USA) using the CUBE T1 sequence, volumetric acquisition with contrast T1 - FSE modified to use higher echo train length (ETL), reducing time, without prejudice to final image. Geometry parameters adjusted to obtain isometric voxels of approximately 0.4mm with interpolation in order to maintain resolution when reformatted, the parameters adjusted for contrast T1-weighted and reduced sensitivity to flow (black blood). The acquired images were subsequently reformatted for better visualization of the vessel of interest, using minMIP (minimum intensity projection).

Results
From the 741 patients studied at MRA 542 (73%) were normal, 95 (13%) had mild arterial wall contour irregularity, 11 (1%) absence of flow, suggestive of thrombosis, one with moyamoya vascularization pattern and two arteriovenous malformation. Four patients (1%) had a concentric wall thickening, two with enhancement, suggestive of vasculitis. T1 hyperintense signal in the vascular wall probably due to dissection/parietal hemorrhage was observed in nine patients (35%). Eccentric wall thickening, with eccentric narrow, probably related to atherosclerotic disease was observed in nine patients (45%). Patients who had aneurysm as main finding were not considered in the analysis. All patients with findings suggestive of arterial dissection, atheroma plaques determining eccentric stenosis and concentric pattern of stenosis showed abnormalities in the sequence T1 Cube.

Conclusions
There was good correlation between the imaging findings of the volumetric T1 Cube and the TOF MRA alterations. The volumetric T1 "black blood" was an efficient method for evaluation of the vascular wall, showing the advantages of high spatial resolution, acquisition of the entire brain volume, without requiring the intervention of the radiologist during the examination, and the possibility of multiplanar reconstruction. Adding this sequence to our protocol has improved the diagnosis, providing greater confidence to demonstrate different pathologies. Larger studies are needed to define the impact of the use of this sequence in the diagnosis and management of patients with cerebrovascular diseases.
Is Diffusion-weighted Imaging at 3T Useful for Evaluating Nodular Disseminated Lesions in Malignant Gliomas?

T Hirai¹, H Uetani¹, K Iwashita¹, H Nakamura¹, S Nishimura¹, Y Yamashita¹
¹Kumamoto University, Kumamoto, Japan

Purpose

The purpose of this study was to evaluate whether diffusion-weighted imaging (DWI) at 3T is useful for the detection of nodular disseminated lesions in malignant gliomas.

Materials and Methods

We included consecutive 12 patients (8 men, 4 women; age range, 11 - 80 years old; mean age, 47 years) with nodular disseminated lesions of malignant gliomas that were confirmed by surgery or follow-up MR imaging. All underwent conventional MR imaging, DWI at b = 1000 and 3000 s/mm², post-contrast T1-weighted and 3D gradient-echo imaging on 3T MRI units. The main lesion per person was qualitatively and quantitatively assessed. Two radiologists independently evaluated the presence of additional information on DWI at b = 1000 or 3000 s/mm² compared with postcontrast T1-weighted and 3D gradient-echo images using a 4-point scoring system. Interobserver agreement was assessed by k statistics. On DW images, one radiologist performed region-of-interest measurements of the signal intensity (SI) of nodular disseminated lesions and the adjacent brain. The lesion-to-brain contrast ratio (LBCR) was calculated.

Results

Radiologists 1 and 2, respectively, assigned as DWI providing more additional information compared with postcontrast study (grade 3 and 4) in 3 (25%) and 2 (17%) DWI at b = 1000 s/mm² studies and 4 (33%) and 5 (42%) DWI at b = 3000 s/mm² studies. Interobserver agreement for DWI at b=1000 s/mm² and b=3000 s/mm² was very good (κ = 0.85; 95% CI, 0.63-1.00) and excellent (κ = 0.93; 95% CI, 0.78-1.00), respectively. The mean LBCR score was higher for DWI at b=3000 s/mm² than DWI at b=1000 s/mm², although there was no significant difference in the mean LBCR between the 2 types of DWI.

Conclusions

DWI at 3T can provide useful information for the detection of nodular disseminated lesions in malignant gliomas. In certain cases, 3T DWI at b = 3000 s/mm² might provide more additional information than b = 1000 s/mm².

KEYWORDS: Diffusion-Weighted Imaging
Is reperfusion mandatory for hemorrhagic transformation occurrence after rtPA treatment in patients with acute ischemic stroke?

A Horsch¹, J Dankbaar¹, Y Van der Graaf², W Mali¹, B Velthuis¹
Purpose
Recombinant tissue Plasminogen Activator (rtPA) is given in acute ischemic stroke patients to achieve recanalization and reperfusion. Hemorrhagic transformation (HT) is a serious complication of treatment with rtPA and even milder grades are known to effect outcome. HT is related to increased permeability after blood-brain barrier (BBB) injury. It is not clear whether this occurs (1) secondary to reperfusion in combination with ischemic BBB injury or (2) as a direct consequence of the disruptive effect of rtPA on the BBB. The aim of this study was to establish whether reperfusion is mandatory for the occurrence of HT.

Materials and Methods
From the Dutch acute Stroke Trial (DUST) patients were selected with (1) an ischemic deficit in the middle cerebral artery territory and (2) admission and follow up non-contrast CT (NCCT) and CT perfusion (CTP). Reperfusion status was divided in 2 groups: a (1) no-reperfusion group and a (2) complete- or partial-reperfusion group. Occurrence of any HT was assessed on follow up NCCT. HT rates between groups were compared with Fischer's exact test.

Results
Inclusion criteria were met in 191 patients of which 130 (68%) were treated with rtPA. Absolute risks of HT for patients treated with rtPA were not significantly different between no-reperfusion and complete- or partial-reperfusion groups (18% versus 15%, P=0.726). In the group without rtPA treatment there was a non-significant trend of higher HT rates in the no-reperfusion group (15% versus 4%, P=0.196).

Conclusions
Our results suggest that the increased risk of HT in acute ischemic stroke treatment is related to the direct effects of rtPA on the BBB and not to reperfusion status. Funded by the Netherlands Heart Association: Project number 2012T061

Lateralization of Temporal Lobe Epilepsy by T2-weighted FSTIR and Echo Spacing Optimized FSE T2 at 3T

S Sarkar\textsuperscript{1}, D Schomer\textsuperscript{2}, D Teich\textsuperscript{2}, R Bhadelia\textsuperscript{3}, S Herman\textsuperscript{2}, T Luu\textsuperscript{3}, M Plum\textsuperscript{3}, D Hackney\textsuperscript{3}  
\textsuperscript{1}Beth Israel Deaconess Medical Center, Harvard medical School, Boston, MA, \textsuperscript{2}Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, \textsuperscript{3}Beth Israel Deaconess Medical Center, Boston, MA

Purpose

Hippocampal substructures that have convoluted mixtures of GM/WM are often involved in temporal lobe epilepsy (TLE) although direct detection of abnormal sub-layers is challenging at 1.5 or 3T. FSE T2w sequences are preferred due to their high signal and tissue contrast imaging ability although with mixed success for hippocampus. We have noted that Fast Spin Echo based inversion recovery sequences (FSTIR and DIR) are sensitive to differentiate between cortical GM and myelin-rich WM due to the T1-weighting inherently built within those sequences (Ref 1). We hypothesize that excess or depletion of GM within the hippocampal subfields may be detectable by adding T2 weighting to FSTIR or by adjusting the echo spacing (ES) for varying T2 weighting in FSE T2 sequence for patients with well characterized temporal lobe epilepsy.

Materials and Methods

Using an IRB-approved criteria we studied 21 patients with chronic temporal lobe epilepsy divided into two subgroups without classifying them per frequency or severity of epileptic events: 13 patients with suspected focal epilepsy (test group) lateralized by clinical assessments and EEGs and 8 patients with no clear lateralization (generalized seizure or controls). None of the patients had any craniotomy, lobectomy or mass lesions. All imaging was done in a 3T GE imager at high resolution (0.6x0.6x2.4 mm3 voxels) in coronal plane orthogonal to hippocampal long axis. For ES based optimization of optimal T2 weighting, six patients (3 with lateralized and 3 with generalized seizures) were imaged with short (8 ms) and long ES (17 ms) at an effective TE of 105 ms. Based on greater cortical GM/WM contrast observed at short ES, the remaining 13 patients were scanned by the short ES T2 sequence as well as by an FSTIR sequence (equivalent to the FSE T2 except for the inversion preparation with 50 ms inversion delay). In addition to radiologic assessment to detect possible seizure foci, the local SNR from bilateral hippocampus were estimated using elliptical ROI (Figure below) placed within the hilar region of dentate gyrus (DG:H) and noise ROI in the mastoid air space. The % SNR asymmetry,

computed by \( \frac{\text{SNR(Rt DG)} - \text{SNR(Lt DG)}}{\text{Mean SNR}} \), was compared for both the sequences and were plotted below.

**Results**

The generalized epilepsy cases showed a mean R>L SNR asymmetry of 5% per FSTIR and 3.8% per FSE T2 (baseline or control, plotted as mottled bars below). The figure below shows ROI locations (left) and the mean % SNR asymmetry for lateralized and generalized epilepsy patients (right) for T2w FSTIR (solid and mottled blue bars) and FSE T2 (solid and mottled pink bars). Eleven patients (test group) lateralized by EEG and clinical assessments were also lateralized with 9.5% SNR asymmetry per FSTIR (solid blue bar) and 5.4% per FSE T2 (solid pink bar). Two patients however showed contralateral correlation with EEG (mismatched laterality) although statistically significant ipsilateral match was observed for the test group over and above the baseline patterns from controls (Wilcoxon Signed Rank Test, P<0.05) for both the sequences.

**Conclusions**

In TLE patient group the affected dentate gyrus has lower SNR compared to the unaffected side in both the sequences. This indicates possible depletion of GM from the dentate gyrus on the affected side and is detectable significantly better by FSTIR since it produced almost twice the SNR asymmetry between the right and left dentate gyri compared to FSE T2 even though short echo spacing helped increase the tissue contrast and SNR asymmetry for FSE T2. Our results indicate that both T2 weighted FSTIR and FSE sequences correlate well in 11/13 cases with EEG and clinical lateralizations and thus can differentiate between lateralized and generalized epilepsy with a high degree of specificity. However, this approach needs to be validated on a larger patient pool and the duration and severity of illness need to be tested for correlation with our approach.

Measurement of Blood Brain Barrier Permeability: Comparison of Delayed Phase Versus First Pass Using a Distributed Parameters Model.

A Vagal¹, A Dunning², D Mir², P Sanelli²
¹University Hospital/University Cincinnati College Of Medicine, Cincinnati, OH, ²Weill Cornell Medical College, New York, NY

Purpose
Prior studies have compared the first pass versus delayed phase for blood-brain barrier permeability measurements using single compartment Patlak model for CT perfusion (CTP). However, similar comparisons for other alternative, non-Patlak permeability models have not been performed. Our primary objective was to compare first pass against delayed acquisition CTP using a distributed parameters permeability model. The secondary objective was to predict delayed phase permeability estimates using first pass data.

Materials and Methods
A retrospective study of patients imaged with a delayed acquisition CTP study was performed using an IRB approved database. Commercially available software (Oleasphere 2.2) was used to generate permeability maps. A distributed parameters model using adiabatic approximation, the Lawrence and Lee model (LL) was utilized. Permeability was measured in first pass (0–60 s after contrast administration) and delayed phase (0-180 s). The parameters included Kep (kinetic constant), Ktrans (volume transfer constant), Perm (permeability), Ve (extravascular extracellular space volume) and Vp (plasmatic volume), F (blood flow), E (extraction constant) and PS (permeability surface area product). Multilevel mixed model was conducted to test the paired differences in first pass and delayed phase CTP. Data were randomly split into development and validation dataset. Multilevel mixed linear model was applied to development dataset using first pass to predict delayed phase parameters. Regression equation from development data was applied to validation dataset and multilevel mixed model was used to test differences in observed and predicted delayed phase parameters.

Results
The study group included 44 patients with a total of 8600 observations. The mean difference between delayed phase and first pass was significant for Kep, Ktrans, Perm, Ve, Vp, F and PS quantitative measurements (p<0.05). There was no statistical significant difference between delayed phase and first pass for E (extraction constant) (p>0.05). Except for the Kep, the mean value of predicted permeability measurements did not differ significantly from the measured/observed value in both the development and validation groups (p>0.05) (Table). The predictive model allowed prediction of majority of delayed phase permeability measurements using the measured first pass data.

Conclusions
Although the use of the delayed versus first pass acquisition can lead to differences in permeability values when using a LL model, majority of the delayed phase permeability parameters can be estimated using the first pass data. This predictive method has important implications with the potential to reduce radiation dose, examination time and motion artifacts related to a longer CTP acquisition. Further studies are warranted in this direction.

Measurement of Blood Brain Barrier Permeability: Comparison of Delayed Phase Versus First Pass Using a Two-Compartment Model

A Vagal¹, A Dunning², D Mir², P Sanelli²

¹University Hospital/University Cincinnati College Of Medicine, Cincinnati, OH, ²Weill Cornell Medical College, New York, NY

Purpose
Prior studies have compared the first pass versus delayed phase for blood-brain barrier permeability measurements using single compartment Patlak model for CT perfusion (CTP). However, similar comparisons for other alternative, non-Patlak permeability models have not been performed. Our primary objective was to compare first pass against delayed acquisition CTP using a two compartment permeability model. The secondary objective was to predict delayed phase permeability estimates using first pass data.

Materials and Methods
A retrospective study of patients imaged with a delayed acquisition CTP study was performed using an IRB approved database. Commercially available software (Oleasphere 2.2) was used to generate permeability maps. A two compartmental Kety Tofts model (KT) was utilized to measure permeability in first pass (0–60 s after contrast administration) and full phase (0-180 s). The parameters measured included Kep (kinetic constant), Ktrans (volume transfer constant), Perm (permeability), Ve (extravascular extracellular space volume) and Vp (plasmatic volume). Multilevel mixed model was conducted to test the paired differences in first pass and delayed phase CTP. Data were randomly split into development and validation dataset. Multilevel mixed linear model was applied to development dataset using first pass to predict delayed phase parameters. Regression equation from development data was applied to validation dataset and multilevel mixed model was used to test differences in observed and predicted delayed phase parameters.

Results
The study group included 44 patients with a total of 8600 observations. The mean difference between the full phase and first pass data was significant for Kep, Ktrans and Ve quantitative
measurements (p<0.05). There was no statistical significant difference between the full phase and first pass for Perm and Vp measurements (p>0.05). The mean value of predicted permeability measurements did not differ significantly from the measured/observed value in both the experimental and validation groups (p>0.05) (Table). The predictive model allowed prediction of full phase permeability measurements using the measured first pass data.

Conclusions
Although the use of the full phase versus first pass acquisition can lead to differences in the Ktrans values when using a KT model, the full delayed phase permeability can be estimated using the first pass data. This predictive method has important implications with the potential to reduce radiation dose, examination time and motion artifacts related to a longer CTP acquisition. Further studies are warranted in this direction.

Mechanical thrombectomy in patients with acute vertebrobasilar occlusion using the Trevo device: a single-centre experience

D Lobsien¹, D Fritzsch², C Hobohm², U Quaesching², K Hoffmann², M Gawlitza²
¹University Hospital Leipzig, Leipzig, Germany, ²University Leipzig, Leipzig, Saxony

Purpose
To investigate the efficacy and safety of mechanical thrombectomy in patients with acute vertebrobasilar artery occlusion (VBAO) using the Trevo Stentriever device.

Materials and Methods
Stent-retriever thrombectomy using the Trevo device was performed in 16 patients with proven VBAO within the first 24 hours after symptom onset. Recanalization rates were assessed and device-related complication rates as well as patient outcome and mortality rates were recorded.

Results
Mean patient age was 70.4 years (± 13.8; range 36 – 85). Mean time from symptom onset until
the beginning of the DSA was 300.2 minutes (± 165.8 minutes; range 82 – 725). VBAO was situated at the basilar artery foot (18.8%), in the middle segment (31.3%), at the basilar apex (43.8%) and in the proximal PCA (6.3%). Six patients received IV rt-PA prior to DSA. The Trevo was used either as the sole device (56.3%) or in conjunction with additional devices or techniques (up to four in one patient). 33 clot retrieval maneuvers were performed (mean 2.1 ± 1.3, range 1 - 5); the device could be deployed and retrieved in all maneuvers (100%). No device-related complications occurred during the intervention. Mean duration of the endovascular intervention was 71.8 (± 39.9; range 22 - 144) minutes. Successful recanalization (TICI ≥ 2b) was achieved in 13 patients (81.3%), eight (50%) of them with TICI 3, five (31.3%) with TICI 2b. In three patients (18.8%) only incomplete reperfusion was achieved. All patients showed an improvement of at least one point in the TICI scale – two patients (12.5%) improved by one, five patients (31.3%) by two, three patients by three (18.8%) and six patients (37.5%) by four points. Eleven patients (68.8%) survived and three patients (18.8%) showed a good clinical outcome at discharge (mRS 0-2).

Conclusions

The present study shows that thrombectomy in patients with acute VBAO using the Trevo Stentriever™ – either as the sole device or in conjunction with other devices - is feasible and that it is as effective and as safe as its application in the anterior circulation. Furthermore, the Trevo device seems to be similarly suitable for the treatment of VBAO as other stent-retriever systems.

Medial Temporal lobe Atrophy is underreported and predicts mortality in medical inpatients

D van Westen¹, G Torisson², L Minthon², L Stavenow², E Londos²
¹Skane University Hospital Lund, Lund, Sweden, ²Skane University Hospital Malmö, Malmö, Sweden

Purpose

Medial temporal lobe atrophy (MTA), a morphological hallmark of Alzheimer disease (AD), also is encountered in normal aging, cerebrovascular disease and neurodegenerative disorders other than AD (1). MTA is assessed easily and reliably from computed tomography (CT) using a visual rating scale that has shown very good agreement with manual volumetric measurement and is related to memory function in AD (2, 3). However, when imaging is performed outside the work up of dementia, MTA may be under-reported, for example when cognitive decline may not yet have been recognized, or when imaging is performed in the acute setting with the aim to rule out obvious pathology such as stroke or hemorrhage. We previously have demonstrated that cognitive decline is frequent and frequently unrecognized in medical inpatients (4). Here, we reassess cranial computed tomography (CT) from these patients for MTA, compare results with cognitive tests and determine the importance of MTA for survival.

Materials and Methods

Medical records from 200 consecutive medical inpatients aged over 60 years who had been
subjected to cognitive tests in our previous intervention study (4, 5), were reviewed for cranial CT performed within a year from cognitive testing. Coronal slices were re-assessed for MTA according to Scheltens visual rating scale (0-4) with abnormal score being >1 under and >2 over the age of 75, respectively. Findings were compared with the original radiological reports and cognitive tests, and survival analysis was performed.

Results
CT had been performed in 94 of 200 (47%) patients. The interval between scan and cognitive testing was 12 days (median, interquartile range 1-132 days). The referral for CT was issued by the emergency department or a hospital ward in 87 patients, by outpatient clinics at the hospital in five patients and by general practitioners in two patients. Symptoms of or simply cognitive impairment were mentioned in 35/94 (37%) of referrals. In 34/94 (36%) MTA was abnormal. None of the patients with abnormal MTA was reported as such originally (Table 1, Figure 1). Patients with abnormal MTA had lower results on cognitive tests. Abnormal MTA independently predicted mortality, with a HR (95%CI) of 2.43(1.39-4.27) in a multivariable model.

Conclusions
Medial temporal lobe atrophy in routine cranial CT performed on medical inpatients over 60 years is under-reported and holds important clinical correlates with prognostic value. Our results suggest that reporting MTA in this population should be part of the routine radiological work up.

Metal Artifact Reduction using C-Arm Cone-Beam CT: A quantitative assessment and evaluation of artifacts after endovascular treatment of cerebral aneurysms

C Cay¹, M Wells¹, J Siewerdsen¹, A Wang¹, T Ehtiati², F Gundlack², C Rohkohl³, B Scholz⁴, M Radvany⁵
Purpose
To evaluate the performance of a metal artifact reduction (MAR) algorithm using C-arm cone-beam CT after endovascular treatment of cerebral aneurysms and examine post-processing artifacts.

Materials and Methods
Studies were conducted using a C-arm (Artis Zeego; Siemens AG) for 3D imaging and a novel MAR algorithm under development. A head phantom incorporating a natural skull in tissue-equivalent plastic and brain-equivalent gelatin was used with plastics representing hemorrhage, vessels, and CSF and metal spheres (steel, titanium, and tungsten with 3.2, 6.4, and 12.8 mm diameter) successively introduced to simulate coiled aneurysms. 3D images were reconstructed with and without MAR, and artifact magnitude was quantified in terms of the voxel value standard deviation in a region adjacent to the metal sphere. A 3D vascular model with a 9 mm aneurysm was also introduced into the phantom and treated with stent assisted coiling. 3D reconstructions were performed and artifact magnitude quantified. The MAR algorithm was then applied to clinical images along with a modified segmentation algorithm and the clinical images evaluated.

Results
The MAR algorithm demonstrated significant reduction in artifact allowing visualization of the metal component and surrounding structures. Artifact magnitude without and with MAR was, respectively: 440 vs 48 HU (3.2 mm tungsten); 472 vs 45 HU (6.4 mm tungsten); 568 vs 43 HU (12.8 mm tungsten). For the 9 mm simulated aneurysm, the MAR reduced artifact magnitude from 360 to 37 HU. Evaluation of the clinical images demonstrated reduced artifact with improved visualization of structures adjacent to the treated aneurysms.

Conclusions
The MAR algorithm provided excellent reduction of artifact magnitude even with large, complex metal components. Ongoing work includes implementing a semi-automatic segmentation algorithm, analysis of tolerance to MAR parameters, and clinical evaluation.

Objective Physiologic Based CSF Flow Assessment in Chiari I Malformation

N Madan1, Y Zhao2, C Heilman1, S Patz3, R Bhadelia4
1Tufts Medical Center, Boston, MA, 2Philips Healthcare, Cleveland, OH, 3Brigham and Women's Hospital, Boston, MA, 4Beth Israel Deaconess Medical Center, Boston, MA

Purpose
While invasive methods have demonstrated altered CSF flow in Chiari patients, with a physiologic challenge such as cough or Valsalva maneuver [1], assessment with MRI has previously not been possible due to the long acquisition time of CSF flow imaging techniques. Such an assessment would be helpful in non-invasively differentiating Chiari I patients who may benefit from surgery. The purpose of this study was to evaluate CSF flow changes in response to a cough maneuver in both normal subjects and patients with Chiari I malformation, using a real-time pencil beam technique with high temporal resolution.

Materials and Methods
A real time pencil beam flow imaging technique (temporal resolution of ~60 msec) was developed. Using this technique, 4 normal subjects and 6 patients with Chiari malformation were evaluated, to assess CSF flow just below the foramen magnum at rest, as well as after a short series of coughs. CSF mean displacement volume (V_CSF) during the cardiac cycle and CSF flow waveform peak to peak amplitude (A_pp) were determined. A t-test was used to compare each parameter at rest and immediately after the cough maneuver in both subject groups.

Results
Both qualitative and quantitative waveform analysis of CSF flow versus time (Figure 1) demonstrated a significant decrease in both V_CSF and A_pp immediately after the cough maneuver (red arrow) in all 6 patients with Chiari I malformation, with no significant decrease seen in any of the normal controls. Quantitative analysis revealed that in normal subjects, there was no significant change in either V_CSF (p = 0.11) between rest (0.66 ± 0.32 mL) and immediately post-cough (0.68 ± 0.40 mL) or A_pp (p = 0.34) at rest (5.49 ± 1.78 mL/s) versus immediately after cough (5.76 ± 1.84 mL/s). However, in patients with a Chiari I malformation, a significant decrease was observed in both V_CSF (p=0.020) at rest (0.44 ± 0.26 mL) versus post-cough (0.22 ± 0.17 mL) as well as in the A_pp (p=0.016) at rest (3.91 ± 2.47 mL/s) versus post-cough (1.90 ± 0.82 mL/s).

Conclusions
Significant decrease in both CSF flow displacement and waveform amplitudes in Chiari I patients indicate CSF flow obstruction at the foramen magnum in response to coughing. This is in keeping with previously published invasive reports [1]. PBI shows promise for identifying and quantifying an altered response to a physiological challenge, and may allow improved identification of patients who would benefit from surgery.

Pathophysiologic Mechanism Underlying MRI Findings of Urea Cycle Disorders: Comparison of Conventional MRI with Diffusion Weighted Imaging

H Tore¹, M Clark², D Nascene¹, A McKinney³
Purpose
Urea cycle disorders (UCD's) are rarely encountered inborn errors of metabolism, and can be well visualized on DWI and FLAIR MRI, presumably due to hyperammonemia (1). Here we present conventional MRI findings of four of the five forms of the UCD's in a single series with their corresponding diffusion weighted imaging findings.

Materials and Methods
This retrospective study included 9 patients (6 males 3 females, ages 1 days - 39 years). We evaluated corresponding axial FLAIR, DWI, susceptibility weighted imaging, and post-contrast T1 weighted imaging (T1WI) for brain involvement. We also recorded serum ammonia levels at the time of presentation and within one week of the imaging studies.

Results
The study cohort included 4 Ornithine transcarbamolase deficiencies (OTCD), 3 Argininosuccinic aciduria (ASA), 1 Carbomoylphosphate synthetase deficiency (CPSD), and 1 Citrullinemia type 1 (CT1). In all 4 patients with OTCD, FLAIR and DWI revealed similar areas of involvement, including diffuse gray-white matter junction in frontal and parietal lobes. However, in one of them with adult-onset OTCD, FLAIR images demonstrated abnormalities of the basal ganglia and cerebellum in addition to the insulae and fronto-parieto-temporal cortices, but without clearly reduced diffusion; this patient had an ammonia level of 485 umol/L at presentation, which was 87 umol/L at the time of MRI. Similarly, in a patient with ASA, FLAIR images demonstrated involvement of basal ganglia in all 3 patients, while DWI was negative; there was brainstem involvement in 2 patients, frontoparietal cortex in 1 patient, and thalami in 1 patient. Additionally, in the one patient with CPSD, there was thalamic and basal ganglia involvement on FLAIR, without reduced diffusion. Finally, in the single patient with citrullinemia, both FLAIR and DWI revealed involvement of the insulae, globi pallidi, and centrum semiovale; DWI also revealed involvement of the cerebral peduncles, which was not visible on FLAIR images.

Conclusions
While this may be the largest combined series of UCD's evaluated by MR imaging, the findings are similar to previous reports, which include involvement of the perirolandic regions and insulae in a majority of patients (2). The pathophysiologic mechanism of involvement is thought related to accumulation of intracellular glutamine, and in turn astrocyte swelling, brain edema and cerebral hypoperfusion (2). Regarding the initial insult, the lack of reduced diffusion in the regions that were clearly abnormal on FLAIR images may be explained by high serum ammonia levels that later normalize with subsequent pseudonormalization on imaging with DWI and FLAIR.

Perfusion-CT Enhanced CTA: an Original Method to Assess Collaterals

E Tong¹, M Wintermark¹

¹University of Virginia, Charlottesville, VA
Purpose
Propose a noninvasive technique that allows objective and reliable quantitative assessment of collateral circulation in healthy and ischemic tissue.

Materials and Methods
Anatomical information embedded in CTA is combined with the temporal information in PCT to construct a virtual sequential CTA. Patients with anterior-circulation occlusion stroke are identified retrospectively. Extent and temporal profile of collateral circulation is evaluated in the stroke patients. The temporal profile is calculated and graded as 'instant', 'early' and 'delayed'. The extent is measured and graded as 'good', 'moderate' and 'poor'. Comparison is made with the contralateral hemisphere and healthy subjects.

Results
There is variability in the extent and promptness of collaterals in both healthy subjects and stroke patients. The variation in the time-of-arrival of collaterals is higher in stroke patients than healthy subjects. The extent of collaterals correlates inversely with the area of ischemic tissue.

Conclusions
Presence of robust collaterals has been associated with better clinical outcome, smaller final infarct size and better recanalization results. Therefore evaluation of collaterals is important in stroke management. Our new imaging tool provides objective analysis in a reproducible manner, thus reducing the interobserver variability that many common collateral scores suffer.

Phosphorus Nuclear Magnetic Spectroscopy in Multiple Sclerosis

P Brugieres¹, A MARAVAL¹, A GASTON², A CREANGE¹
¹HENRI MONDOR, CRETEIL, France, ²HENRI MONDOR, CRETEIL, IDF

Purpose
To define the Phosphorus Nuclear Magnetic Resonance (NMR) spectroscopy profiles of multiple sclerosis (MS) patients according to disease severity

Materials and Methods
18 patients with MS (n=9 relapsing-remitting (RR-MS) patients with EDSS<6 and n=9 secondary progressive (SP-MS) patients with EDSS >6) and 10 controls were investigated by monovoxel 31-P MRS on a 3T imager with the following parameters:TR=450 ms, BW=3000 Hz, 128 acquisitions. The following metabolites were analyzed: Phosphocreatine (PCr), total Phosphoate (Pt), inorganic phosphate (Pi), glycerol-3-phosphoryl choline (GPC), glycerol-3-phosphoryl ethanolamine (GPE), Phospho-ethanolamine (PE), phospho-monoester compounds (PME), phosphodiester compounds, and the 3 peaks of ATP. the following ratios were calculated: PCr/Pt, Pi/Pt, alpha-ATP/Pt, beta-ATP/Pt, gamma-ATP/Pt, GPC/Pt, GPE/Pt, PME/PDE. Intra-cellular pH was also calculated.

Results
Compared with controls, patients had higher PCr/Pt (0.261 vs. 0.241, p=0.02) and PME/PDE (1.003 vs. 0.860, p=0.05) and lower GPC/Pt (0.084 vs. 0.100, p=0.01) ratios. Compared to controls, patients with EDSS<6 had lower Pi/PCr (0.230 vs. 0.279, p=0.01) and Pi/Pt (0.060 vs.
Compared to patients with an EDSS<6, those with EDSS>6 have elevated Pi/Pt ratio (0.068 vs 0.060, p=0.03) and PE/Pt (0.107 vs. 0.091, p=0.05) and decreased ratio beta;ATP/Pt (0.050 vs. 0.066, p=0.05).

Conclusions
Saltatory transmission of myelinated fibers required less energy than the continuous transmission of demyelinated fibers. Patients with RR-MS and an EDSS <6 have an increase of high energy phosphorus that could offset the increased energy demand associated with demyelination. This is no longer the case in the more severe forms (SP-MS with EDSS > 6) in which is observed a fall of beta-ATP. Phosphorus NMR spectroscopy is a tool for assessing encephalic energy capacities of patients with multiple sclerosis and differentiates low and high EDSS.

KEYWORDS: MR Spectroscopy, Multiple Sclerosis, Phosphorus Spectroscopy
Primary Intraosseous Venous Malformations of the Skull Base: Case Series and Review of the Literature

S Saipriya\textsuperscript{1}, R Siripurapu\textsuperscript{2}, C Hilditch\textsuperscript{1}, S Lloyd\textsuperscript{3}, S Freeman\textsuperscript{3}, C Ward\textsuperscript{1}, S Rutherford\textsuperscript{3}, A King\textsuperscript{1}, G Potter\textsuperscript{2}
Purpose
Primary intraosseous venous malformations (PIVM), previously known as intraosseous hemangiomas, are uncommon, benign skeletal vascular malformations, consisting of sinusoidal spaces with an endothelial lining. Normally found in the vertebral column, PIVM are relatively uncommon in the craniofacial skeleton, and are found only rarely in the skull base. Skull base PIVM may be assessed using a combination of CT and MRI. We present clinical and imaging findings in five patients with skull base PIVM and a review of the literature, including pathological features and management of PIVM.

Materials and Methods
We retrospectively reviewed demographics, clinical notes, CT and MRI findings in five patients with skull base PIVM presenting to a tertiary neurosciences and skull base institution.

Results
Three patients were female and two male, with an age range of 32 to 94 years. Four patients underwent both CT and MR imaging, and one patient had CT alone. The sphenoid bone was involved in three cases (Figure 1), with involvement of the clivus in one patient and the occipital bone, extending to the mastoid bone, in another. All lesions were incidental findings with radiologically benign appearances. Progressive filling between early and delayed postcontrast MR imaging was demonstrated in two cases. No cases had relevant associated findings, and all cases were asymptomatic, without compression of adjacent structures. In all cases, further follow-up imaging and clinical review were deemed unnecessary.

Conclusions
Skull base PIVM are rare, benign lesions, which may be found incidentally on cross-sectional imaging, with CT and MRI providing complementary diagnostic information. Lesions producing symptoms due to compression of local structures may be treated with surgery or radiotherapy. In our patients, all lesions were asymptomatic with benign appearances requiring no further clinical or imaging follow up.

Quantitative Flow Differences Between Multiple Sclerosis and Healthy Control Subjects

E Haacke¹, A Daugherty¹, W Feng¹, J Hewett², N Raz³, S Sethi⁴, D Utriainen⁴

¹Wayne State University, Detroit, MI, ²Synergy Health, Newport Beach, CA, ³Institute of Gerontology and Department of Psychology, Detroit, MI, ⁴Magnetic Resonance Innovations, Inc., Detroit, MI

Purpose
Previous research has reported reduced outflow through the internal jugular veins (IJV) in the Multiple Sclerosis (MS) population with large variability in the function of stenotic (ST) versus non-stenotic (NST) IJVs (1). The goal of this work is to provide a retrospective, statistical analysis on a group of healthy control (HC), ST-MS, and NST-MS subjects imaged using MRI to determine the optimum flow thresholds which differentiate HC from MS.

Materials and Methods
A group of 138 MS and 67 HC subjects were imaged on 3T Siemens scanners between two sites. Both 2D TOF MRV and 3D time resolved CE MRAV were used to determine if IJV stenosis was present, subdividing the MS group into ST-MS and NST-MS. The 2D PC was used to quantify flow through the major arteries and IJVs at both C2 and C6 levels. The ratio between the larger IJV flow (dJ) versus the smaller IJV flow (sdJ) was calculated as sdJ/dJ. IJV flow was then normalized to the total arterial flow (tA), providing two major criteria for both levels, the tIJV/tA, where tIJV is the sum of both IJV flows, and sdJ/tA. MANOVA and ROC curve analysis were done. Significance was determined at p=0.05.
Results
In the MS sample, 66 (48%) were NST-MS and 72 (52%) were ST-MS. Figure 1 shows the normalized flow measurements at both levels for right and left IJVs. The ST-MS demonstrated lower normalized flow (MANOVA, p<0.001) compared to HC for all calculations and optimum thresholds were determined to be: 0.62 for C6tIJV/tA, 0.66 for C2tIJV/tA, 0.16 for C6sdJ/tA, 0.10 for C2sdJ/tA, 0.31 for C6sdJ/dJ, and 0.14 for C2sdJ/dJ. The subjects that meet both: tIJV/tA criteria are 9% HC, 11% NST, and 61% of ST; sdJ/tA criteria are 13% HC, 6% NST-MS, and 60% ST-MS; and sdJ/dJ criteria are 13% HC, 7% NST, and 44% ST. Sensitivity ranged from 0.70 to 0.85 and specificity ranged from 0.57 to 0.81 with AUC being significant for all measurements (p<0.001).

Conclusions
The current sample of MS patients and HC indicates that there is a statistically significant difference in venous outflow through the IJV between the groups. These criteria may provide the means of assessing vascular abnormalities in MS subjects quickly using MRI.

Rapid imaging protocol before reperfusion therapy in Acute Stroke by Area Detector CT

T Mori¹, T Iwata¹, Y Miyazaki¹, Y Tanno¹, S Kasakura¹, Y Aoyagi¹
¹Shonan Kamakura General Hospital Stroke Center, Kamakura, Japan

Purpose
The wide area detector CT (ADCT) enables volume scanning (VS) for the whole brain within one rotation and can provide whole brain CT perfusion (CTP) and dynamic vascular analysis (3D/4D-CTA) in one examination with small volume of contrast medium. It is beneficial for ischemic stroke patients, because further contrast medium is required if endovascular reperfusion therapy is attempted. However, image reconstruction and transfer are too time-consuming in acute stroke setting, because of much volumetric data (VD). The aim of this study was to design the acute stroke protocol of ADCT scanning with short time of image reconstruction and transfer within acceptable limits of quality loss.

Materials and Methods
VS using the ADCT (Aquilion ONE, Toshiba) for CTA and CTP of the whole brain was performed with injecting non-ionic contrast medium 40ml (iopamidol 370,Fuji PHARMACEUTICAL) at a rate of 4mL/s. CTP used 1 s single rotation intermittent dataset scans acquired at 80kVp. Beginning 8 s after contrast medium injection, 18 intermittent volume scans at 100mA are acquired every other second for 34 s during the contrast medium arrival. Ten datasets were then acquired every 5 s for 45 s to complete a 28 volume dataset. Each volume consisted of 160 images of 1-mm thickness with z-axis coverage of 16-cm. After transferring VD to a workstation (Ziostation 2, AMIN/ZIO), CTA and CTP maps were generated with a macro-palette in 3 patients by 7 radiological technicians. Examination time and image quality were evaluated.

Results
VD was transferred to workstation in about 12 minutes 28 seconds since starting VS and both CTP and CTA was generated in mean 2 minutes 11 seconds. Total time until viewing images on PACS was about 14 minutes 39 seconds. Image quality of CTA and CTP maps was enough in acute stroke setting. Compared to initial protocol of a 0.5-mm thickness with z-axis, total operation time became about a half, because VD became a half.

Conclusions
Our protocol can provide the whole brain CTA and CTP images of ADCT with only 40ml contrast medium within 15 minutes in acute stroke setting.

KEYWORDS: CT Angiogram, Volumetric Analysis, Volumetric Perfusion CT
Purpose
Computed tomographic angiography (CTA) is commonly used for the noninvasive detection of cerebrovascular lesions responsible for subarachnoid hemorrhage, but rebleeding may occur during this procedure. We investigated imaging findings and related factors in patients who experienced rebleeding during CTA in our hospital.

Materials and Methods
Participants comprised 112 patients who underwent CTA for ruptured cerebral aneurysm in our hospital between January 2009 and December 2012. Computed tomographic angiography was performed using a 64-row detector system.

Results
Rebleeding occurred during CTA in 5 of 112 patients, representing a rebleeding rate of 4.5%. Mean time from initial onset of hemorrhage to CTA was shorter in patients with rebleeding (median, 92 minutes) than in patients without rebleeding (median, 256 minutes; P=0.051), and blood pressure at the time of initial treatment tended to be higher for patients with rebleeding. Patients with rebleeding showed either: a) spiral or wave-shaped hemorrhage into the cistern in which the aneurysm was located; or b) tear-drop-shaped hemorrhage within the hematoma. Patients with rebleeding were all grade 5 according to the World Federation of Neurological Surgeons (WFNS) and underwent CTA within 3 h of onset.

Conclusions
Computed tomographic angiography offers excellent performance for the diagnosis of cerebral aneurysm, but the use of intravenous contrast agent may carry some risk of rebleeding. History of recent severe subarachnoid hemorrhage also appears to represent a risk factor for rebleeding. As contrast agent injection may produce hemodynamic effects, management of fluctuations in blood pressure during CTA is crucial.

Remote Microhemorrhages and Hematomas Are Common in Patients Treated for High Grade Glioma

F Charbonneau¹, D Psimaras², A Gueguen¹, S Julien³

¹Fondation Rothschild, Paris, France, ²Groupe Hospitalier Pitié-Salpêtrière, Paris, France, ³Fondation Rothschild, France, France

Purpose
High grade glioma affects patients of all ages. Over the past ten years, prognosis has considerably improved due to advances in surgery and adjuvant therapy. Patients with prolonged survival (greater than 5 years) are more numerous, and may experience delayed complications secondary to adjuvant therapy. Microhemorrhages or cavernous angiomas are recognized complications seen during the follow-up of central nervous system tumors in pediatric patients, but have not been well described during the surveillance of gliomas in the adult population. Our goal was to study the prevalence of remote microhemorrhages and larger hematomas using susceptibility weighted imaging among patients treated for high grade gliomas.

Materials and Methods
A retrospective study was performed of 57 patients with high grade glioma who underwent MR imaging between January 2009 and December 2010. Of these, 51 (89%) patients had been
treated with stereotactic radiation therapy (60 Gray). Over the course of follow-up each patient underwent from 2 to 16 1.5T MRI examinations, which included a susceptibility weighted sequence. All patients were followed until March 2013 or until demise; the average follow-up period was 569 days. A total of 430 examinations were reviewed by a senior neuroradiologist. We studied the prevalence of microhemorrhages and larger hematomas distant to the original tumor site and their potential relationship with previous stereotactic radiation therapy.

Results
31 patients (54%) had developed remote microhemorrhages, with 13 patients (23%) having more than 10 lesions. 7 patients (12%) presented during the course of their follow-up with a remote hematoma or a typical cavernous angioma with signs of multiple hemorrhages on all sequences. The prevalence of microhemorrhage among patients with previous radiation therapy was 61%, versus 0% without previous radiation therapy (p=0.0139). The patients who developed remote microhemorrhage (Mean age 47.0 +/- 13.0 versus 59.4 +/- 14.4; p=0.001) and hematomas (Mean age 39.7 +/- 12.9 versus 54.4 +/- 14.3; p=0.01) were younger.

Conclusions
Microhemorrhages and hematomas at locations remote from the primary tumor are frequent complications seen during the follow-up of treated high grade gliomas, and appear to be more common among patients treated with radiation therapy.

Role of Echo-Planar Gradient-Recalled Echo (EPI-GRE) in Acute Stroke Patients: A Comparative Analysis with Conventional GRE
G Choudhary¹, W Kubal², R Khan², A Meshksar³, K Nael²
¹University of Arizona, TUCSON, AZ, ²University of Arizona, Department of Medical Imaging, Tucson, AZ, ³University of Arizona Medical Center, Tucson, AZ

Purpose
To evaluate the feasibility of implementing an EPI-GRE sequence into an acute MR stroke protocol with potential improved image quality and reduction in scan time and to compare the results with conventional GRE images.

Materials and Methods
Fifty patients with clinical suspicion of acute stroke (30 Male, age range: 45-99 y/o) were prospectively evaluated using an acute stroke MR protocol, which included both conventional GRE and EPI-GRE on a 3T MR scanner (Skyra, Siemens). The EPI-GRE was performed using a gradient-EPI sequence (TR/TE: 1860/48 msec, FA 90°, matrix 192 mm, voxel size 1.7 x 1.7 x 3 mm³). Generalized autocalibrating partially parallel acquisitions (GRAPPA) with acceleration factor of 2 was integrated to both GRE and EPI-GRE. The image acquisition time was 52 seconds for EPI-GRE and 3 minutes for conventional GRE. The image quality in terms of motion and susceptibility related artifact was assessed on both GRE and EPI-GRE studies independently by two neuroradiologists. The presence of intracranial hemorrhage (ICH) and clot within proximal arteries were evaluated on both GRE and EPI-GRE in separate reading session. Noncontrast CT studies were available for all patients and used as the standard of reference for detection of acute hemorrhage.

Results
All (100%) of EPI-GRE and 82% of GRE images were rated of diagnostic image quality by both observers, with interobserver agreements of k = 0.871, 95% CI 0.71-0.94 for EPI-GRE and k = 0.79, 95% CI 0.57-0.91 for GRE. A total of 13 patients had acute ICH detected on both GRE and EPI-GRE (See figure), confirmed on non-contrast CT. Four petechial hemorrhages associated with acute infarction not seen on non-contrast CT were detected on both GRE and EPI-GRE. There was no false negative for acute ICH for GRE and EPI-GRE in comparison to CT. Chronic micro hemorrhages went undetected on CT identified by on GRE (n=11) and EPI-GRE (n=6). In one patient proximal arterial blood clot was identified by both GRE and EPI-GRE.

Conclusions
In patients with acute stroke, EPI-GRE is feasible for detection of acute ICH with comparable or better qualitative results to conventional GRE and results in reduction in acquisition time.

Semiautomated Segmentation Techniques in Glioblastoma Multiforme: Interobserver Reproducibility Based On Training Level

P Chang\textsuperscript{1}, D Chow\textsuperscript{1}, K Cauley\textsuperscript{2}, A Lignelli\textsuperscript{3}, C Filippi\textsuperscript{1}

\textsuperscript{1}Columbia University Medical Center, New York, NY, \textsuperscript{2}Columbia Presbyterian, New York, NY, \textsuperscript{3}Columbia University, New York, NY

Purpose
The rising potential of quantitative imaging metrics in neuroimaging has fueled a growing demand for reliable and efficient lesion segmentation techniques. To this end various automated algorithms have been developed, increasingly favored over manual segmentation for improved reproducibility and speed of implementation. Widespread adoption of these automated techniques will require a clear understanding of the generalizability and limits of such
technology. In this study we aim to identify these potential difficulties by comparing segmentation results between users of various training levels.

Materials and Methods
Participants of various training levels were recruited for this study including a first year (PGY-2) radiology resident, a third year (PGY-4) radiology resident and two CAQ attending neuroradiologists. Each participant subsequently utilized an in house proprietary semiautomated segmentation algorithm to identify enhancing tumor in 25 cases of glioblastoma multiforme (GBM) and peritumor FLAIR signal abnormality in 28 cases of GBM. The tumor dataset was obtained from the previously deidentified Cancer Genome Atlas (TCGA). Total segmented volumes were compared using a two-tailed t-test.

Results
No significant difference was demonstrated in FLAIR hyperintensity volumes identified by residents of all training levels compared to attending neuroradiologist (p = 0.21). In addition, no significant difference was demonstrated in enhancing GBM volumes identified by attending neuroradiologists (p = 0.33) or by senior resident (PGY-4) and attending neuroradiologist (p = 0.78). However, a significant difference was demonstrated in enhancing GBM volumes identified by the most junior resident (PGY-2) compared to attending neuroradiologist (p = 0.0071).

Conclusions
The identification of peritumor FLAIR signal abnormality was highly reproducible across all training levels. By contrast, the identification of enhancing tumor appeared to be experience dependent, where modest training made a significant difference in segmented volumes. Further work in this area may involve identification of specific tumor components that are commonly mislabeled by novice users, in an effort to both improve segmentation algorithms and facilitate education in this area.

Sphenoid wing capillary hemangioma presenting as sudden unilateral vision loss

M Iqbal1, A Abraham2, J Homan3, A Joshi1, S Iqbal1, A Zuberi1
1University of Kansas SOM Wichita, Wichita, KS, 2University of Kansas Medical Center, Kansas City, MO, 3Kansas University Wichita, Wichita, KS

Purpose
Calvarial Hemangiomas are uncommon primary tumors of the bone comprising only 1% of primary bone tumors. Classic appearance has been described and these are recognized easily. However, rarely Calvarial Hemangioma can have atypical presentation, and these can be mistaken for other etiologies. Majority are slow growing and asymptomatic. The atypical tumors can mimic other lesions on imaging and can present with vague symptoms including vision loss depending on location.

Materials and Methods
MR imaging (MRI) details the pathologically proven right sphenoid wing hemangioma resulting in compression of the orbital apex. Additionally, a full clinical work up of the patient is
presented to explore the presenting symptoms. Detailed history, complete ophthalmologic exam, and biopsy for pathologic diagnosis are reviewed. Postsurgical clinical progress also are presented.

Results
MR imaging in a young female demonstrates an intraosseous lesion in the right sphenoid wing with resultant mass effect on the lateral orbital wall, specifically on the optic nerve apex. Sphenoid wing meningioma commonly has been described in the literature; however pathology obtained by neurological surgery confirmed capillary type hemangioma.

Conclusions
We describe an unusual case of a right sphenoid wing capillary hemangioma, a presentation commonly associated with sphenoid meningioma.

Spontaneous Retroclival Subdural Hematoma: A Perimesencephalic Hemorrhage Variant
Purpose
To describe unusual presentation of retroclival subdural hematomas in patients with subarachnoid hemorrhage.

Materials and Methods
Over a two year period, we collected data on all patients with spontaneous retroclival subdural hematomas at our institution. Data included clinical history, laboratory results, treatment, and review of all imaging studies performed.

Results
Four patients were identified demonstrating unusual presentation of retroclival subdural hematoma in the absence of trauma or anticoagulation/anti-platelet effect. These patients also demonstrated subarachnoid and fourth ventricular blood. All patients underwent noncontrast CT, CT angiography of the head, MRI of the head and spine, and conventional catheter angiography. No anatomic or structural cause of subarachnoid hemorrhage was identified. No vascular lesions were identified. CT and MR imaging confirmed the location of the retroclival collection to the subdural space crossing the basioccipital synchondrosis. An average of 12 month follow-up post discharge from initial hospitalization revealed a benign natural history similar to angiogram negative perimesencephalic subtype subarachnoid hemorrhage.

Conclusions
Retroclival hematomas are rare with limited description, mostly a post-traumatic phenomenon. Spontaneous retroclival subdural hematomas in the absence of trauma has few descriptions in the literature [1-3]. None of the reported clinical descriptions describe patients with a combination of spontaneous retroclival and perimesencephalic subarachnoid hemorrhage. Nevertheless, despite extensive description of idiopathic or angiogram-negative subarachnoid hemorrhage, including sub-categories such as perimesencephalic subarachnoid hemorrhage, the relationship between perimesencephalic hemorrhage and spontaneous retroclival hemorrhage remain unexamined. We report the first series of four patients with combination of spontaneous retroclival subdural hematoma and idiopathic subarachnoid hemorrhage.

Stroke in Stoke - An Early experience of more than 100 cases.

C Jadun¹, J Chembala², Inatarajan³, S NAYAK⁴, C Roffe⁵, R Sanyal⁶
¹University hospital of North Staffs, STOKE ON TRENT, Staffordshire, ²University hospital of North Staffs, stoke on trent, staffordshire, ³University hospital of North Staffs, Stoke on Trent, Staffordshire, ⁴University hospital of North Staffordshire, stoke on trent, staffordshire, ⁵University hospital of North Staffordshire, STOKE ON TRENT, Staffordshire, ⁶UHNS, Stoke on Trent, United Kingdom

Purpose
Endovascular treatments have the potential to accelerate reperfusion in acute ischaemic stroke with large vessel occlusion. In the UK only a few stroke centres offer this interventional option. The University Hospital of North Staffordshire (UHNS) has treated the largest number of cases in the UK. Endovascular treatment (EVT) is offered to Revascularize in cases of large vessel occlusion. We present our initial experience of more than 100 cases of mechanical thrombectomy. We also present the Recanalization rate, outcome at 01 week and 90 day. in addition we present our complication rate for the mechanical thrombectomy cases.

Materials and Methods
All patients treated with EVT (intra-arterial thrombolysis (IAT), mechanical thrombectomy (MT) or both, or an attempt at intervention) for acute stroke at UHNS, Stoke-on-Trent, UK, were entered into a prospective register. Baseline demographic and clinical data, the National Institutes for Health Stroke Scale (NIHSS), imaging results including Thrombolysis In Cerebral Infarction (TICI) score, and complications were recorded. Mortality, and modified Rankin score (mRS) were assessed at 90 days.

Results
From December 2009 to January 2013 106 patients (mean age 64 years, median baseline NIHSS 18) were treated with EVT (thrombectomy ± IAT 83%, IAT alone 13%, neither 4%). Seventy-eight per cent of occlusions were in the anterior circulation. Intravenous bridging thrombolysis was performed in 81%. Revascularization was successful (TICI 2b/3) in 84%. The median time from stroke onset to the end of the procedure was 6 h 03 min. A good outcome (mRS≤2) at 90 days was achieved in 48% with a mortality of 15%. Fatal or nonfatal symptomatic intracranial haemorrhage (sICH) within 10 days occurred in 9%. The median length of stay was 14 days (31% discharged home ≤7 days).

Conclusions
Our initial experience suggests that Endovascular recanalization is a relatively safe procedure with 1.4 relative risk of better outcomes than thrombolysis alone in large vessel occlusions. EVT led to good clinical outcomes in almost 50% of patients with severe strokes.

Superior parietal lobule connections of the temporoparietal white matter pathways of the human brain. A high resolution diffusion tensor tractography.

A Kamali¹, E Motuzko¹, P Adapa², T Siegal¹
¹University of Medicine and Dentistry Cooper University Hospital, Camden, NJ, ²University of Nebraska Medical Center, Omaha, NE

Purpose
Inferior parietal lobule connections of the language pathways such as the middle longitudinal fasciculus (MdLF) and temporoparietal connections of the superior longitudinal fasciculus (TP SLF) have been described in the literature. Extensive crossing fibers at the corona radiata at the level of the lateral ventricles as well as lack of adequate imaging sensitivity and spatial resolution, so far, impeded depiction of superior parietal lobule connections of the temporoparietal language pathways in prior diffusion tensor imaging (DTI) studies. This work aimed to explore the acuity and feasibility of visualization of white matter pathways connecting the temporal lobe with the superior parietal lobule using a high resolution diffusion tensor imaging and deterministic tractography approach.

Materials and Methods
Subjects: Five healthy men (age range 24-37 years) were studied and written informed consent was obtained from all subjects. Conventional and DTI Acquisition: Data were acquired using a Philips 3.0 T Intera system using a SENSE receive head coil. Diffusion-weighted image (DWI) data were acquired axially using a single-shot multi-slice 2-D spin-echo diffusion with the balanced Icosa21 tensor encoding scheme. The b-factor = 500 sec mm⁻², TR/TE = 14460/60 msec, FOV = 256 mm x 256 mm and slice thickness/gap/#slices = 1 mm / 0 mm / 120. The EPI phase encoding used a SENSE k-space undersampling factor of two, with an effective k-space matrix of 112x112 and an image matrix after zero-filling of 256x256. Fiber Tracking: We used the FACT algorithm (DTIStudio) to reconstruct the superior parietal lobule connections of the temporoparietal white matter pathways of the human brain with a fractional anisotropy (FA) threshold of 0.22 and angle threshold of 60 degrees. Statistical comparisons were made using analysis of variance (Student t-test) and the Mann-Whitney tests.

Results
Using higher resolution combined with higher magnetic field reduced the partial volume effects and incoherency within the voxel. This allowed us to trace the superior parietal lobule connections of the temporoparietal pathways and reveal more anatomical details of the temporoparietal language pathways. In our experience these superior parietal lobule connections of the temporoparietal fibers are not traceable using slice thickness ~ 3 mm. This is attributable to mixing of fibers in different orientations within the voxel leading to lack of adequate anisotropy in larger voxel volume which was solved by using thinner slices and smaller voxel volume.

Conclusions
In this report we demonstrate for the first time the feasibility of in vivo tracing the superior parietal lobule connections of the temporoparietal white matter pathways using high resolution diffusion tensor tractography.

**SURGICAL TREATMENT OF BRAIN TUMORS WITH USING DT-TRACTOGRAPHY**

D Murodova¹

¹Republic Sientific center of Neurosurgery, Tashkent, Uzbekistan

Purpose
Diffusion-tensor MR tractography - a diagnostic method to visualize the orientation and integrity of the pathways of the brain in vivo. State of pathways in the depths of the brain may be estimated at present, while only using diffusion-tensor MR tractography. The purpose of the study Evaluation of the results of surgical treatment of brain tumors are supratentorial localization method using DT-tractography, accompanied by intraoperative monitoring.

Materials and Methods
We analyzed the results of treatment of 112 patients who were hospitalized at the Republican Scientific Center of Neurosurgery, Ministry of Health and operated under identical conditions.

Results
Of the patients operated on our core group of marked regression of neurological deficit to 46.9%,
which contributed to the leakage of the postoperative period without complications and improve quality of life and its duration. For the noninvasive and more complete removal of the tumor with maximum preservation of pathways, we used data mechanogram to visualize increase of the amplitude of muscle potentials and the appearance of sharp peaks in the motor tract irritation, allowing surgeons to more accurately determine the angle of attack, the amount of tumor resection. Surgery was performed under the control of intraoperative monitoring in the form mechanogram using needle electrodes in m.bicepsbrachi, m.quadricepsbrachi and m. quadricepsfemoris, installed with geterolateralnoy side. We used a computer system with software SYNAPSIS "Neyrotex", Russia.

Conclusions
1. Data Analysis MR tractography allows you to select the optimal surgical approach to tumors, to identify areas available for the removal and disposal to adequately perform the volume preserving FVZ and white matter pathways in the brain. 2. Removal of intracranial tumors under the control of intraoperative monitoring mechanogram using data from MRI tractography, intraoperative ensure accuracy and safety of surgery to minimize surgical trauma, helps reduce the risk of neurological deficit, which determines the efficiency of operations and good quality of life of patients. 3. The method of MR tractography can noninvasively visualize the pathways of white matter and assess the extent of their defeat in tumors of the cerebral hemispheres.

The Hyperdense Artery Sign: How Dense is too Dense?

M Frankel¹, V Wadhwa¹, D Lindsay¹
¹University of Manitoba, Winnipeg, Manitoba

Purpose
To determine a threshold computed tomographic attenuation ratio that can be used to increase the specificity of the hyperdense artery sign in predicting thrombus in patients with acute stroke.

Materials and Methods
We retrospectively analyzed non-contrast enhanced CT scans of the brain in 33 patients presenting with acute non-hemorrhagic infarction who demonstrated a hyperdense artery sign. The images were axially acquired at a slice thickness of 2.5 mm. Using an ovoid region of interest, the average CT density (in Hounsfield units) of the hyperdense arterial segment was measured. Density measurements of the contralateral middle cerebral artery (MCA) and superior sagittal sinus were also measured. Patients were excluded if there was evidence of intracranial hemorrhage, lack of a hyperdense artery sign or a hyperdense segment limited to the distal MCA (M3/M4) branches. Similar measurements were performed in 30 randomly selected control patients presenting with non-stroke symptoms. In the majority of stroke patients CT angiography of the Circle of Willis, performed immediately following uninfused CT, was reviewed to confirm the presence or absence of thrombus. For the stroke patients who did not undergo CT angiography, follow up imaging that demonstrated evidence of an evolving infarct was used to confirm the suspicion of intraluminal thrombus. Attenuation ratios of the denser artery over the contralateral MCA as well as the denser artery over the superior sagittal sinus were calculated in
both cases and controls. Receiver operating curve (ROC) analysis was used to compare case and control data. All measurements were taken independently by two observers and inter-observer agreement was evaluated using Cohen's kappa analysis.

Results
The area under the curve for the ROC analysis of the attenuation ratio of the denser artery over the contralateral MCA was 0.97 while the area under the curve for the attenuation ratio of the denser artery over the superior sagittal sinus was 0.93. Based on these values, a ratio greater than 1.3 using the contralateral MCA and a ratio greater than 0.9 using the superior sagittal sinus, have a 97% specificity for predicting thrombus.

Conclusions
Attenuation ratios greater than 1.3 and 0.9 for the hyperdense artery over the contralateral MCA and superior sagittal sinus respectively, have a specificity of 97% in predicting thrombus in acute stroke.

The significance of lactate peak that predicts grade in primary neuroepithelial tumor
H Nakamura1, M Doi2, M Hoshikawa3, Y Nakajima3, M Takagi3, Y Tanaka3, Y Yoshida1, T Suzuki3, M Uchida4

1St, Marianna University of Medicine, Kawasaki, Kanagawa, 2St. Marianna University of Medicine, Kawasaki, Kanagawa, 3St. Marianna University of Medicine, Kawasaki, Kanagawa, 4St, Marianna University of Medicine, Kawasaki, Kanagawa

Purpose
Lactate is seen due to the various causes. These include hyperglucose metabolism, the reduced clearance of the necrotic area, the hypoxic state because of the tumor outgrow with inadequate blood supply. It is said that lactate peak is not a useful maker in predicting tumor grade. This study is to examine the significance of the lactate peak in the judgment of the grade of the neuroepithelial tumor.

Materials and Methods
Fifty-five patients (grade 1 (3 cases), grade 2 (11 cases), grade 3 (15 cases), grade 4 (26 cases)) with a pathological diagnosis of neuroepithelial tumors were enrolled. The biopsy cases were excluded. The magnetic resonance spectroscopy (MRS) was acquired using a 1.5T clinical scanner (Gyroscan, Intera, Philips Medical systems, Netherlands). Point-resolved spectroscopy (PRESS) (TR, 2000ms, TE, 144 ms, 128 acquisitions) spectra were acquired. The voxel was positioned at the solid tumor area avoiding the cysts. The size was 1.5×1.5×1.5 cm3. As controls for quantification, a voxel was also placed contralaterally or in a remote area. The lactate peak was defined as downward peak around 1.3ppm, whereas the lipid peak was upward. For the reference, lactate peak height / normal Creatine ratio was used (concurrent lipid cases were excluded)

Results
Results 1) The frequency of lactate is seen (Table1) Grade 2 is statistically different. 2) The frequency of lipid is grade 1 and 2( 0%), grade 3 (8.3%), grade 4 (44%). Grade 4 is statistically different among grades. 3) The height of lactate is not significantly different between grades.

Conclusions
When lactate peak is seen, we can consider grade1, 3 or 4 except 2. The etiology producing lactate peak is different between grade 1 and 3, 4. Grade 1 is due to hypermetabolism of glucose and grade 3 or 4 is due to the hypoxic state because of the tumor outgrow. In differentiating between 3 and 4, lipid peak may make us consider grade 4. Because grade 1 has a characteristic finding pathologically and radiologically, it is important to judge the routine imaging findings not to confuse with lactate peak. In conclusion, when we see the lactate peak, first of all we see the routine imaging findings to judge if the tumor is grade1 or not and secondary when we are unable to see the lipid peak, the grade 3 is more likely.

KEYWORDS: Glioma, Lactate
This calcification wasn’t supposed to be here! Series of 6 cases of intracranial calcified emboli

M Iani¹, F Nascimento¹, A Vaz¹, G Dias¹, B Handfas¹, R Iquizli¹, A Barbosa¹, M Funari¹

¹Hospital Israelita Albert Einstein, São Paulo, Brazil
Purpose
Calcified cerebral emboli is a rare disease and the literature on the subject is scarce. As far as we know, there is no series with more than four cases reported, and the prevalence in stroke patients has not been estimated yet. They can occur due to embolization from distant source, most commonly associated with aortic valve calcification, surgical manipulation of the carotid or even spontaneous and without a known source. In this poster we describe key findings that help neuroradiologist distinguishing calcified embolus from other physiological intracranial extra-axial calcifications, a usual finding on head CT.

Materials and Methods
Retrospective analysis of database in the past six years.

Results
We present six cases of patients attending our hospital in the last six years with acute neurological complaints, showing calcium foci in the subarachnoid space, matching the topography of cerebral arteries, some of them demonstrating areas of restricted diffusion in the correspondent arterial territories, documented through CT scans, MRI. These patients had performed brain exams shortly before with no evidence of calcification at the same area allowing the diagnosis of recent calcified emboli.

Conclusions
The finding of a calcium foci in cerebral circulation may explain acute neurological symptoms and help in the diagnosis of stroke. It is important to define the presence of calcium in the acute emboli, given that the approach to be taken by the attending physician as the indication of mechanical or chemical thrombolysis in these cases is still controversial. Calcified emboli should conduct prompt evaluation of carotid, aortic arch and heart for the most common sources of embolization. Although calcified emboli is a rare condition it is important to be familiarized with the imaging findings. They can be missed easily or mistaken by other benign intracranial calcifications, and the treatment of these cases is still controversial.

Thrombolysis in Real-Time: Imaging Evidence of Early Arterial Recanalization During Administration of Intravenous Alteplase in the CT Scanner

J Tan1, A Aysenne1, V Singh1, E Yuh1
1University of California, San Francisco, San Francisco, CA

Purpose
The aim of this study was to demonstrate imaging findings of early recanalization. The imaging protocol for acute ischemic stroke at our institution includes noncontrast CT, followed by perfusion CT at two levels, and then CTA of the head and neck. Patients at our institution presenting with acute ischemic stroke are currently receiving intravenous recombinant tissue plasminogen activator (rt-PA) in the CT scanner. They may receive the rt-PA immediately after the noncontrast CT or immediately after the perfusion CT. This presents a unique circumstance whereby we can visualize recanalization in real time between different phases of imaging.
Materials and Methods
25 consecutive patients with signs and symptoms of acute ischemic stroke who received rt-pa on the CT scanner were included. The CT imaging at initial presentation was reviewed. Follow-up imaging performed within one week of initial presentation was also reviewed.

Results
Of the 25 patients, seven demonstrated evidence of early recanalization. Of these 7, three demonstrated early recanalization on the initial CT, and four demonstrated recanalization on follow-up imaging. In one patient, hyperdense clot was seen in the left M1 segment on noncontrast CT. CTA performed after rt -PA administration demonstrates distal migration of thrombus, into the left M2 segment. In another patient, noncontrast CT demonstrate hyperdense thrombus at the left M1-M2 junction. CTA performed after rt-PA administration demonstrates no narrowing or occlusion in the left middle cerebral artery (MCA) territory. A third patient who presented with acute left MCA syndrome demonstrates evidence of reperfusion on perfusion imaging, with diminished mean transit time, elevated cerebral blood flow, and elevated cerebral blood volume in the left MCA territory.

Conclusions
Intravenous rt-PA takes immediate effect in some patients, allowing us to see thrombolysis in real time. Some of the findings of early recanalization include decreased attenuation of thrombus, distal migration of clot, and elevated cerebral blood flow on perfusion CT. We will do further work to evaluate the incidence of early recanalization in patients who did not receive rt-PA.

Transverse Sinus Stenting for Pseudotumor Cerebri: 6-Month Follow-Up 320 CT Venography in 21 Patients

I Kaminsky1, D San Millan2, S Kathuria1, D Solomon1, P Subramaniam1, A Moghekar1, M Radvany3, R Daniele1, P Gailloud1
1The Johns Hopkins Hospital, Baltimore, MD, 2Hôpital de Sion, Réseau Santé Valais, Sion, Switzerland, 3The Johns Hopkins University School of Medicine, Baltimore, MD

Purpose
Dural sinus stenting has recently emerged as a new treatment modality for patients with pseudotumor cerebri (PTC) caused by an underlying transverse sinus stenosis. However, stent patency in dural sinuses is not well documented. The purpose of this report was to evaluate the anatomic result of transverse sinus stenting at 6 months using 320 subtracted CT venography (CTV).

Materials and Methods
33 patients were treated with venous sinus stenting for underlying stenoses in the setting of PTC. All patients had exhausted conventional medical management and had progressive visual impairment. Six-month follow-up CTV was available in 21 of these patients. CTV was obtained with a standard protocol, including images in the native (Fig. 1A) and subtracted (Fig. 1B).
modes, with multiplanar reconstructions using a 320-row detector CT scanner (Aquilion One, Toshiba, Japan). The studies were retrospectively reviewed by two neuroradiologists.

Results
All 21 patients with 6-month follow up CTV had fully patent stents (100%), without evidence of neointimal hyperplasia or in-stent restenosis. Stent sizing was initially based upon maximal sinus diameter measurement. Two patients in that group developed new stenoses proximal to the patent stent, a phenomenon, which was believed to be secondary to deformation of the sinus by oversizing of the stent. All subsequent procedures were performed with smaller stents (5 or 6mm x 40 mm), without evidence of newly developed stenoses. 320 CTV images proved adequate to evaluate the stent integrity (native images) as well as the stent patency (subtracted images).

Conclusions
Venous sinus stenting is an effective and clinically durable modality for the treatment of PTC in an appropriately selected patient population. 320 subtracted CTV provides a high quality, noninvasive imaging method for the assessment of stent integrity and patency. At the 6-month follow-up evaluation, all the imaged stents were patent, without evidence of in-stent stenosis.

Usefulness of acute stroke imaging with wide area detector CT before endovascular reperfusion therapy in the anterior cerebral circulation

T Mori¹, T Iwata¹, Y Miyazaki¹, Y Tanno¹, S Kasakura¹, Y Aoyagi¹
¹Shonan Kamakura General Hospital Stroke Center, Kamakura, Japan

Purpose
Background and purpose: The wide area detector CT (ADCT) enables volume scanning (VS) for the whole brain and can provide whole brain CT perfusion (CTP) and dynamic vascular analysis (3D/4D-CTA) in one examination. Whole brain 4D-CTA can dynamically display the affected
cerebral artery, other cerebral arteries and intracranial arterial communication like digital subtraction angiography (DSA). Therefore, 4D-CTA may allow us to perform reperfusion therapy directly to the target vessel without diagnostic whole brain angiography. The aim of this study was to investigate the usefulness of ADCT before endovascular reperfusion therapy in the anterior cerebral circulation (ACC).

Materials and Methods
Included in our retrospective analysis were patients 1) who were transferred to our institution from November 2010 to November 2013, 2) who underwent ADCT (Aquilion ONE, Toshiba) before endovascular reperfusion therapy (ERT) and 3) who underwent ERT for the affected artery in the ACC within 8 hours of the onset. Acute imaging protocol for stroke diagnosis and reperfusion therapy consists of pre-contrast CT and subsequent MRI set (DWI, MRA, T2WI, T2*WI) and subsequently helical 3D-CTA from the aorta to the distal neck arteries and whole brain VS for 3D-,4D-CTA and CTP. Each volume consisted of 160 images of 1-mm thickness with z-axis coverage of 16-cm. Evaluated were onset-to-puncture time (OPT), door-to-puncture time (DPT) and successful ERT. Successful ERT was defined as TICI of 2b or 3.

Results
During the study period, 17 patients matched to our inclusive criteria. Aortocervical 3D-CTA helped endovascular therapists to decide which approach was suitable to patients, transfemoral or transbrachial. Intracranial 4D-CTA gave them useful information to perform a direct access to the target artery without diagnostic whole brain angiography. Median OPT and DPT were 3.5 and 2.1 hours, respectively. Successful ERT rate was 76% (14/17).

Conclusions
Our acute stroke imaging protocol using ADCT can provide endovascular therapists with useful information rapidly just before ERT in acute stroke setting.

**Utility of Gadoxetate Disodium as a Craniospinal and MR angiographic Contrast Agent: Preliminary Experience**

R Gawande1, P Pezeshk2, J Rykken2, A McKinney3

1University of Minnesota and Hennepin County Medical Centres, Minneapolis, MN, 2University of Minnesota, Minneapolis, MN, 3University of Minnesota and Hennepin County Medical Centers, Roseville, MN

Purpose
Nephrogenic systemic fibrosis (NSF) is a rare, but potentially debilitating condition in patients with renal insufficiency who receive intravenous gadolinium-based contrast agents (GBCA's), particularly in FDA-approved Group 1 "non-ionic linear" agents (gadodiamide, gadopentetate dimeglumine, and gadoversetamide). As of yet, there have been no cases of NSF reported in the newly approved Group 3 agents including gadofosveset and gadoxetate disodium (aka Eovist, Bayer Healthcare Pharmaceuticals). Gadoxetate disodium is the only FDA-approved GBCA with a 50-50% renal-biliary excretion, and has the highest thermodynamic and conditional stability and has been utilized extensively for body imaging, but not well studied with regards to
neuroimaging. A prior study showed that gadoxetate disodium adequately depicts normal enhancing structures that lack a blood-brain barrier, as well as vasculature (1). The purpose of our study was to preliminarily evaluate the utility of gadoxetate disodium as a craniospinal and MR angiographic contrast agent in imaging abnormalities.

Materials and Methods

IRB approval was obtained. Over a 3 year period, intravenous gadoxetate disodium was administered in 24 patients in whom enhanced neuroimaging was a medical necessity since the use of routinely administered group 1 agents was contraindicated due to renal dysfunction or sensitivity to other gadolinium agents. Patient consent was obtained in those with a GFR of <30. A 10cc dosage (one half of the recommended maximum dosage utilized in body imaging) was administered intravenously and imaging was performed after a 5 minute delay. A review of imaging studies of these patients was performed by 3 neuroradiologists, with respect to detection of pathology, which included brain MRI (n=21), skull base/neck MRI (n=4), head/neck MRA (n=3), head MRV (n=1) and spine imaging (n=4); notably, several patients had more than one of the aforementioned regions evaluated. The studies were performed on both 1.5T (n=13) and 3T (n=11) magnets with spin echo (n=13) and gradient echo (n=11) T1WI's, and dynamic CEMRA (n=4).

Results

The mean age of the 24 patients was 63.5 years (range 29-85 years). The GFR range of the patients with renal impairment was 10-48 (mean=31.1, SD=±8.8 ; n=22). The indications for contrast and the corresponding findings in patients were as follows: 2 patients with normal renal function with sensitivity to other GBCA's (negative for metastatic disease), 9 patients with systemic malignancy (7 were negative and 2 positive for metastatic disease), 6 patients for stroke (5 were negative, with one patient having pontine myelinolysis, and one with a meningioma), 1 patient for 6th nerve palsy (negative), 2 with severe headache (one with glioblastoma, the other with pseudotumor cerebri), 1 with pharyngitis (phlegmon without abscess), and 1 for vertigo (>80% stenosis of the internal carotid on MRA). Regarding the 4 patients with spine imaging, all 4 were positive, one having a meningioma causing severe cord edema, two patients with bone metastases to the spine, and one with osteomyelitis from an adjacent large peritonsillar abscess.

Conclusions

Gadoxetate disodium, at one-half of the dose utilized in body imaging, may serve as an alternative contrast agent for craniospinal and angiographic MR imaging, especially in patients with moderate-severe renal impairment. The risk of NSF may be decreased, although this needs to be proven prospectively. This preliminary study, and our prior study (1), demonstrate that abnormalities of the blood-brain barrier, vasculature, and spine can be adequately depicted.

Utility of of follow-up imaging in Isolated Perimesencephalic Subarachnoid Hemorrhage

B Jeun¹, V Kalra², D Durand², C Matouk¹, A Malhotra²
¹Yale University, New Haven, CT, ²Yale University School of Medicine, New Haven, CT

Purpose
To determine the utility of follow-up imaging in isolated perimesencephalic subarachnoid hemorrhage as assessed on initial CTA.

Materials and Methods
Retrospective review of patients with perimesencephalic hemorrhage was performed over the last 5 years in our large academic center. Search was performed through the radiology database for the words "perimesencephalic hemorrhage" at a single, large academic institution for cases in the past five years, after obtaining IRB approval. Perimesencephalic subarachnoid hemorrhage
was defined as hemorrhage centered in the anterior mesencephalon without greater than trace blood in the interhemispheric and/or proximal Sylvian fissures. Studies were excluded if there was a history of trauma or imaging findings showed extensive/diffuse subarachnoid hemorrhage. The keyword search resulted in 213 CTAs. All studies were retrospectively reviewed by a Neuroradiology fellow and a CAQ certified Neuroradiologist with over 5 years experience. 17 patients met the inclusion criteria. Patients ranged in age from 26 to 75 years (mean 50.4, SD 12.6) with 10 men and 7 women. Number of follow-up imaging studies, including CT/CTAs, MRI/MRAs, DSAs, and transcranial dopplers, were tabulated.

Results

17 patients with isolated perimesencephalic subarachnoid hemorrhage were identified on initial non contrast CT with negative initial CTA. Of these 17 patients, follow-up imaging was obtained in 15 patients. All follow-up studies including CTAs, MRI/MRAs, and DSAs were negative in all patients. There were a total of 41 follow-up CT/CTAs, 40 MRI/MRAs, and 15 DSAs, resulting in an average of 2.41 CT/CTAs, 2.35 MRI/MRAs, and 0.88 DSAs per patient. A total of 15 follow-up transcranial dopplers were performed, which showed unexplained left MCA vasospasm in three patients, with all spontaneously resolving without intervention.

Conclusions

Imaging follow-up in patients who meet the strict radiographic criteria for isolated perimesencephalic subarachnoid hemorrhage with no source identified on initial CTA has been described as unnecessary in a previously published study from two large academic centers of 28 patients that showed completely negative DSAs and other follow-up imaging (Agid et al AJNR 31: 696-705). The authors concluded that DSA and subsequent imaging is not needed in these patients. We retrospectively reviewed patients with perimesencephalic hemorrhage at our institution over the last 5 years to determine efficacy of follow up imaging in patients who meet strict radiographic criteria on initial CTA. All 15 patients in our study had multiple negative follow-up imaging studies. Our data further supports that follow-up imaging is not necessary if the initial CTA is negative when strict radiographic criteria for isolated perimesencephalic subarachnoid hemorrhage are being followed. Interobserver and Intraobserver disagreement in CT Characterization of Nonaneurysmal perimesencephalic SAH has been reported (Brinjikji et al AJNR 31:1103-05.) However, the disagreement was all in cases which were called as not being NAPH (nonaneurysmal perimesencephalic hemorrhage). There was complete agreement in cases which met strict radiographic criteria of NAPH. We hope this will stimulate a debate and challenge the practise pattern in these subgroup of patients.

Utility of whole-brain 4D-CTA using a 320-detector row CT scanner in the evaluation of cerebral arteriovenous malformations

H Tajiri
1Shonan Kamakura General Hospital, Kamakura, Kanagawa

Purpose

Higher Spetzler-Martin grade (SMG) cerebral arteriovenous malformations (cAVMs) are known
to be associated with more severe postoperative deficits and poorer clinical outcomes. Recently, the 320-detector row CT scanner has offered a new and promising method in the diagnosis of patients with cardiovascular disease, but few reports concerning cerebrovascular disease have been described. The purpose of this retrospective study was to investigate the utility of whole-brain four-dimensional computed tomography angiography (4D-CTA) for evaluating cAVMs compared with cerebral angiography (CAG) as the gold standard reference.

Materials and Methods
Patients with cAVMs who underwent both 4D-CTA and CAG during hospitalization from November 2010 to October 2013 were enrolled. AVM detection rate, diagnostic quality, and SMG were investigated. Each component of the AVM (feeders, nidi, drainers) was scored using a 4-point grading scale (excellent=3, good=2, fair=1, poor=0). Two experienced neuroradiologists evaluated the examinations dependently and reached a final diagnosis by consensus.

Results
During the study period, 20 consecutive patients met our criteria (16 men, 4 women; mean age, 59.0 ± 17.9 years; range, 26–84 years). The 4D-CTA was able to detect all AVMs. Average scores for feeders, nidi, and drainers were 2.2, 2.4, and 2.5 on 4D-CTA and 2.5, 2.5, and 2.6 on CAG (P<.005), respectively. Visibilities of small cAVMs were slightly but not significantly lower with 4D-CTA than with CAG. AVM scores of all components assessed using 4D-CTA showed good interobserver agreement (kappa values ranging from 0.68 to 0.80). Median SMG score was 2.0 for both, and results from both modalities were in complete accord.

Conclusions
Although 4D-CTA shows limitations in terms of lower temporal and spatial resolution, 4D-CTA using 320-detector row CT showed complete agreement with CAG in terms of SMG and thus appears reliable for evaluating cAVMs.

Utilizing Dual Energy CT to Improve CT Diagnosis of Posterior Fossa Ischemia

H Hixson¹, C Leiva-Salinas¹, S Sumer¹, J Patrié¹, W Xin¹, M Wintermark¹

¹University of Virginia, Charlottesville, VA
Purpose
Noncontrast head CT sensitivity to posterior fossa infarcts is notoriously limited because of artifacts from the petrous temporal bones and dental amalgam. The goal of this study was to determine if virtual monochromatic images reconstructed from dual energy head CT would improve image quality and the detection of posterior fossa infarcts compared to standard polychromatic CT.

Materials and Methods
30 consecutive patients were retrospectively identified during the time period from March through October of 2012 who presented with symptoms suggestive of a possible posterior fossa infarct and received unenhanced head CTs on a single scanner and a brain MRI within 24 hours of the head CT as part of their standard of care. The MRI DWI findings were used as reference standard for the presence or absence of infarct. Monochromatic images were reconstructed from the routine noncontrast head CT studies at 60, 80, 100, 120 keV and the original polychromatic CT were interpreted independently by two blinded radiologists for the presence and location of infarct and for the image quality (overall effects from artifacts, homogeneity of the pons, and ability to see the cerebellar folia, the vermis, and the basilar artery quantified on a Likert scale). Statistical analysis was then performed using McNemar test and GEE logistic regression.

Results
Sensitivity, specificity, negative and positive predictive, and accuracy values of the monochromatic and standard CT datasets are presented in the attached table. No p-values for these metrics measured <0.05, but there was a trend toward significance at 100 keV for specificity (p=0.096) and a marginal trend toward significance at 80 keV for sensitivity (p=0.157). Overall effects from artifacts were significantly improved at 80, 100, and 120 keV (p<0.001, p=0.001, and p=0.027), homogeneity of the pons was significantly greater at 80 and 100 keV (p<0.001 for both), and the ability to see the basilar artery was significantly improved at 80 and 100 keV (p=0.004 and 0.02). The sum of all the quality metrics and also a more homogenous pons were significantly associated with a higher rate of detection of posterior fossa infarcts (p=0.022 and 0.015).

Conclusions
Virtual monochromatic head CT reconstruction at 80 and 100 keV significantly reduces artifacts and increases the perceived quality of the posterior fossa on head CT. A higher perceived quality is associated with a higher detection of posterior fossa infarcts. There is a trend toward higher specificity with monochromatic reconstructions at 100 keV and a less significant trend toward an increase in sensitivity at 80 keV. However, a negative 80 or 100 keV monochromatic head CT still warrants obtaining a brain MRI if clinical suspicion for posterior fossa ischemia is sufficient.

**Value of Noncontrast Time-resolved MR Angiography Using Arterial Spin Labeling in the Diagnosis of Moyamoya Disease**

K Tsuchiya¹, M Gomyo², A Ohara²

¹Tokyo Teishin Hospital, Tokyo, Japan, ²Kyorin University, Tokyo, Japan

**Purpose**

Our purpose was to assess the value of noncontrast time-resolved MR angiography developed based on the arterial spin labeling technique in the evaluation of the hemodynamic status of moyamoya disease.

**Materials and Methods**

The study group comprised a total of 20 patients (6 men and 14 women; age range, 15-76 years; mean age, 51.6 years) with established diagnosis of moyamoya disease by conventional digital subtraction angiography (DSA). Among them, 10 patients were in the status of post bypass surgery. Noncontrast time-resolved MR angiography was performed on a 3 T system using a 3D fast field-echo sequence with parameters as follows: TR/TE/FA, 4.5 ms/2.1 ms/15 deg; FOV, 230×256 mm; imaging matrix, 256×256; slab thickness, 96 mm; and section thickness, 3 mm. As to magnetically label the blood as a tracer, we placed a tag pulse band of 200 mm thickness inferior to the scan slab placing an interval of 17 mm. No cardiac or peripheral pulse gating was used. Changing a labeling delay time by 300-500 ms, we performed 3-5 scans in the axial plane. Visual assessment regarding the visualization of the steno-occlusive lesion and collateral vessels was performed comparing with 3D time-of-flight (TOF) MR angiograms in all patients using a four-point grading system. Comparison also was done with DSA in 12 patients and brain perfusion single photon emission tomography (SPECT) in 17 patients.

**Results**

Noncontrast time-resolved MR angiography better depicted the steno-occlusive lesion and collateral vessels than 3D-TOF MR angiography in 16 patients (80%) achieving a better result in the assessment by scoring (Wilcoxon rank-sum test, P<0.01). Its findings were comparable with digital subtraction angiography in all of the 12 patients and with SPECT in 14 of the 17 patients.
Conclusions
In assessing the hemodynamic status of occlusive diseases of the major intracranial arteries, noncontrast time-resolved MR angiography by using the arterial spin labeling technique is superior to 3D TOF MR angiography, while it is equivalent to conventional digital subtraction angiography and SPECT.

Value of the contrast material in the CT diagnosis of carotid artery dissection

L Saba¹, E Raz², R Montisci³
¹University of Cagliari, Monserrato, Italy, ²New York University Medical Center, New York, NY, ³University of Cagliari, Cagliari, Italy

Purpose
The purpose of this work was to evaluate if the use of contrast material in the MDCTA study of carotid artery dissection (CAD) modify the diagnostic performance.

Materials and Methods
One hundred patients (61 men, 39 women; mean age, 51 years; range, 25 – 78 years) 40 with and 60 without CAD, that underwent MDCTA for suspected CAD formed the study cohort. In this study patients from three different groups were included (patients with MR confirmation of CAD, n = 40; patients with MR confirmation of CAD absence, n = 20; patients that underwent MDCTA of carotid arteries for atherosclerosis analysis, n = 40). Three blinded observers with different level of expertise analyzed the randomized basal scan and after three months the observers evaluated the same datasets by using basal scans (BS) and after administration of
Results
The ROC curve analysis showed that for the three observers the use of BS versus BS and CM produced an improvement of the diagnostic confidence with AUC values from 0.894 to 0.926 (p value = 0.91); from 0.856 to 0.879 (p value = 0.365); and from 0.819 to 0.982 (p value = 0.01). The Cohen kappa analysis showed no significant difference in concordance with the use of BS versus BS and CM. The prevalence of uncertain findings was in 16%, 20.5% and 33% in the BS and 15%, 17.5% and 29% in BS and CM for observer one, two and three respectively.

Conclusions
Results of our study suggest that the use of BS instead the classic BS and CM determines a small reduction in the diagnostic confidence of the readers, that is statistically significant in only the junior one. Therefore the use of the only BS in the suspect of CAD may help in reducing cost and risk related to the administration of contrast material.

Visual Deficits and Pituitary Adenomas: The Myth of Bitemporal Hemianopia

I Lee¹, F Tavares², E Zan², A Blitz², D Yousem³
¹The Johns Hopkins Medical Institutions, Fulton, MD, ²The Johns Hopkins Medical Institutions, Baltimore, MD, ³Johns Hopkins Medical Institution, Baltimore, MD

Purpose
Our goals in this project were to test the hypothesis that bitemporal hemianopsia is the most common visual field deficit in patients with pituitary adenomas, to assess the degree of optic chiasm compression necessary to produce such a deficit, and to determine the frequency by which asymmetric visual deficits are associated with pituitary adenomas that impact the pre-chiasmal optic nerves or post-chiasmal optic tracts.

Materials and Methods
We retrospectively reviewed the imaging findings and medical records of 86 consecutive patients with pathologically proven pituitary macroadenoma or presumed pituitary macroadenoma between September 2009 and October 2012. We reviewed the clinical findings and ophthalmologic records which included documentation of visual field defects, reported vision disturbances by the patient, visual evoked potentials and optical coherence tomography in all patients. We evaluated the degree of displacement of pre-chiasmal optic nerve, optic chiasm, and post-chiasmal optic tract with sellar, suprasellar and parasellar masses attributed to pituitary macroadenoma in all patients. We also evaluated the degree of optic pathway displacement from the unaffected side or expected normal location, the changes on T2 or FLAIR signal intensity, atrophy or enhancement anywhere along the optic pathway, and the presence of hemorrhage in the masses. We correlated the clinical findings with these MR imaging findings.

Results
Patient's symptoms ranged from nonspecific ocular symptoms to bitemporal hemianopsia. 56 patients had no visual symptoms. Bitemporal hemianopsia (n=21) was the most common symptom, followed by unilateral temporal defect (n=2), homonymous hemianopsia (n=2), and miscellaneous (n=5). The relationship between the masses and optic chiasm showed compression (n=18), elevation (n=27), and no contact (n=41). Although 5 patients with chiasmal compression showed visual symptoms and 3 patients with chiasmal elevation did not show any visual symptoms, most ocular symptoms were caused by chiasmal elevation due to masses. The displacement of the optic pathway by the mass ranged from 0.2 cm to 1 cm. There was atrophy of optic chiasm in 3 cases and hemorrhage in the mass in ten. We did not find any signal change on T2WI or enhancement along the optic pathway compromised by the pituitary adenoma.

Conclusions
As our hypothesis, the bitemporal hemianopsia is the most common visual field deficit in patients with pituitary macroadenoma. The smallest displacement to produce such a deficit was 4 mm in the patients with chiasmal elevation.

Visualization of carotid artery stenosis using 3D fast spin-echo T1 black blood imaging techniques with and without improved motion-sensitized driven-equilibrium (iMSDE): preliminary experience

M Maeda\(^1\), M Umino\(^1\), H Sakuma\(^1\)
\(^1\)Mie University School of Medicine, Tsu, Japan

Purpose

Recently, 3D fast spin-echo (FSE) T1 black blood imaging (BBI) has become available, allowing full coverage of cervical carotid arteries with high spatial resolution and multiplanar reformation. Despite its inherent flow-void capability, 3D FSE T1BBI might exhibit plaque-mimicking artifacts because of insufficient blood suppression at the carotid bifurcation. Consequently, further improvement in blood signal suppression is desired for 3D FSE T1BBI. To improve blood suppression, several reports have been proposed and described, such as flow-dephasing BBI with improved motion-sensitized driven-equilibrium (iMSDE). However, its efficiency has not been studied sufficiently in patients with cervical carotid stenosis in a clinical setting. This study was designed to compare 3D FSE T1BBI with iMSDE prepared 3D FSE T1BBI for the evaluation of carotid artery stenosis.

Materials and Methods

Twenty-eight patients (mean 75 years; 22 men, 6 women) with cervical carotid artery stenosis were studied consecutively. 3D FSE T1BBI sequences with and without iMSDE were performed using 3 T MRI (Achieva, Quasar Dual; Philips) with a 16 channel NV array coil. The respective voxel sizes and scanning times for 3D FSE T1BBI and iMSDE were 0.9 × 0.9 × 0.9 mm and 0.93 × 0.93 × 1 mm, 3 min and 48 s and 4 min and 7 s. Visual assessment was made of the two sequence images by two radiologists in consensus. Blood signal suppression was rated for opposite normal vessels as well as stenotic vessels using four-point scoring where 4 = no artifact, 3 = partial or mild artifact, 2 = substantial artifact, and 1 = impossible to differentiate between the lumen and wall because of the flow artifact. Signal ratios of the plaque to the sternocleidomastoid muscle were obtained for quantitative analyses.

Results

Four vessels were excluded from this study because of post-carotid stenting vessels. Visual assessment showed that assigned scores were significantly higher for iMSDE prepared 3D FSE T1BBI than those for 3D FSE T1BBI (3.35 +/- 0.65 vs. 3.06 +/- 0.66, p=0.018). The 3D FSE T1BBI prepared with iMSDE was particularly effective for the visualization of ulcer plaque caused by blood signal suppression (Figure 1). However, 3D FSE T1BBI prepared with iMSDE showed blurring of images in seven vessels, which degraded the vessel wall visualization. Signal ratios were obtained from 22 vessels with plaque. The values were not significantly different between the two sequences (1.7 +/- 0.58 and 1.81 +/- 0.81, p=0.19).

Conclusions

Our preliminary results suggest that 3D FSE T1BBI prepared with iMSDE improves blood signal suppression, yielding better visualization of plaque morphology. This result was also true for a normal carotid artery, improving the interpretation of carotid plaque. However, blurring of images occasionally was apparent in 3D FSE T1BBI prepared with iMSDE, which can present difficulties. Further investigations should be conducted with more clinical cases.

Visualization of Cerebrospinal Fluid Dynamics in the Response to Driving Force by Arterial Spin labeling Real Time Imaging.

S Yamada¹, S Matsumoto², M Miyazaki³, T Yamaoto⁴, M YUi⁴, T Shiodera⁵, T Takeguchi⁵
¹Toshiba Rinkan Hospital, Sagamihara, Kanagawa, ²Sales Division, Otawara, Tochigi, ³Toshiba Medical Research Institute, Vernon Hills, IL, ⁴Toshiba Medical Systems Corporation, Otawara, Tochigi, ⁵Toshiba Corporation, Kawasaki, Japan
Purpose
CSF movement associated with cardiac pulsation and respiration can be seen in the external ventricular drainage tube as well as during neurosurgical operation. Purpose of this study is visualized CSF movement in the response to cardiac pulsation, respiration and head inertia in undisturbed normal physiological condition using an MRI time spatial labeling inversion pulse (Time-SLIP) technique with single-shot fast spin echo (SS FSE) and real time balanced steady-state free precession (bSSFP) imaging.

Materials and Methods
A series of 2D images with incremental inversion recovery times were acquired by 1.5T MRI scanner using Time-SLIP sequence with SS FSE and bSSFP real time imaging. The bSSFP scanning conditions were FOV = 24.0 x 26.3 cm, matrix = 64 x 192, slice thickness = 7 mm, TR/TE = 4.2/2.1, FA = 90, initial inversion time (TI) = 0.6 s and TI step = 0.101 s. All images were acquired on normal volunteers using a head coil. Volunteers were asked to hold breath (cardiac pulsation), to deep breath (deep inspiration and expiration) and to move head (inertia) during the examination.

Results
Real time CSF dynamics were observed using the MRI Time-SLIP sequence with FSE and bSSFP. Cerebrospinal fluid dynamics in response to CSF driving force were demonstrated using MRI Time-SLIP with FSE and real time bSSFP imaging technique.

Conclusions
Significant amount CSF was moved by cardiac pulsation, respiration and head inertia.

Age- and disease-related changes in signal intensity in the superior cerebellar peduncles on 3 dimensional T2-weighted FLAIR

K Toyoda¹, H Oba¹, J Kotoku², T Kanda¹, M Osawa¹, R Hiraoka¹, S Furui¹
¹Teikyo University School of Medicine, Tokyo, Japan, ²Teikyo University, Tokyo, Japan

Purpose
In the three-dimensional T2-weighted fluid-attenuated inversion recovery (3D T2 FLAIR) technique, contrast imaging of the normal brain stem demonstrates higher signal intensity in the superior cerebellar peduncles, decussation of the superior cerebellar peduncles, middle cerebellar peduncle, and corticospinal and central tegmental tracts compared with surrounding regions, and it displays greater contrast than 2D FLAIR or 2D T2-weighted images. The present study investigated whether signal intensity in the region from the superior cerebellar peduncles to the decussation of the superior cerebellar peduncles increases with age in subjects who had no lesion
of the brain stem nor cerebellum, as well as signal intensity changes associated with progressive supranuclear palsy and multiple system atrophy.

Materials and Methods
3D T2 FLAIR images from 305 subjects with a normal brain stem and cerebellum were reviewed retrospectively. Using a 3 T MR imaging (MRI) unit, the imaging protocol was as follows: 8000/105/2260 (TR/TE/TI); ETL, 140 or 150; slice thickness, 1.4 mm; matrix, 256 × 244; and NEX, 1. Signal intensity in the superior cerebellar peduncles was evaluated visually and classified into the following three categories: grade 0, no high signal intensity; grade I, high signal intensity in comparison with surrounding white matter (pons, cerebellum); and grade II, fan-shaped distribution of high intensity covering the brainstem tegmentum. Three hundred five subjects were grouped based on age as follows: 0–29 years (n=40), 30–49 years (n=50), 50–59 years (n=50), 60–69 years (n=60), 70–79 years (n=65), and 80 years (n=40). Significant differences among the age groups were investigated based on the comparative incidence of grades 0–II. Grades of signal intensity in the superior cerebellar peduncles also were investigated in images from 19 patients with progressive supranuclear palsy and 10 patients with multiple system atrophy. The FLAIR protocol for these diseases was the same as for normal subjects.

Results
In normal subjects, a greater incidence of grade II signal intensity in the superior cerebellar peduncles and an increase in the area of high signal intensity were observed visually and statistically with age. Incidence of grade II was 56.7% in 60-69 years and 66.2% in 70-79 years, respectively. In multiple system atrophy patients, the mean age was 62.1 years, and 60% showed grade II signal intensity in the superior cerebellar peduncles, indicating that signal intensity was preserved. Conversely, in progressive supranuclear palsy patients, the mean age was 73.8 years, but only 15.8% had grade II signal intensity (grade I incidence, 73.7%), and atrophy of the superior cerebellar peduncles themselves was observed.

Conclusions
On 3D T2 FLAIR, marked high signal intensity was observed in the superior cerebellar peduncles with age. Meanwhile, signal intensity decreased in progressive supranuclear palsy, which affects the superior cerebellar peduncles. The present findings suggest that decreased signal intensity in the superior cerebellar peduncles on 3DT2 FLAIR in elderly patients may constitute an abnormal imaging finding indicative of disease.

Application of Dynamic Contrast Enhanced MR Imaging in Head and Neck Squamous Cell Carcinoma: A Correlation study of DCE Parameters with Clinicopathologic Characteristics by Histogram Analysis

J Kim\textsuperscript{1}, S Lee\textsuperscript{1}, A Lerner\textsuperscript{2}, C Liu\textsuperscript{3}, M Park\textsuperscript{1}, M Shiroishi\textsuperscript{2}, J Go\textsuperscript{4}, M Law\textsuperscript{5}
\textsuperscript{1}Yonsei University College of Medicine, Seoul, Korea, \textsuperscript{2}University of Southern California Keck School of Medicine, Los Angeles, CA, \textsuperscript{3}University of Southern California, Los Angeles, CA, \textsuperscript{4}LAC/University of Southern California Medical Center, Los Angeles, CA, \textsuperscript{5}Keck Medical Center of University of Southern California, Los Angeles, CA
Purpose
The purpose of this study was to investigate the usefulness of histogram analysis of dynamic contrast-enhanced MR imaging (DCE-MRI) parameters for assessing the clinicopathologic characteristics in the patients with head and neck squamous cell carcinoma (HNSCC).

Materials and Methods
Dynamic contrast-enhanced MRI was performed in a total of 18 consecutive patients with pathologically confirmed head and neck SCC, and DCE-MRI parameter maps including Ktrans (microvascular permeability), Ve (extravascular-extracellular space volume), and Vp (plasma volume) were obtained. Enhancing tumors were segmented manually on each slice of parameter maps and data were collected to obtain a histogram for the entire tumor volume. Mean, median, skewness, and kurtosis of the parameters were calculated and they were correlated with the clinicopathologic characteristics including tumor differentiation, T stage, N stage, TNM stage, presence of lymphovascular and perineural invasion.

Results
From the histogram analysis of Ktrans maps, mean, median, and kurtosis of the tumors with poor or moderate differentiation, higher stage, presence of lymphovascular and perineural invasion were lower than those of the tumors with well differentiation, lower stage, absence of lymphovascular and perineural invasion, but no significant difference was observed among them. Only the skewness of Ktrans value was significantly different between the tumors according to tumor differentiation (P = 0.005), tumor stage (P = 0.018), and presence of perineural invasion (P = 0.046). Other DCE parameters including Ve and Vp, did not significantly differ between the groups.

Conclusions
Our preliminary evidence using histogram analysis of DCE-MRI parameters (Ktrans) based on whole tumor volume suggests that it may be useful to predict clinicopathologic characteristics of HNSCC.

Chordoid Meningioma: Differentiating this atypical WHO grade II tumor from other meningioma histologic subtypes by standard MRI imaging

J Pond1, T Morgan1, Z Yetkin1, K Hatanpaa1, B Mickey1, D Mendelsohn1
1University of Texas Southwestern Medical Center, Dallas, TX

Purpose
The chordoid meningioma is an atypical WHO grade II tumor with a reportedly more aggressive clinical course and greater propensity for recurrence. Attempts to distinguish benign from atypical and malignant meningiomas on MR imaging (MRI) have been undertaken with variable results though no data analysis specifically examining the chordoid morphologic variant has been performed. A retrospective review was performed of preoperative MR examinations of intracranial chordoid meningiomas at our institution in an effort to determine if distinguishing MR characteristics exist that can aid in differentiating this atypical variant from other histologic subtypes.
Materials and Methods
Ten cases of WHO grade II chordoid meningiomas were diagnosed at our institution over an 11-year span, eight of which had preoperative MR exams available for review and were included in our analysis. Chordoid meningioma imaging characteristics were compared to 80 consecutive cases of WHO grade I, 21 consecutive cases of nonchordoid WHO grade II, and one WHO grade III meningioma from our institution in which preoperative MR imaging was available. Studies were analyzed for tumor location, size, signal characteristics, peritumoral edema, enhancement characteristics, cystic necrosis, bone changes, restricted diffusion, ADC value and normalized ADC (NADC) ratio. Statistical analysis of absolute ADC and NADC ratios was performed using a generalized linear model and the Tukey-Kramer method.

Results
Preoperative MR imaging in our study cohort revealed no significant differences in size, location, signal characteristics and contrast enhancement of chordoid meningiomas compared to other meningiomas. There was variable presence and degree of peritumoral edema and involvement/invasion of the adjacent calvarium, not allowing for reliable differentiation between the histologic subtypes. There were, however, clear differences in ADC values and NADC ratios with a mean absolute ADC value of 1.62 ± 0.33 x10-3 mm2/s and a mean NADC ratio of 2.22 ± 0.47 x10-3 mm2/s in chordoid meningiomas compared to mean ADC and NADC values of 0.88 ± 0.13 x10-3 mm2/s and 1.17 ± 0.16 x10-3 mm2/s in benign WHO grade I meningiomas, 0.84 ± 0.11 x10-3 mm2/s and 1.11 ± 0.15 x10-3 mm2/s in non-chordoid WHO grade II meningiomas, and 0.57 x10-3 mm2/s and 0.75 x10-3 mm2/s in the case of WHO grade III meningioma. Analysis of these values demonstrated a statistically significant difference in ADC values and NADC ratios of chordoid meningiomas compared to all other WHO grade I, II and III subtypes (all pair-wise p values < 0.01).

Conclusions
Pre-operative identification of the atypical meningioma variant chordoid meningioma would be beneficial for neurosurgical treatment planning and follow-up surveillance. Our review revealed a statistically significant elevation of ADC and NADC values in chordoid meningiomas when compared to all other WHO grade I, II and III subtypes allowing for a reliable prediction of this atypical histopathologic diagnosis.

Clinical applications of Dynamic CT of the Cervical Spine.

D Tampieri\textsuperscript{1}, M Cortes\textsuperscript{1}, C Therrien\textsuperscript{1}, R LaPiana\textsuperscript{1}, D Melanson\textsuperscript{1}

\textsuperscript{1}Montreal Neurological Institute and Hospital, Montreal, Quebec, Canada

Purpose
Spinal instability is defined as the loss of ability of the spine to limit displacement so as to not damage or irritate the spinal cord and nerve roots and, in addition, to prevent incapacitating deformity or pain due to structural changes. Flexion-extension radiographs so far have been the gold standard for evaluating instability of the cervical spine. Conventional CT scans, although superior to radiographs for defining bone anatomy and providing details on disk, ligaments and soft tissues have limited benefits due to the lack of information regarding abnormal spinal movements. Recently, 320-row multidetector computed tomography (CT) was introduced, allowing low-dose volumetric in vivo image acquisition while the joints are in motion. The aim of this study is to assess the diagnostic performance of low-dose 320-row CT in the evaluation of cervical spine instability. Dynamic x-ray films serve as the standard of reference.

Materials and Methods
The patients referred to our institution for suspect cervical instability are examined using
dynamic CT of the cervical spine. Clinically the patients present with neck pain with or without radiculopathy. The subjects included in the study undergo both dynamic x-ray films and flexion-extension CT scanning. CT examinations are performed using the 320-row Aquilion ONE scanner (Toshiba), using four or five volumetric acquisitions while the patient moves from the extension to the flexion position. Each volume is acquired with the following parameters: 320 detector of 0.5mm each, covering 16cm with120Kv, mA modulated from scout views, rotation time one sec, scan field of view 240mm, display field of view 200-240mm. Then time resolved 4D flexion and extension cine loops, axial and sagittal soft tissues and bone algorithms reformatted images are obtained. CT images then are evaluated, using the x-ray films as a reference, in order to assess the normal and abnormal range of motion.

Results
Multidetector CT scanning has tremendous advantages particularly when a large volume can be covered. The advantage of CT scan in comparison with plain x-ray is related to the amount of the additional information concerning mainly soft tissues, intervertebral disks and facets that can be obtained. In particular changes in disk height, facets subluxation and vertebral bodies’ instability are better detected and depicted with dynamic CT. This technique enables a panoramic view of the cervical spine with excellent anatomical detail, which of course is useful in case fusion is indicated. The aim of our presentation is to illustrate the advantages of dynamic CT of the cervical spine to assess stability and evaluate vertebral bodies, disks and facets movements during flexion and extension.

Conclusions
Dynamic CT of the cervical spine was found extremely useful in the dynamic evaluation of the cervical spine since the quality of the information and the spatial resolution is superior to that of conventional plain x-ray. CT proved to be very useful for the assessment of facets subluxation, spondyloysis and disk changes as the patients passes from the extended to the flexion position. In consideration of the multiple information provided by CT with excellent display of the soft tissues, disks and vertebrae dynamic CT of the spine seems a promising imaging technique for the evaluation of the cervical spine in patients with degenerative disk disease. The dose of exposure of this type of examination when compared with conventional x-ray does not represent a significant limit to this exam particularly because it is a more complete and accurate imaging evaluation. This is particularly true in those cases requiring fusion due to the instability.

Cord Compression due to Extramedullary Hematopoiesis: A Rare Presentation in Patient with Beta Thalassemia Major

F Al Azri

1Sultan Qaboos University Hospital, Seeb, Oman
Purpose
To describe the role of magnetic resonance imaging (MRI) in a patient with β thalassemia major and mid thoracic pain and abnormal gait due to extra medullary hematopoiesis, a rare complication in these patient.

Materials and Methods
A 32-year-old male with β thalassemia major and mid thoracic pain and abnormal gait. He is on chronic blood transfusion with very stable hemoglobin and low serum ferreting level due to optimal treatment with chelation agents. He has not major organ failure due to thalassemia and recurrent blood transfusion such diabetes, or liver fibrosis. Thoracic and lumbar spine MR imaging (MRI) demonstrated hematopoietic marrow throughout the spine, para-spinal soft tissue masses and epidural masses causing cord compression consistent with extramedullary hematopoiesis. These masses showed positive uptake on nano sulphur colloid scan. He received radiation therapy and steroid which resulted in marked improvement of the symptoms. However the para-spinal masses showed no significant change in size on the follow-up MRI.

Results
Extramedullary hematopoiesis causing cord compression in patient with thalassemia major with well maintained hemoglobin and serum ferritin is very rare. The imaging finding with MRI and sulfur colloid scan have well recognized imaging features for which patient with similar presentation, the diagnosis should be considered and invasive procedure, such as surgery or biopsy, could be avoided to confirm the diagnosis.

Conclusions
In clinical setting thalassemia, major patient with no apparent thalassemia complications due to chronic anemia and repeat blood transfusion and characteristic appearance of the extramedullary hematopoiesis, MRI could play a major role in diagnosis and treatment of these patients.

CT and MR Appearance of Rathke’s Cleft Cyst and its Radiologic Mimickers

E Bilinsky¹, R Al-Khalili¹, H Lee²
¹Rutgers New Jersey Medical School, Newark, NJ, ²Univ. Hosp. - UMDNJ - NJ Med. Sch., Newark, NJ

Purpose
To review and identify distinguishing imaging findings of Rathke's cleft cyst and its common radiologic mimickers.

Materials and Methods
A total of twenty one cases of cystic like intrasellar and suprasellar masses imaged from 2006 to 2013 are presented. Followup pathologic identification was obtained when available. Sixteen cases are imaged with contrast enhanced MRI, utilizing sagittal and coronal T1 and T2 imaging, axial Flair sequence. Two cases include both enhanced CT and MRI and two cases were performed with unenhanced CT and enhanced MRI. One case was imaged with unenhanced CT and MRI. CT scan protocol is acquired in 1.25 mm axial slices with coronal and sagittal reformatted images.
Results
Nineteen cases proceeded to surgical intervention. Pathological examination reveals fifteen Rathke's cleft cysts, two craniopharyngiomas and two pituitary adenomas. The other two cases are identified radiologically as arachnoid cyst and empty sella. On T1 weighted imaging, 7 cases (50%) display increased signal intensity, 3 (20%) cases are isointense, 4 cases (26%) display low signal intensity and 1 (4%) case exhibits mixed signal intensity. On T2 weighted imaging, 9 cases exhibit high signal intensity (60%), 2 cases display low signal (13%) intensity, 2 cases (13%) are isointense and 2 cases have mixed signal. All fifteen cases show lack of central contrast enhancement and lesion with epicenter in the sella. Arachnoid cyst and empty sella are identified by their typical simple cerebrospinal fluid signal. Craniopharyngioma is identified by its heterogenous signal and enhancement pattern. Pituitary cystic adenoma provides a diagnostic challenge, frequently mimicking Rathke's Cleft cyst.

Conclusions
Imaging findings of Rathke's cleft cyst and its radiologic mimickers, including pituitary cystic adenoma and craniopharyngioma are evaluated in attempt to identify differentiating findings. In our study, arachnoid cyst and empty sella can be easily differentiated by their MR cerebrospinal fluid signal intensity. Enhancement pattern is helpful in identifying neoplasms such as craniopharyngioma. Pituitary cystic adenoma remains a diagnostic challenge. Rathke's cleft cysts are benign, epithelium-lined intrasellar cysts which originate from remnants of Rathke's pouch. Rathke's pouch arises from the primitive oral cavity and migrates rostrally to form the anterior pituitary lobe and the pars intermedia. This developmental pattern constitutes the basis for the consistent intrasellar epicenter of Rathke's cleft cysts. Rathke's cleft cysts display a wide array of signal characteristics, which reflects their varied chemical composition. In our study, 60% of cases exhibit increased T2 signal. About 50% of cyst are represented by high signal intensity on T1 weighted imaging. This reflects components of hemorrhage and cholesterol. Only about 26% of cases display both high T1 and T2 signal. High T1 signal intensity and lesion within the sella are typical features helpful in identifying Rathke's cleft cysts in our study.

How Dark is too Dark? : Age-related Quantitative Analysis of Normal T2 Hypointensity of Central Gray Matter Structures on 3T

U Barad1, M Crosby1, C Ho1
1Indiana University School of Medicine, Indianapolis, IN

Purpose
Due to the inherent increase in magnetic susceptibility on 3 T imaging, differentiation between normal T2 hypointensity of central gray matter structures versus pathologic metal or mineral deposition can be a challenge. Previous studies have demonstrated that iron deposition is a normal function of aging. We present a set of normal brain MR imaging (MRI) T2 sequences from birth to the seventh decade of life as a template for clinical imaging on 3 T.

Materials and Methods
Brain MRI with standard T2 clinical sequences were obtained restrospectively from a PACS
database performed on 3 T scanners (Magnetom Trio and Verio, Siemens, Malvern, PA, USA). Inclusion criteria required a normal result from the scan. Patients with central nervous system (CNS) pathology and pathology known to cause iron and mineral deposition to the brain were excluded after a search through a clinical patient database. The central gray structures were evaluated subjectively for hypointensity compared to the surrounding structures. Regions of interests (ROI) were drawn around the bilateral putamen, globus pallidus (GP), red nucleus (RN), and dentate nucleus (DN). A 30mm2 ROI also was obtained in the white matter (WM) of the centrum semiovale. Signal intensity values of all central gray structures were compared to the putamen as well as the white matter as ratios. Pearson's Rho correlation was performed between age and signal intensity ratios.

Results
Ninety patients (0.05–67 years, mean 25.6 years) with at least five per decade of life were obtained. Pearson's Rho correlation were significant (p<0.0001) for GP/Putamen (r=-0.69), GP/WM (r=-0.85), RN/WM (r=-0.65) and Putamen/WM (r=-0.55). Subjectively, the GP appears darker than the putamen as early as seven years, but is consistent in the second decade of life. The DN is consistently darker than the adjacent cerebellar white matter by the third decade. Conversely, the RN is visualized after the first year of life.

Conclusions
Our results correlate well to previous 1.5 T radiographic and histologic studies of brain iron accumulation by age and represent a normal quantitative template for clinical 3 T imaging.

Imaging of Idiopathic Intracranial Hypertension (IIH) Pre and Post Venous Stenting

C Gamss¹, A Patsalides², M Dinkin³, L Heier²
¹Weill Cornell Medical College, NY, NY, ²Weill Cornell Medical College, New York, NY, ³Weill Cornell Medical College, NEW YORK, NY

Purpose
Hypothesis: Non-invasive imaging can predict and identify dural sinus stent responders in idiopathic intracranial hypertension. Idiopathic intracranial hypertension (IIH) is characterized by headache, tinnitus and visual changes. Clinically these patients demonstrate papilledema and elevated opening pressures on lumbar puncture. The pathophysiology of the disease is controversial but recent literature has suggested dural venous sinus stenosis as an underlying mechanism for the increased pressure and lack of CSF reabsorption. Venous sinus angioplasty and stenting has emerged as a treatment strategy. A small number of case studies have evaluated patient symptomatology and response to therapy based on clinical data including papilledema and headache but the effects of stenting on the radiological signs of increased intracranial pressure has not been well demonstrated. In our study, we utilized MRI/MRV and CT/CTV to assess for changes in radiological signs of IIH post-stenting.

Materials and Methods
Materials and Methods: 6 patients (5 females and 1 male) aged 16-32 were diagnosed with IIH based on the Dandy criteria. Using CT or MR, the presence of radiologic papilledema, perioptic space dilation, empty sella, and dural venous sinus stenosis was recorded pre and post venous stenting. Prior to stenting the diagnosis was confirmed invasively with OP on LP and measurement of the intravenous pressure gradient across the stenosis.

Results
Results: Headache and MRI/CT findings of papilledema, perioptic space dilation, empty sella, and dural venous sinus stenosis < 2mm (in the dominant transverse sinus or bilateral in codominant sinuses) were found in all 6. All 6 had OP > 30 cm of H20 and pressure gradients > 14 mm of Hg across the stenosis. Post stenting, all 6 patients experienced resolution of headache, and imaging demonstrated resolution or improvement of papilledema, perioptic space dilation, empty sella, and dural venous sinus stenosis.

Conclusions
Conclusion: Venous stenting of transverse sinus stenosis in IIH leads to resolution of radiological features of intracranial hypertension including empty sella and perioptic space dilation. A prospective trial of venous stenting verses ventriculoperitoneal shunting for medically refractory patients is proposed.

KEYWORDS: Idiopathic Intracranial Hypotension, Venous Sinus Stenting, Venous Stenosis

Midsagittal Pituitary Measurement Exaggerates Pituitary Height when compared to Coronal Measurement with 3 Tesla Magnet.
R Hakimelahi\textsuperscript{1}, C Cotes\textsuperscript{2}, A Lal\textsuperscript{2}, J Heymann\textsuperscript{3}, O Ashikyan\textsuperscript{4}, R Riascos\textsuperscript{4}
\textsuperscript{1}UT Medical Branch, Galveston, TX, \textsuperscript{2}The University of Texas Medical Branch, Galveston, TX, \textsuperscript{3}UTMB, Galveston, TX, \textsuperscript{4}University of Texas Medical Branch, Galveston, TX

Purpose
Measurement of the pituitary height on MR studies plays an important role in multiple occasions including borderline pituitary abnormalities such as physiological hypertrophy, inflammatory disease, and masses. The measurement is traditionally measured on midsagittal T1 sequence. On the other hand, the coronal plane offers the best single view for evaluating the sellar structures. We sought to assess and compare pituitary height on midsagittal and coronal images.

Materials and Methods
Thirty three healthy adults (3 females; age ranging 35-55) with thin slice isovolumetric sagittal and coronal T1 sequence scanned between 2010 and 2013 were included. The isovolumetric T1 sequences were performed with 1 mm voxel size on a 3T MR scanner (Verio, Siemens, Germany) in direct sagittal, coronal reformatted images were obtained to correlate. The sagittal and coronal images were analyzed by an experienced neuroradiologist independently. The pituitary heights were measured on midsagittal and also on coronal images at the level of the stalk.

Results
The pituitary height was 4.6 ± 0.28 mm (mean ± SEM) on midsagittal images and measured 3.7 ± 0.27 mm (mean ± SEM) on coronal image. Both measurements were within the previously reported normal limits for age and sex. Pituitary height measured at midsagittal image is significantly longer than those on coronal images (p=0.0001).

Conclusions
MR imaging is the optimal imaging technique for evaluating the pituitary gland. Measurement of the pituitary height is important in many borderline pathologies, which is traditionally performed on midsagittal images. Our study showed that the midsagittal measurements significantly exaggerate the pituitary height by approximately 0.9 mm on average when compared to coronal images. Thin slice coronal views may provide a more accurate quantitative evaluation of the pituitary gland.

MR imaging of the superior cervical ganglion: Anatomical features and distance from the common carotid artery bifurcation

H Yokota\textsuperscript{1}, H Mukai\textsuperscript{1}, T Horikoshi\textsuperscript{1}, K Motoori\textsuperscript{1}, T Uno\textsuperscript{1}
\textsuperscript{1}Chiba University Hospital, Chiba, Japan

Purpose
The superior cervical ganglion (SG) is the largest ganglion of the cervical sympathetic trunk. Nerve block for SG is performed as treatments for vasospasm and neuralgia. Some reports have described the location and structural features of the SG by autopsy; however there are few reports about imaging anatomy. We describe imaging findings of the SG and analyze the
distance from its inferior pole to the common carotid artery bifurcation (CCAB), which is considered a good landmark for anesthetic block.

Materials and Methods
Eighteen cases (mean age, 43.3; range, 17-74 years) without obvious sympathetic symptoms were included. They underwent MR neurography (Philips 1.5 T Achieva, 3D-STIR VISTA, coronal acquisition, TR1600, TE200, TI180, thickness 2.4mm, overlap 1.2mm). The MR images corresponded with anatomical reports of SG. Additionally, ordinary least-squares multiple regression analysis was performed using gender, height, side and level of the CCAB to predict the SG-CCAB distance.

Results
Thirty-six SGs of all 18 cases could be visualized. The SG presented spindle shape and hyperintense on STIR and lay on the longus capitis muscle within the range from C1 to C4 level. The mean long axis was 29.1 ± 6.6mm and mean short axis was 5.3 ± 1.6mm. The model significantly predicted the SG-CCAB distance (R2=0.389, p=0.003). Gender, height and the level of CCAB contributed significantly to the variance in this model.

Conclusions
3D-STIR can visualize the SG and evaluate anatomical feature. The CCAB is a good landmark for localizing the SG.

Normal Variants of Paranasal Sinuses and Nasal Cavity on CT

K Shpilberg¹, S Daniel¹, P Som¹
¹Mount Sinai Hospital, New York, NY

Purpose
Normal variants of the paranasal sinuses and nasal cavity are very common. Some of these variants such as bilateral concha bullosa, Haller cells and hypertrophic ethmoid bulla have been found to be associated with chronic rhinosinusitis. Other variants such as Onodi cells are of importance to functional endoscopic sinus surgeons as their presence is associated with an increased risk of injury to optic nerves or carotid arteries. The purpose of this educational exhibit is to discuss the prevalence of anatomical variants of the paranasal sinuses and nasal cavity and to present multiple computed tomography (CT) images of different variants as a pictorial essay.

Materials and Methods
We retrospectively analyzed 214 CTs of the sinuses performed at our institution between 5/8/2013 and 11/5/2013. None of the patients underwent prior sinus surgery. Each CT was analyzed for the presence of the following normal variants: Agger nasi cells, Haller cells, Onodi cells, prominent ethmoid bulla, sphenoid sinuses extending into the posterior nasal septum, dehiscent lamina papyracea, pneumatized anterior clinoid, pneumatized pterygoid process, pneumatized hard palate, pneumatized floor of the sella turcica, pneumatized uncinate process, supraorbital cells, pneumatized crista galli, pneumatized superior turbinates, paradoxically bent middle turbinates, pneumatized lamina of middle turbinates, concha bullosa, pneumatized inferior turbinates, nasal septal deviation and nasal septal spur. Prevalence of the above variants was calculated.

Results
The most common anatomical variant in our study was deviation of the nasal septum, present in 98% of patients although in 37% it was minimal. The second most common variant was Agger nasi cells, present in 83% of patients. Other common variants were extension of sphenoid sinuses into the posterior nasal septum (78%), pneumatization of the floor of the sella turcica (68%), prominent ethmoid bulla (62%), Haller cells (46%) and pneumatized lamina of middle turbinates (36%). Onodi cells were found in 32% of our patients. Concha bullosa was present in 25% and was bilateral in 10%.

Conclusions
There is a wide variety of normal anatomical variants of the paranasal sinuses and nasal cavity, some of which occur very frequently. The most prevalent variants in our study were deviation of the nasal septum and presence of Agger nasi cells. It is important to be aware of normal variants as some may be associated with chronic rhinosinusitis and others with a higher rate of complications from functional endoscopic sinus surgery.

KEYWORDS: Normal Variant, Paranasal, Sinonasal Disease
Radiological changes in irradiation of mandible bone with increasing irradiation doses in minipigs: detection of osteoradionecrosis with MR-imaging and CT.

L Poort¹, A Postma², A Stadler¹, R Böckmann¹, F Hoebers³, P Kessler¹
¹MUMC+, Maastricht, Netherlands, ²MUMC, Maastricht, Netherlands, ³Maastro clinic, Maastricht, Netherlands

Purpose
To investigate radiological changes in mandibular bone after irradiation in various doses with and without surgery to identify the imaging characteristics of osteoradionecrosis.
Materials and Methods
Sixteen Göttingen minipigs were divided into four groups and were irradiated with equivalent doses of 0, 25, 50 and 70 Gy. Three months after irradiation, mandibular premolars and molars on the left side were removed and four dental implants were placed. A CT-scan and MRI-scan were obtained before irradiation. Six months after irradiation and implantation - CT and MRI-scans were repeated under general anaesthesia. Immediately after imaging the animals were sacrificed. Macroscopic and microscopic pathologic evaluation was done. The MR-imaging protocol consisted of coronal T1, T2-TSE and T2-SPIR, transverse STIR images and post-gadolinium T1-weighted images of the mandible. Signal intensities on all sequences of MR were scored by two head-neck radiologists independently and in consensus, as well as enhancement and cortical destruction. Cortical destruction and location and presence of implants was recorded from the CT-scan. A final decision of detection of osteoradionecrosis on MR and CT-scans was given separately. Gold standard for the diagnosis of osteoradionecrosis was clinical examination revealing persistent intra-oral exposed bone.

Results
Two animals had clinical signs of osteoradionecrosis; one animal in the 50 Gy and one in the 70 Gy group (fig 1). Increasing scores of signal changes were recorded with increasing radiation dose in the operated and non-operated mandible at MR. The T1-weighted images with gadolinium showed the highest signal intensity in the two pigs with suggested osteoradionecrosis. Other sequences showed more variable signal changes of the bone marrow. Cortical destruction based on MR after irradiation was noted in 3 animals, CT scan revealed clear cortical destruction in same three animals and some minor cortical changes in some other animals. The radiologists addressed two animals with osteoradionecrosis: in one animal the radiological findings matched the clinical diagnosis; in the other animal with a smaller intraoral area of exposed bone the radiological imaging failed to detect osteoradionecrosis. Another animal was radiologically diagnosed with osteoradionecrosis, but did not show any clinical signs – and therefore did not meet the diagnostic criteria of osteoradionecrosis. Preliminary histological evaluation, however, showed extensive radiation damage in this animal.

Conclusions
MR imaging showed increasing signal alterations in mandibles irradiated with higher dosages. The clinical diagnosis of osteoradionecrosis does not parallel the diagnosis of osteoradionecrosis on imaging, intramedullary changes are better visualized on MR.

Signal intensity of perirolandic white matter on phase difference enhanced imaging

S Kakeda¹, T Yoneda², S Ide¹, K Futatsuya¹, Y Hiai³, K Watanabe¹, J Moriya¹, Y Korogi¹
¹University of Occupational and Environmental Health, School of Medicine, Kitakyushu-shi, Fukuoka-ken, ²Kumamoto University, Kumamoto, Japan, ³Kumamoto University, Kumamoto-shi, Kumamoto-ken
Purpose
The phase difference enhanced (PADRE) imaging was developed to enhance the contrast between the target tissue and surrounding tissue by choosing the appropriate phase difference. On PADRE images, the signal-intensity (SI) of a certain WM may reflect its myelin content. Our purpose is to evaluate relative SI of the superficial white matter (SWM) in the precentral and postcentral gyri on PADRE.

Materials and Methods
All studies were performed at 3T MR. First, the echo time (TE) was optimized for the PADRE; TE of 58.3 msec was selected analyzing the best depiction of the optic radiations. The study population consisted of 44 normal subjects (29 women, 15 men: mean age 52.9 years: range 22-90 years). By consensus of two observers, the precentral gyri, postcentral gyri and superior frontal cortex (SFC) was identified based on the previously established anatomic methods. The SI of the SWM in the precentral and postcentral gyri on PADRE images was divided into three grades in comparison with that of the SFC; grade I: isointense, grade II: slightly hypointense, and grade III: markedly hypointense.

Results
The SWM in the precentral and postcentral gyri showed hypointense on PADRE images (Figure). For the SI analyses on PADRE images, the grade I, grade II, and grade III appearances were found in 1 (1%), 21 (24%), and 66 (75%) of 88 precentral gyri (44 subjects), respectively, and in 1 (1%), 25 (28%), and 62 (70%) of 88 postcentral gyri, respectively. Figure. PADRE image of a 29-year-old female. The superficial white matters in the bilateral precentral (arrows) and postcentral (arrowhead) gyri show marked hypointense (grade III).

Conclusions
On PADRE images, the perirolandic SWM showed hypointense to other cerebral cortices, which probably reflects differences in the concentration of the nerve fibers as well as the higher myelin content. PADRE may be useful for identification of the central sulcus by assessing the SI of the SWM.

KEYWORDS: Anatomy, Motor Cortex, Phase Contrast Imaging
Figure. PADRE image of a 29-year-old female. The superficial white matters in the bilateral precentral (arrows) and postcentral (arrowhead) gyri show marked hypointense (grade III).
Strategies for Reducing Ionizing Radiation Dose during Parathyroid 4DCT in Patients with Primary Hyperparathyroidism

A Mahajan\textsuperscript{1}, M Ghita\textsuperscript{1}, R Udelsman\textsuperscript{1}, T Carling\textsuperscript{1}, G Sze\textsuperscript{1}

\textsuperscript{1}Yale University School of Medicine, New Haven, CT

Purpose
Evaluate strategies to reduce radiation dose in patients undergoing Parathyroid 4DCT in patients with Primary Hyperparathyroidism

Materials and Methods
4DCT was performed using a 16 (20 mm beam collimation) and a 64 (40 mm beam collimation) detector row GE CT scanner in one non- and 2 or 3 post-contrast phases at 1.25 mm slice thickness from the angle of the mandible to the tracheal carina. The scanning protocol underwent several subsequent adjustments with the purpose of reducing the radiation dose without compromising the diagnostic quality of the studies such as: use of a lower tube voltage, acquisition of fewer phases, use of automated tube current modulation instead of fixed mA. The patient radiation dose was estimated using the ImPACT (Imaging Performance Assessment of CT Scanners) calculator and expressed as absorbed dose in various organs. The effective dose was calculated from the organ specific doses using tissue weighting factors according to the recommendations of the ICRP (International Commission on Radiological Protection) 103.

Results
For the 64-slice scanner, lowering the x-ray tube voltage from 140 to 120 kV in a 4 phase scan reduced the calculated patient effective dose from 18 to 8.8 mSv. The effective dose estimated for a similar 4 phase acquisition protocol (120 kV, 200 mA, 0.8 sec rotation time and pitch of 0.968 for all the phases) performed on the 16-slice scanner was 10.4 mSv, 18% higher than for the 64-slice scanner. Further, reducing the number of phases from 4 to 3 resulted in a decrease to 6.6 mSv. Combining these alterations to the protocol lowered the thyroid dose from a 4DCT study from 172 to 66 mGy. Based on the age and gender-dependent risk factors from the multiplicative model from the Biological Effects of Ionizing Radiation Committee VII (BEIR VII), the calculated risk of thyroid cancer for a 20 year old female patient from 4DCT would be reduced by 62% (from 1944 cases/million persons exposed to 746 cases/million persons exposed) by the altered protocol. Using automated tube current modulation (with the maximum tube current set at the fixed mA scan value of 180 mA) instead of fixed mA, resulted in a further decrease of the radiation dose by varying percentage, depending on the patient body habitus.

Conclusions
4DCT is associated with a high thyroid radiation dose. By reducing the X ray tube voltage and the number of phases used, the thyroid dose can be significantly reduced. This may lead to a lower risk of thyroid cancer formation, especially in young individuals.

The Adult Face of PHACES.

L Conley¹, D Shatzkes¹
¹Lenox Hill Hospital, New York, NY

Purpose
In PHACES syndrome, infantile hemangioma is accompanied by multisystem malformations that include brain, cardiac and eye anomalies. While this syndrome frequently is diagnosed in early childhood due to the presence of a typical segmental facial hemangioma, we have encountered several cases that have been identified later in life. This delayed diagnosis typically occurs when one of the associated malformations is identified on an imaging study performed for an unrelated indication, with the accompanying facial lesion long forgotten.

Materials and Methods
This poster will include three case presentations, utilizing clinical photographs and images from radiologic examinations, as well as a comprehensive review of clinical and imaging findings in PHACES syndrome.

Results
Subject one is a 20-year-old male presenting with dizziness while exercising. On CT he was found to have an absent right internal carotid artery as well as ipsilateral aberrant subclavian artery and cerebellar hypoplasia. Subject two is a 25-year-old female with left-sided hearing loss since infancy. On CT a persistent stapedial artery and ipsilateral cerebellar hypoplasia were noted as well as a wide internal auditory canal and cochlear dysplasia. Subject three is a 33-year-old female with history of trauma found to have multiple anomalies of the intracranial vasculature with ipsilateral cerebellar hypoplasia. All subjects had a remote history of a facial hemangioma.

Conclusions
When PHACES-related anomalies are encountered in the absence of history of facial hemangioma, findings such as absent or ectatic cerebral vessels may be a cause of significant clinical concern, and inappropriate work up may be initiated. With the knowledge of the typical patterns of PHACES-related anomalies, the diagnosis may be suggested and confirmed with history.

The Human Foramen Magnum - Normal Anatomy of the Cisterna Magna in Adults.

N Branting¹, N Whitney¹, H Sun¹, D Ross¹, J Pollock¹
¹Oregon Health and Science University, Portland, OR

Purpose
The goal of this study was to radiologically describe the anatomical characteristics of the cistern magna (CM) with regard to presence, dimension, and configuration.
Materials and Methods
In this retrospective study, 523 records were reviewed. We defined five CM types, the range of which covered all normal variants found in the study population. Characteristics of the CM were recorded and correlations between various posterior fossa dimensions and CM volume determined.

Results
There were 268 female (mean age 50.9 ± 16.9 years) and 255 male (mean age 54.1 ± 15.8 years) patients. CM volume was smaller in females than in males and correlated with age (Pearson correlation, r=0.1494, p=0.0006) and gender (unpaired t test, r²=0.0608, p<0.0001). Clivus length correlated with CM volume (Pearson correlation, r=0.211, p<0.0001) and gender (unpaired t test, r²=0.0163, p<0.0035). The anterior-posterior dimension of cerebrospinal fluid anterior to the brainstem correlated with CM volume (Pearson correlation, r=0.181, p<0.0001) and gender (unpaired t test, r²=0.0205, p=0.001).

Conclusions
The anatomical description and simple classification system we define allows for a more precise description of posterior fossa anatomy and could potentially contribute to the understanding of Chiari malformation anatomy and management.

KEYWORDS: Anatomy, Foramen, Posterior Fossa

Fig. 1 T1-weighted mid-sagittal MR image showing study measurements as follows: A the height of the cisterna magna (CM); (B not shown) the maximum width of the CM measured on an axial T2 image; C the maximum depth of the CM perpendicular to the occipital dura, volume of the CM calculated as A × B × C/6, (D McRae’s line) the foramen magnum diameter; E the CSF depth between the brainstem and the dura, anterior to the brainstem along McRae's line; F the clivus length measured from the posterior clinoid process to the basion; and G the tentorial angle measured as the largest angle between Twining's line and the tentorium

Chemical exchange saturation transfer imaging of Choline

Z Dai, T Zhang, G Yan, R Wu
1Shantou University Medical College, Shantou, Guangdong, 2Shantou University Medical College, Shantou, guangdong, 3Shantou university, Shantou, AK, 4Shantou University, Shantou, Guangdong

Purpose
We aim to detect the choline using chemical exchange saturation transfer imaging.

Materials and Methods
MRI experiments were conducted under an Agilent 7T small hole MRI system with a standard volume coil for RF transmission and reception. Choline phantoms were prepared to reach concentrations of 5, 10 and 20 mM, and their pH was titrated to 7.0. Choline imaging was obtained by the standard CW-CEST sequence. Parameters were used: offset frequency at 0.5 ppm and -0.5 ppm, pre-saturation time=5000 ms, TR/TE=6000/2.5 ms, slices=1, slice thickness=2mm, NEX=4, FOV=60*60 mm2, imaging matrix=64*64 and bandwidth=50 kHz. The pre-saturation power was 6 μT. Z-spectra were obtained in phantoms. All data were processed in Matlab.

Results
We could see clearly the choline effect at about 0.5 ppm in the Z-spectra. The Choline imaging signal increased with its concentration.

Conclusions
Our study demonstrates the specific choline imaging can be obtained using chemical exchange saturation transfer technic, which offset frequency is at about 0.5 ppm.

KEYWORDS: Choline
MR study of the brain. The purpose of this educational exhibit is to demonstrate normal anatomy of the orbit, common pathologies and incidental lesions occurring in the orbit. "Do not miss lesions" in the orbit also will be highlighted. The target audience is radiology residents and general radiologists.

Materials and Methods
After a brief review of the normal orbital structures seen on CT and MRI, high resolution and detailed images of the various orbital lesions will be presented, with pertinent clinical/pathological correlation and ancillary imaging findings, wherever applicable.

Results
1. Recognize the incidental findings of venous varix, vascular malformations, optic nerve drusen, scleral and trochlear calcification. 2. Distinguish retinal or choroidal detachment. 3. Learn the expected imaging appearance of cataract surgery, lens implants, retinal and choroidal reattachment procedures. 4. Gain knowledge of systemic conditions affecting the orbits such as Graves' ophthalmopathy, idiopathic orbital inflammatory syndrome, optic neuritis, lymphoma, sarcoidosis. 5. Be aware of the do not miss lesions of the orbit such as post septal cellulitis, subperiosteal abscess, subtle primary tumors in children and adults as well as subtle metastasis.

Conclusions
The orbits can be affected with a number of local or systemic pathologies. There are several imaging features and patterns that distinguish physiological calcifications and other incidental findings within the orbits from other conditions that may require emergent intervention. When utilizing a template for voice recognition dictation, we recommend a separate field with specific comments on the orbital contents as it encourages the resident to review the orbits systematically and decreases the chance of missing lesions especially early in the training.

Detection of 99mTc-Sestamibi Negative Parathyroid Adenomas with Multi-Phase CT: Preliminary Experience

R Fitzgerald¹, T Bartel¹, S Medarametla¹, R Samant¹, M Kumar¹, R Ramakrishnaiah¹, R Van Hemert¹, E Angtuaco¹, B Stack¹
¹University of Arkansas for Medical Sciences, Little Rock, AR

Purpose
Pre-operative parathyroid adenoma localization in patients with primary hyperparathyroidism facilitates minimally invasive parathyroidectomy. Many practices rely on congruent localization by two modalities, typically 99mTc-sestamibi (MIBI) scintigraphy with or without single photon-emission computed tomography/computer tomography (SPECT/CT) and cervical ultrasound prior. In patients whose adenomas are not localizable by 99mTc-MIBI imaging and/or ultrasound, bilateral neck exploration may be required. Multi-phase CT (MPCT) has been recognized as a complimentary modality for the detection of parathyroid adenomas. We investigated the utility of MPCT for the detection of adenomas that are non-localizing on 99mTc-MIBI imaging.
Materials and Methods
MPCT was performed on a Phillips 64-slice CT scanner (mA 180-200, kV 120) with acquisitions prior to and following injection of 75ml non-ionic contrast at 3 mL/s at 30, 60, and 90 seconds. Images were reviewed by a subspecialty-certified neuroradiologist and otolaryngology surgeon. Enhancement kinetics of identified lesions were compared to those of non-pathological lymph node in each patient. Accuracy of MPCT localization was correlated with findings at surgery.

Results
Two patients with primary hyperparathyroidism were included, one with 2 negative 99mTc-MIBI planar exams, 1 negative 99mTc-MIBI single photon-emission computed tomography/computer tomography (SPECT/CT) exam, and 1 negative ultrasound exam and the other with 1 negative 99mTc-MIBI planar exam and a positive ultrasound. Adenoma localization was accomplished in both patients with MPCT and confirmed at surgical resection. Parathyroid adenomas showed early enhancement followed by contrast washout compared with continuous contrast accumulation in lymph nodes.

Conclusions
MPCT detects parathyroid adenomas that are non-localizing by 99mTc-MIBI scintigraphy. Given the implications of pre-operative localization for minimization of surgical morbidity, further investigation into the utility of MPCT in this population is warranted.

KEYWORDS: CT, Parathyroid
Diffusion-weighted MR imaging in lymph node metastases of squamous cell carcinoma: Does discrimination of the carcinomas possible with apparent diffusion coefficient values?

Y Pekcevik¹, I Cukurova¹, I Arslan¹
¹Izmir Tepecik Training and Research Hospital, Izmir, Turkey

Purpose
We aim to compare apparent diffusion coefficient (ADC) values of nodal metastases in head and neck squamous cell carcinoma (SCC).

Materials and Methods
Ethics committee approval and informed consent were obtained. Patients with nodal metastases underwent 1.5 Tesla MR imaging, including diffusion weighted echo planar imaging performed with b values of 0 and 1000 sec/mm². ADC values of the histologically proven nodal metastases (1 cm or greater in short-axis diameter) of head and neck SCC retrospectively evaluated. A
region of interest was drawn around the malignant node on ADC maps. Mean ADC values were compared using Kruskal-Wallis test. Receiver operating characteristic analysis was employed to investigate whether ADC-based differentiation is possible among squamous cell carcinomas depending on their histologic characteristics.

Results
Twenty-seven patients (24 men, three women; mean age, 60.7 years) with 42 nodes underwent imaging. Mean ADC values for nodal metastases of the nasopharyngeal carcinoma (n:15), oropharyngeal carcinoma (n:12), laryngeal carcinoma (n:10) and hypopharyngeal carcinoma (n:5) were (0.710 ± 0.160 [standard deviation]) x 10-3 mm2/s, (0.960±0.190) x 10-3 mm2/s, (0.900±0.250) x 10-3 mm2/s, and (1.060±0.150) x 10-3 mm2/s, respectively. Significant differences were found between the nasopharyngeal and other SCC metastases. There were no significant differences among the other groups. By selecting 0.850 x 10-3 mm2/s as an ADC threshold value, we can differentiate nasopharyngeal carcinoma metastases from other carcinomas metastases with sensitivity of 80% and specificity of 85% (area under the curve, 0.890).

Conclusions
The present study demonstrates that ADC values of the nodal metastases in head and neck squamous cell carcinomas are similar other than the nasopharyngeal carcinoma. Diffusion weighted imaging may help distinguish nasopharyngeal carcinoma metastases from other SCC metastases.

Does the ‘Taller-than-Wide’ Sign Apply to Metastases to the Thyroid?

(Debnam¹, M Kwon², B Edeiken-Monroe¹, B Fornage³)

¹ Debnam, ² M Kwon, ³ B Edeiken-Monroe, ⁴ B Fornage
The University of Texas MD Anderson Cancer Center, Houston, TX, The University of Texas MD Anderson Cancer Center, Houston, TX, The University of Texas MD Anderson Cancer Center, Houston, TX

Purpose
An anteroposterior (AP)/transverse (TV) ratio of thyroid nodules greater than 1 (the so-called "taller-than-wide sign") has been reported as a sign of malignancy in primary thyroid cancer. The purpose of this study was to determine if this sign also applies to metastases to the thyroid from extrathyroid primary.

Materials and Methods
Thirty-three patients with a solitary nodule, or a dominant/suspicious nodule as part of a multinodular thyroid, and a cytological diagnosis of metastasis to the thyroid gland were included. The AP and TV dimensions of the nodules were measured in both the transverse and longitudinal planes and the AP/TV ratio was calculated in both planes.

Results
The thirty-three nodular metastases appeared as a solitary nodule (n=14) or a dominant/suspicious nodule in a multinodular thyroid (n=19). For the solitary nodules, the AP/TV ratio in the either the transverse or longitudinal plane was > 1 in 5 of 14 (36%) lesions. The AP/TV ratio in the either plane was > 1 in 8 of 19 (42%) dominant/suspicious nodules in a multinodular thyroid. In total, 13 of 33 (39%) lesions demonstrated an AP/TV ratio > 1.

Conclusions
The taller-than-wide sign is not a reliable sonographic sign of metastasis to the thyroid gland from an extrathyroid malignancy.

Dynamic Contrast-Enhanced MRI (DCE-MRI) in Head and Neck Squamous Cell Carcinoma and Nodal Metastases: Correlation with 18F-FDG PET/CT Changes and Clinical Response

B Chen1, N Muradyan2, J Chao1, C Torricelli1, T Tong1, E Maghami1, N Vora1
1City of Hope Medical Center, Duarte, CA, 2iCAD, Nashua, NH

Purpose
To evaluate the usefulness of pretreatment quantitative dynamic contrast-enhanced MR imaging (MRI) DCE-MRI analysis in predicting chemoradiation response as assessed by 18F-FDG PET/CT changes and clinical response in head and neck squamous cell carcinoma (HNSCC) primary sites and nodal metastases.

Materials and Methods
Twelve patients underwent pretreatment DCE-MRI. All patients had both pretreatment and three-month post-treatment 18F-FDG PET/CT. Regions of interest (ROI) were placed on the primary tumor and nodal metastases. Dynamic contrast-enhanced MRI scans were postprocessed with iCAD software. Seven parameters: ROI volume, the transfer constant (Ktrans), extracellular extravascular volume fraction (Ve), fractional plasma volume (Vp), precontrast tissue relaxation
rate (T10), efflux rate (Kep) and initial area under gadolinium curve for 60 sec (iAUGC) were recorded. 18F-FDG PET/CT analysis was performed with Advanced Workstation and the Maximal Standard Uptake Value (SUVmax) was obtained. Dynamic contrast-enhanced MRI studies were divided into responders (Rs) and nonresponders (NRs) based on clinical assessment and/or PET/CT changes.

Results
In the 10 HNSCC cases with primary site assessed, five were deemed responders and five nonresponders. The average tumor volume was 22.75cc in the Rs and 34cc in the NRs. Ktrans(1/min) was higher in the Rs with average of 2.57 compared to 0.58 in the NRs. Kep(1/min) was also higher in Rs with average of 6.1 compared to 1.23 in the NRs. Ve showed increase in NRs, while iAUGC and T10 were higher in Rs. In the 11 exams with DCE-MRI available and nodal metastases assessed, seven were deemed Rs and four NRs. The average node volume was higher in the Rs with 7cc compared to 5.43cc in NRs. Ktrans was higher in Rs with average of 1.4 compared to 0.99 of NRs. iAUGC (mMsec) was higher in Rs 18.64 compared to 8.86 in NRs. Kep and T10 also were elevated in the Rs group, while Ve and Vp did not show much difference between two groups. 18F-FDG PET/CT findings showed resolution of FDG activity in the Rs and greater reduction of SUVmax values than the NRs.

Conclusions
The pretreatment DCE-MRI parameters of both HNSCC primary sites and nodal metastases may correlate with 18F-FDG PET/CT changes and clinical response. Multimodality imaging with both DCE-MRI and 18F-FDG PET/CT may be a helpful imaging biomarker to predict treatment response to chemoradiation in HNSCC.

Effects of ROI Measurement Technique on the Quantitative Assessment of Recurrent Thyroid Cancer During Multiphasic Multidetector CT

J Debnam1, N Guha-Thakurta2, W Wei3, D Schellingerhout4
1University of Texas M. D. Anderson Cancer Center, Houston, TX, 2MD Anderson Cancer Center, Houston, TX, 3University of Texas MD Anderson Cancer Center, Houston, TX, 4UT MD Anderson Cancer Center, Houston, TX

Purpose
Multi-phase multidetector dynamic CT studies (4D-MDCT) allow the assessment of complex contrast enhancement patterns. The quantitative assessment of these patterns is complex, and highly dependent on ROI selection. We compare the results of three different ROI techniques in the setting of recurrent thyroid carcinoma.

Materials and Methods
Twenty-four patients (with 29 nodules) with pathologically-proven recurrent thyroid carcinoma underwent 4D-MDCT imaging of the neck prior to surgical resection or biopsy. Our 4D-MDCT protocol has 4 phases: initial non-contrast, 25 seconds after injection (arterial phase), and 55 seconds (venous phase) and 85 seconds (delayed phase). Regions of interest (ROI) analysis was done in three different ways: a) a small hand drawn ROI was placed over the area of highest
enhancement in the lesion (Max Enhancement), b) a freeform ROI was contoured to the outline of the lesion through different phases of enhancement, with no requirement for the ROI size to remain constant (Contouring), and c) the ROI was drawn freehand around the lesion on the phase of highest conspicuity, and then copied over to the other phases, with size being held constant (Size Constant). Average Hounsfield density was recorded for each ROI for each phase in each patient. Linear mixed model was used to estimate and compare densities between phases and ROI drawing methods.

Results
At baseline the Hounsfeld densities (HU) for Max Enhance, Contouring and Size Constant methodologies HU were 40+/-18, 37 +/-18 and 40+/-16 (Mean+/-SD). Arterial phase was 112 +/-38, 100 +/-38 and 116 +/-43. Venous phase was 102 +/-26, 91 +/-32, and 106 +/-26. Delayed phase was 98 +/-27, 88 +/-29 and 99 +/-27. Coefficient of variation were 44%, 34%, 26% and 28% for Max Enhance, 48%, 38%, 35% and 33% for Contouring, and 41%, 37%, 25% and 27% for Size Constant measurements for each phase respectively. (See figure comparing mean +/-standard deviations for these three measurement techniques). Based on linear mixed model estimates, Contouring method obtained significantly lower densities compared to Max Enhancing (mean difference = -11, 95% CI: -16 - -7, adjusted p < 0.0001) and Size Constant ROIs (mean difference = -9, 95% CI: -14 - -5 adjusted p < 0.0001). There was no difference between Size Constant and Max Enhancing (adjusted p = 0.45).

Conclusions
The way an ROI is placed is very important, and can influence the results of quantitative analysis. Coefficients of variation were smallest for the Size Constant method, suggesting it to be the more repeatable methodology, but further research based on diagnostic accuracy is needed. Research into ROI technique and analysis is necessary, and important for standardizing quantitative methods.

Evaluation of Histogram Parameters of ADC Values in Oropharyngeal Carcinomas: Correlation with Human Papilloma Virus Status

N Saito, M Nakahira, H Yamaguchi, M Obara, K Buch, O Sakai, A Uchino, F Kimura
1Saitama International Medical Center, Saitama Medical University, Hidaka, Saitama, Japan, 2Philips Electronics Japan, Minato-ku, Tokyo, Japan, 3Boston Medical Center, Boston University School of Medicine, Boston, MA

Purpose
Predicting the human papilloma virus (HPV) status of oropharyngeal squamous cell carcinoma (SCC) based on conventional imaging is challenging, however recent studies have reported the utility of CT perfusion parameters and mean apparent diffusion coefficient (ADC) value in determining HPV status. Apparent diffusion coefficient histogram analysis could provide a better assessment of tumors by quantifying tissue heterogeneity characteristics. The purpose of this study was to assess the ability of ADC histogram analysis to identify HPV status in oropharyngeal SCCs.

Materials and Methods
Clinical and imaging data of 19 patients with oropharyngeal SCC who underwent MR imaging prior to biopsy between April 2011 and November 2013 were retrospectively evaluated. MR imaging including diffusion weighted imaging was performed on each patient using a 3T MR scanner. Apparent diffusion coefficient map was generated by using 2 b-values (0 and 1000 s/
The regions of interest were drawn manually around the entire tumor on each slice to generate ADC histogram. Peak ADC value, skewness, and kurtosis were extracted from the histograms. These parameters were compared with HPV status using p16 immunohistochemistry as a surrogate marker for HPV infection. The histogram parameters were correlated with HPV status and evaluated by Mann-Whitney u test.

Results
Apparent diffusion coefficient histograms of representative cases are demonstrated in the figure. Significant differences were noted between HPV-positive SCC and HPV-negative SCC in peak ADC value (0.68 × 10⁻³ mm²/s versus 0.94 × 10⁻³ mm²/s, p=0.008). There were no significant differences in HPV status and skewness (p=0.48) or kurtosis (p=0.72).

Conclusions
Oropharyngeal SCCs show a distinct ADC histogram feature with peak ADC values in HPV-positive SCCs being significantly lower compared to HPV-negative SCCs. Apparent diffusion coefficient histogram analysis may be useful in determining HPV status in patients with oropharyngeal SCCs.

Evaluation of Tracheal Size with Changes in Body Mass Index (BMI).

H Kale1, B Branstetter2, D Tudorascu3, A Reynolds1
1University of Pittsburgh Medical Center, Pittsburgh, PA, 2Univ. Of Pittsburgh Med. Ctr., Pittsburgh, PA, 3University of Pittsburgh, Pittsburgh, PA

Purpose
Enlarged thyroid gland is a potential cause of Positional Dyspnea. If there is substantial narrowing of the trachea near the thoracic inlet, patients are treated with partial thyroidectomy. However, it is not clear whether other factors, such as obesity, may influence baseline tracheal diameters and mimic tracheal compression, resulting in unnecessary surgery. This is especially important because Positional Dyspnea is linked with obstructive sleep apnea, which itself is associated with obesity. Our aim was to evaluate whether the baseline diameter of the trachea is influenced by patients' body mass index (BMI).

Materials and Methods
After institutional review board approval, 179 patients, 18 to 70 years old, who underwent CT angiography or CT of the cervical spine in the emergency room were randomly selected and their imaging was retrospectively evaluated. The BMI was calculated from weight and height, or taken directly from the clinical notes. The diameter of the trachea in anteroposterior (AP) and transverse (Trans) dimensions, as well as the cross-sectional area (using free hand region of interest tool), was measured at the first tracheal ring and in the sub sternal region. Pearson correlation coefficients along with the 95% confidence interval (CI) were computed to compare BMI and tracheal dimensions. Two-sample t-tests were used to compare male and female patients. All tests were two-tailed and deemed statistical significant when p<.05. All our analyses were conducted using SAS 9.3 statistical software, Copyright, SAS Institute Inc.

Results
No statistically significant association was found between BMI and any other variable. (Table 1). Statistically significant differences were found between the mean of males and mean of females for each of the tracheal dimensions. All p-values were <.0001 with males having larger tracheas than females.

Conclusions
No association was found between BMI and tracheal size. Tracheal compression in patients with goiter can be safely attributed to glandular enlargement, regardless of obesity status.

**IDIOPATHIC TRIGEMINAL NEUROPATHY: CLINICORADIOLOGICAL ASPECTS IN TWO CASES**

C Agostinis¹, G Bonaldi², L MOSCHINI³, g pezzetti⁴

¹Ospedale Papa Giovanni XXIII, Alzano Lombardo, Italy, ²Ospedale Papa Giovanni XXIII, Bergamo, Italy, ³POLICLINICO SAN MARCO ZINGONIA, Bergamo, Italy, ⁴ospedale san raffaele Milano, Bergamo, Italy

**Purpose**

To present two cases of idiopathic gasserian ganglion enhancement.

**Materials and Methods**

Two male patients aged 50 and 43 years, respectively, with uneventful medical histories were evaluated because of subacute onset of subcontinous headache with neuralgic attacks and unilateral facial numbness. Neurologic examination revealed global hypoesthesia in the second and third division of the trigeminal nerve of the symptomatic side in both cases.

**Results**

Both patients had MRI showing enhancement of the gasserian ganglion on the symptomatic side extending to the mandibular nerve in both and to the cisternal segment of the trigeminal nerve in one case. In both cases the adjacent meninges of middle cranial fossa and parasellar region were also involved. Laboratory testing showed normal values for all routine measurements in both patients. They were treated with steroids over 10 days; one patient also received acyclovir for one week. In both cases symptoms progressively improved during the following weeks, with persistence of mild hypoesthesia at a 6-month clinical follow up. MRI with gadolinium 3 and 5 months later, respectively, demonstrated resolution of abnormal findings.

**Conclusions**

These cases can be considered as idiopathic inflammatory trigeminal sensory neuropathy. Few cases of this condition have been reported. Radiologist should be aware of this benign entity, which usually resolves within weeks and must be differentiated from other conditions such as perineural spread of head and neck neoplasms, lymphoma, sarcoidosis and bacterial and fungal infections. The similarity of MRI findings and clinical evolution with Bell's palsy suggests a similar etiology.
Imaging characteristics of nodal metastasis in HPV-positive HNSCC: Does extracapsular spread influence the prognosis?

Purpose
Human papillomavirus (HPV)-positive head and neck cancers have been recognized as a distinct subtype of head and neck squamous cell carcinoma (HNSCC). Certain imaging features specific to HPV-positive lymph nodes have been described such as a cystic appearance. While nodal metastasis with extracapsular spread has been associated with a poorer prognosis in HNSCC, this feature has not been established as a poor prognostic feature in HPV-positive HNSCC patients. The purpose of this study was to evaluate imaging features distinguishing the nodal metastasis of HPV-positive from HPV-negative HNSCC. Additionally, these imaging features and HPV status of HNSCC were correlated with short term clinical outcomes and prognosis.

Materials and Methods
Following IRB approval, 142 patients with HNSCC (65 oropharynx, 40 oral cavity, 22 larynx, 9 hypopharynx, and 6 others) with known HPV status between December 2009 and October 2013 were reviewed retrospectively. Several imaging features of the nodal metastasis including internal consistency (solid, necrotic, or cystic), number, size, and presence extracapsular spread were assessed on pretreatment contrast-enhanced CT or MR exams. The TNM stage and treatment methods were recorded to correlate with the one-year short term outcomes. Basic descriptive statistics including a Student's t-test and Fischer's exact test were performed. P values less than 0.05 were considered statistically significant.

Results
Of 142 patients with HNSCC, 59 patients were HPV-positive (42 oropharynx, 6 oral cavity, 8 larynx, and 3 others) and 83 patients were HPV-negative (23 oropharynx, 34 oral cavity, 14 larynx, 9 hypopharynx, and 3 others). Nodal metastasis were more common in HPV-positive HNSCC with 44 patients (75%) compared to 45 patients with HPV-negative HNSCC (54%) (P = 0.01). There was no significant difference in the TNM stage and treatment method between patients with HPV-positive and HPV-negative HNSCCs. There was no significant difference in the prevalence of necrotic nodal metastasis between HPV-positive patients [26/44 (59%)] and HPV-negative patients [26/45 (58%)]. Cystic changes were noted exclusively in 7/44 (16%) HPV-positive patients with six of the seven (86%) HNSCC occurring in the oropharynx (one patient was unknown primary). Three patients with HPV-positive HNSCC had both necrotic and cystic changes. HPV-positive patients [34/44 (77%)] tended to demonstrate a higher prevalence of extracapsular spread of nodal metastasis compared to HPV-negative patients [26/45 (58%)]. Although the number and size of nodal metastasis were larger in HPV-positive patients, these results were not statistically significant. These features also did not correlate with presence of necrotic/cystic internal change or extracapsular spread. A total of 49 patients with nodal
metastasis completed a one-year follow-up evaluation after initial treatment with significant differences in disease free survival rates of 90% (19/21) in HPV-positive HNSCC and 46% (13/28) in HPV-negative HNSCC (P = 0.002).

Conclusions
While cystic nodal metastases were seen exclusively in HPV-positive HNSCC, there were no statistically significant differences in the presence of necrotic nodes and extracapsular extension in HPV-positive versus HPV-negative HNSCC. Nodal metastases were significantly more common in HPV-positive HNSCC while the prevalence of disease recurrence was significantly more common in HPV-negative HNSCC. Even though extracapsular spread was noted in the majority of the HPV-positive patients with nodal metastasis, the one-year disease recurrence rates were better compared to HPV-negative patients, which suggest that extracapsular spread of nodal metastasis may not be a poor prognostic factor for HPV-positive HNSCC.

**Imaging of Phosphaturic Mesenchymal Tumors of the Head and Neck: Rare Tumors in Rare Places**

T Howard¹, C Hunt¹, A Kotsenas¹, C Giannini¹, J Morris¹
¹Mayo Clinic, Rochester, MN

**Purpose**
Phosphaturic mesenchymal tumors (PMT) are rare tumors of the soft tissues and skeleton that often present with oncogenic osteomalacia, a paraneoplastic process due to production of fibroblast growth factor-23 (FGF23). The purpose of this study is to describe the typical imaging features of these rare tumors when they occur in the head and neck.

**Materials and Methods**
A retrospective review of all pathologically confirmed PMT was performed at our institution occurring in the head and neck. Clinical presentation, serum laboratory values, and all available imaging were reviewed. Available MR imaging (MRI) and CT images were reviewed for typical features in consensus by two fellowship trained neuroradiologists.

**Results**
A total of four PMT were identified involving the head and neck, representing 24% of the PMT previously identified at our institution. While oncogenic osteomalacia is the classic paraneoplastic presentation for PMT, none of our patients with head and neck involvement presented with this finding, even though all had evidence of amplification of the FGF23 gene. The tumors with head and neck involvement were centered in the paranasal sinuses (n=2), skull base (n=1), and a frontal lobe mass with extraaxial extension (n=1). Imaging features were fairly uniform throughout our tumors. All tumors were heterogeneous but mostly iso- to hypointense on T1 and hyperintense on T2-weighted sequences. Cystic changes were common (2 of 4). Intense gadolinium enhancement was seen in all tumors, corresponding with hypervascular changes on conventional angiography. Involved bones were expanded with preserved morphology. Vascular encasement also was seen without evidence for luminal narrowing. Matrix
calcification production was not typical (1 of 4). Macroscopic fat was demonstrated in the frontal lobe mass with extraaxial extension (1 of 4).

Conclusions
PMT are rare tumors, but, when present, tumor involvement of the head and neck is not uncommon. Typical imaging features include expansion of the involved bone, intense enhancement, and vascular encasement without evidence for luminal narrowing. These imaging features, especially in the presence of an elevated FGF23, should strongly suggest the diagnosis of phosphaturic mesenchymal tumor.

Incidental Paranasal Sinusitis on Routine Brain MRI - Exploring a potential biomarker for links to Co-Morbidities of Periodontal Disease.

P Rosenthal¹, K Lundy¹, D Massoglia¹, M Gebregziabher², E Payne², G Gilbert³
¹Ralph H Johnson VA Medical Center, Charleston, SC, ²Medical University of South Carolina, Charleston, SC, ³Health Care Simulation South Carolina, Charleston, SC

Purpose
Incidental Paranasal Sinusitis (IPS) is common on imaging for unrelated disorders and thought not to be clinically significant in asymptomatic subjects (1,2,3). Recent Cone-Beam CT studies (4,5) have shown strong correlations of Periodontal Disease (PD) to IPS at the base of the maxillary sinuses, where, in our experience (6), IPS is most often seen on Brain MRs. Since PD is a risk factor for atherosclerosis (7) and is linked to other inflammatory disorders (8), our study tests if IPS may serve as a clinically relevant biomarker for underlying PD.

Materials and Methods
Expedited review and waiver obtained. Subjects random, the first 15 MR Brain scans here by month Jan - Dec 2009, excluding duplicate scans. Two MR and 1 EMR reviewers, each blinded to the others' findings. All MR scans from 1.5 Tesla Magnet, Siemens Avanto, with primary Sagittal T2 weighted Fast Spin Echo scan (5.0 / 5.5 mm), Matrix 384sq; TR4390.0–5150.0/TE97.0; view 230 mm. Other sequences were also available. IPS was scored as 0 normal, 1 mild, 2 moderate, 3 severe for each non-maxillary sinus. Maxillary sinuses, being larger, were scored from 0 - 6 in a similar way. The IPS scores by subject were summed for total out of 30. Significant IPS was summed score >/=6, equivalent to at least 1 fully inflamed maxillary sinus. Number of posterior maxillary teeth on MR also read. Reader 1 read all 180 MRs, reader 2 read only 115 contrast scans, to check IPS score accuracy. EMR review by subject drawn from Vista-CPRS, the Veterans Health Administration EMR. History of Cerebrovascular Disease, Coronary Artery Disease, Aortic Aneurysm, Peripheral Arterial Disease, erectile dysfunction; smoking, diabetes, hypertension, obesity, hyperlipidemia, statin use, rhinosinusitis, ENT surgery and treatment for allergies noted. Other entities possibly linked to PD also noted. Raw Odds Ratios (OR) correlating significant IPS to demographics, PD co-morbidities and risk factors were calculated. Modified ORs were then calculated to assess for effect modifiers or confounders.

Results
Of 180 exams, 7 excluded for nasal tubes, large dental artifacts, recent ENT surgery. 173
subjects analyzed, M:F:156:17, age 23.3 - 97.7 yrs (Means - all 62.4, M 64.1, F 46.3), Race 104 white, 69 non-white. Indications for MR - table. IPS scores: 0/30, sinuses all clear, N=48(27.7%); 0.5/30, sinuses clear except for tiny mural foci, N=29(16.8%); 1-2/30, minimal IPS up to 5mm thick, N=47(27.2%); 3-5/30, mild IPS, >5mm thickening, N=29(16.8%); >/=6/30, significant IPS, N=20(11.5%). Reader comparison - no significant difference (mean difference of IPS score by exam 0.46/30; SD 0.60). Significant correlations of IPS score >/=6 were most marked for: history of Cerebrovascular Disease - (stroke, transient cerebral ischemia (TIA) and carotid disease), (N 57, OR 5.969; p<.001); hypothyroidism (N 13, OR 6.042; p<0.005) and race, OR 7.011, more common in whites than non-whites (p=.0107). Milder significant IPS correlations were to: smoking, hypertension, statin use, rhinosinusitis and Grave's disease. None of the other atherosclerotic diseases or proxies showed correlations to IPS >/=6. There were Nonsignificant trends to IPS >/= 6: males at 5 times risk to females (p<.2), temporal arteritis (OR 7.993, p<.2) and history of autoimmune disease (OR 2.693, p<.2) Of scenarios controlling for age, race, smoking, hypertension, rhinosinusitis, statin use, Grave's and hypothyroidism, only hypothyroidism had a significant modifying effect on the IPS correlation to carotid disease and sequelae, OR 10.142, p<0.0007

Conclusions
Our study has several implications. It suggests that IPS may serve as a biomarker for chronic PD, with correlations to several entities previously linked to PD. In the absence of ostial or nasal passage obstruction on MR, IPS may be reported as likely due to underlying PD. Further, significant IPS on MR may signify almost a 6-fold increased risk for carotid artery disease and its cerebral ischemic sequelae, as compared with subjects with sub-significant or no IPS. The study results support prior studies favoring a causal link between PD and carotid intimal thickening (9) and basal maxillary sinus thickening (3,4,10) respectively. The passage of inflammatory agents via small veins and lymphatics has been suggested as a mechanism for IPS causation from PD (10). While not in equal proximity to the gums as the maxillary sinuses, our results suggest that a similar pathway may purvey inflammatory agents from the gums to the carotid arteries.

Measurements of Normal Inner ear in Children with Congenital Sensorineural Hearing Loss and a “Normal Temporal Bone CT Scan”.

F Bahador¹, J Nabi¹, L Lewin², M Darke², J Connors¹, A Fallahian¹
¹University of Missouri Health Care, Columbia, MO, ²University of Missouri School of Medicine, Columbia, MO

Purpose
The purpose of this study was to use standardized measurements of the inner ear to see whether there are subtle bony malformations in children with congenital sensorineural hearing loss whose temporal bone computed tomography are normal based on the current criteria.

Materials and Methods
IRB approval was obtained. Medical records and the pure-tone audiometric results of 339 patients, diagnosed with sensorineural hearing loss in our tertiary referral center were reviewed. Children with perinatal infections were excluded from the study. The high resolution temporal bone CT scans of the remaining 112 patients were reviewed retrospectively by two reviewers independently. Patients with cochlear, labyrinthine, aqueductal or IAC anomalies also were excluded. Fifty-six patients with 90 ears met the eligibility criteria. The control subjects, who included 55 patients with 90 ears, had undergone CT for the evaluation of cholesteatoma, mastoiditis, external ear disease or trauma. The CT scans of the SNHL and the control groups were performed between June 2004 and September 2011, and between September 2005 and August 2011, respectively. Two readers including a mid-level radiology resident and a radiologist with 11 years experience who did not have any knowledge of the other reader’s interpretations or audiometric results reviewed all CT scans independently. Standardized measurements including maximal height and length of cochlea and vestibule, canal lumen width and bony island width of superior semicircular canal (SSCC) and lateral semicircular canal (LSCC), canal lumen width and inferior limb length of posterior semicircular canal (PSCC) were made on axial and coronal CT images. Correlation was made with short and long axes to avoid error in measurements.

Results
Student’s t test was performed to compare the measurements of the two groups. No significant difference in the measurements of the inner ear structures was found in children with SNHL and without SNHL for both readers.

Conclusions
Prior studies demonstrated mixed results with regard to meaningful differences in inner ear structures between the patients with SNHL and control group, however the results of our study do not support those findings and we believe studies with larger sample groups are required to elucidate any meaningful difference. On the other hand, while measurements of the inner ear demonstrate good reproducibility, however, given to the susceptibility to systematic errors in measurement, they could be difficult to interpret. Audiometric evaluation remains the main component of evaluation in patients with sensorineural hearing loss and radiologic evaluation of the inner ear is more helpful in identifying vestibulocochlear dysplasias and should be considered to complement audiometric analysis, until more data is available.

(Filename: TCT_eP-134b_Results.jpg)
D Singh, S Bhuta, C Hsu, G Kwan

Gold Coast University Hospital, Gold Coast, Australia

Purpose
Iatrogenic injury of the chorda tympani nerve is a recognized complication of otologic surgery. The aim of the study is to define the normal anatomical variation of the chordae tympani through the posterior canaliculus of the mastoid temporal bone on high resolution CT (HRCT).

Materials and Methods
Retrospective review of 13 consecutive normal HRCT temporal bones study (8 males and 5 females, mean age 41 years) was performed. Scanning protocol included Ultra Hi-res algorithm on a Siemens Flash dual source CT scanner with parameters of 120KvP, 230 mAs. Images were obtained at 0.3 mm thickness and reconstructed at 0.4 mm for interpretation was reviewed by two independent authors (DS and CC-TH) using a standardized approach to enable reproducible measurements of two distances: a) origin of chorda tympani from posterior genu of facial nerve and b) lateral most position of the chorda tympani from the mastoid segment of facial nerve. Right- and left-sided comparison to assess symmetry was analyzed with paired t-test.

Results
The chorda tympani nerve was identified in all patients. The mean distance of the chorda tympani origin form the mastoid segment of the facial nerve was 11.6 mm (standard deviation, SD=3.4, 95% CI: 10.2-13.0). This distance was 10.8±3.3 mm on the right side and 12.4±3.5 mm on the left (mean±SD), with no statistical significance between each side (p=0.27). The most lateral position of the chorda tympani from the facial nerve extended to a mean distance of 1.3 mm (SD of 0.6, 95% CI: 1.2-1.7), range 0 to 2.5 mm and was 1.3±0.6 mm 1.3±0.8 mm on the right side (mean±SD). No statistical significance between each side was observed (p = 0.11). In all patients chorda tympani entered the middle ear cleft immediately posterior to the tympanic membrane.

Conclusions
Chorda tympani can be identified reliably on HRCT temporal bone studies on 0.4 mm thickness images. Reproducible measurements demonstrate variability in both origin from the mastoid segment of the facial nerve and its lateral most course. No significant right- versus left-sided asymmetry was found. Precise description of the course of the chorda tympani with HRCT study may be useful for planning of otologic surgery to limit inadvertent injury to the nerve during surgery.

NEW APPLICATION OF ULTRASOUND FOR THE ASSESSMENT OF ORAL CAVITY CANCER – PILOT STUDY

S Foster, Y Anzai, J Dillon

University of Washington, Seattle, WA

Purpose
Oral cavity cancer (OCC) imposes particular challenges to radiologists. Clinical examination may underestimate the depth of tumor involvement and CT or MR imaging (MRI) evaluation
often is limited by artifact secondary to dental work. The accurate assessment of the size and extent of OCC is critical for treatment planning especially in regards to decisions for surgery versus chemotherapy and radiotherapy. Ultrasound (US) is a minimally invasive imaging modality to characterize OCC without ionizing radiation. The goal of this pilot study is to apply US for evaluation of OCC to compare size and extent with CT/MR as well as surgical specimen.

Materials and Methods

Patients with newly diagnosed OCC from the Oral Surgery Clinic in our institution were recruited prospectively for this study. Written informed consent was obtained from all patients. These patients undergo a standard clinical assessment as well as MRI or CT as part of their routine staging. The ultrasound was performed within one to two weeks of the MRI or CT. The ultrasound was performed using both an intra-oral and submental approach. The intra-oral scan was performed using a 7-15MHz hockey stick probe and the external submental scan was performed using a linear 7-25MHz probe. The tumors were assessed for size in AP, transverse, and cranial caudal dimensions. Both intra-oral and submental scans were obtained in coronal and para-sagittal planes. Additionally, invasion of neurovascular structures within the sublingual space, involvement of extrinsic tongue muscles and distance from the midline raphe of the tongue were assessed when applicable. The size and extent of the tumors was compared between preoperative clinical assessment by the surgeon, MRI, ultrasound and with the pathological report from the surgical resection when available.

Results

Ultrasound adequately visualized the tumors in five out of seven patients. While the tumors were not clearly visualized with MRI/CT due to significant dental hardware artifact in two out of seven patients, ultrasound was successful in visualizing the lesions. In the five patients that went on to surgical resection, the ultrasound measurements correlated closely with the actual lesion size in three of the patients, minimally underestimated the size in one patient and minimally overestimated size in one patient. Ultrasound measurement closely correlated with estimated clinical size in six out of seven patients. Compared with the MRI measurements of the lesions, ultrasound correlated well in all comparable cases except one in which, neither MRI, ultrasound or clinical estimate of tumor size were comparable with the actual tumor size on pathological specimen.

Conclusions

Ultrasound is a useful adjunct imaging technique for assessment of oral cavity tumors, in particular when CT or MR is limited due to dental hardware. The assessment of tumor size on ultrasound appears to correlate well with the measurements of the lesions based on clinical assessment, MRI and pathological size in the majority of cases. The potential clinical application of ultrasound for evaluation of OCC is assessment of depth in relatively superficial tongue cancer or evaluation of deep extension to the neurovascular bundles.

Optimization and Diagnostic Utility of Dual Energy Multi-detector CT in Non-contrast CT Examination of the Head

Purpose
Dual Energy CT (DECT) allows for user-defined contributions from 80kVp and 140kVp weighting within the image. The diagnostic utility and optimal parameters of DECT for brain imaging have not been fully addressed in the literature. The aim of this study is to assess for the...
optimal parameters of DECT in evaluation of routine non-contrast head CT, by prescribing precise percentile contributions of the two different energy spectra and to compare image quality between routine non-contrast DECT versus conventional single energy CT (SECT).

**Materials and Methods**

Thirty patients underwent DECT of the head (Somatom Flash dual source CT, Siemens, Forcheim, Germany) using tube voltages of 80 and 140kVp. All patients had identical CT acquisition parameters. Studies were prospectively collected. Raw data were reconstructed using a soft convolution kernel and fused images were post-processed using a range of weighting factors which by convention are described as the percentage contribution of the 80kVp tube (0.1, 0.3, 0.5, 0.7, 0.9). Five sets of images were generated for each case. Three neuroradiologists blinded to the weighting factor and patient demographics evaluated these images independently based on 7 criteria: 1. pons visualization with regard to beam-hardening artifact; 2. clarity of the temporal lobes at the level of the ventricular horns; 3. distinctness of the insular cortex; 4. sharpness of the boundaries between the different components of basal ganglia; 5. centrum semiovale gray-white differentiation; 6. cortical sulcal clarity; and 7. overall image quality. The 7 criteria were assessed independently to avoid intra-observer bias. The reviewers selected the best and worst image for each criterion. Rank analysis was performed. In four patients, a previous non-contrast SECT of the head was performed utilizing the same scanner. Redacted SECT images were presented alongside 0.3 and 0.7 DECT images and ranked based on pontine artifact; deep nuclei visualization, gray-white matter distinction, cortical sulcal visualization and overall image quality.

**Results**

For pontine and cortical sulcal evaluation a low weighting factor (average of ~0.2) was considered to yield the optimal diagnostic image, whereas a high weighting factor was deemed the worst. For basal ganglia, gray-white differentiation and insular cortex evaluation, a high weighting factor (> 0.6) was considered to yield better diagnostic images. The categories of temporal lobe visualization and overall image quality showed high variance and no weighting factor was clearly superior. Radiation dose between DECT and SECT groups did not differ. DECT image quality consistently ranked higher than SECT for all criteria.

**Conclusions**

This study demonstrates that kV weighting factor renders a dramatic influence on the diagnostic quality of DECT brain imaging. Generally, a low weighting factor (0.2) is optimal for beam hardening artifact reduction and structural definition, whereas a high weighting factor (>0.6) is optimal for tissue contrast and conspicuity. Our findings indicate that two different weighting factors should routinely be included in DECT exam of the head to provide best diagnostic quality. Furthermore, our results suggest that DECT is superior to SECT for routine evaluation of the brain.

Prevalence of venous sinus stenosis in pseudo tumor cerebra using digital subtraction angiography

M Ibrahim¹
Purpose: To Study the prevalence of intracranial venous stenosis in Pseudo cerebra patients.

Materials and Methods
Patients and methods: Thirty patients diagnosed as pseudo cerebra according to Dandy criteria. All underwent general and neurological assessment. Radiological assessment included CT scan brain +/- MRI brain without contrast, MRV. All underwent digital subtraction cerebral Angiography (DSA) (venous phase) to confirm the validity of filing gaps seen at the level of MRV.

Results

Results: MRV brain showed that 24 patients (80%) showed filling gaps. Digital subtraction cerebral angiography (venous phase) showed 9 patients (30%) had stenosis in their dural sinuses. MRV showed to be a good screening tool since it had 100% sensitivity and negative predictive value. However, since it has a moderate specificity (62%) with a positive predictive value (PPV) of only 35%, then lesions detected should be confirmed with digital subtraction cerebral angiography (venous phase) particularly those involving the transverse and sigmoid sinus.

Conclusions
Confirm with digital subtraction cerebral angiography (venous phase) particularly those involving the transverse and sigmoid sinus.

Progression of Optic Nerve Ischemia on MR Imaging after Spinal Surgery

L Robinson1, J Yi2
1Bryn Mawr Hospital, Philadelphia, PA, 2Bryn Mawr Hospital, Bryn Mawr, PA

Purpose
Spine surgery is a risk factor for the development of optic nerve ischemia. While the ischemic pattern of the brain has been well documented with MR imaging (MRI), there are very few cases that show evolution of optic nerve ischemia with MRI. The MRI characteristics of posterior ischemic optic neuropathy has similar imaging characteristics and evolution to brain ischemia. MR imaging may be of benefit in identifying early cases of posterior ischemic optic neuropathy.

Materials and Methods
MR images of the orbits and brain were obtained over a three-week period.

Results
This case shows evolution of optic nerve ischemia similar to what is seen with brain ischemia, a finding that has not been described completely in the literature. Initial imaging showed restricted diffusion without significant enhancement. Imaging two weeks later showed resolution of restricted diffusion with development of bilateral optic nerve enhancement. These findings coincided with the patient's timing and clinical presentation of loss of vision and bilateral optic nerve infarcts. There have not been any articles published showing the progression of an optic
nerve infarct using DWI to confirm lack of diffusion with progression to optic nerve enhancement.

Conclusions
The MR imaging characteristics of stroke have been described very well in the brain, findings that also are seen in optic nerve ischemia. In the acute phase of ischemia increased signal can be seen on the diffusion-weighted images within 30 minutes of onset and lasts up to 10 to 14 days. Enhancement can be seen in the subacute phase starting between days four to seven and can last up to eight weeks. There are several types of visual loss that can occur following nonocular surgery including anterior ischemic optic neuropathy (AION), posterior ischemic optic neuropathy (PION), central retinal artery occlusion (CRAO), pituitary apoplexy and cortical blindness. Of these subtypes PION is the most frequent to occur following spinal surgery. The rate of postoperative vision loss varies in the literature between 0.1% to 0.2%. Risk factors from back surgery includes prone surgery, long operative time, massive hemorrhage and anemia. The patient had several risk factors for ischemic neuropathy of the optic nerve including obesity, position from back surgery and diabetes mellitus. The pathogenesis of postoperative PION is currently unknown. Several possible causes of postoperative PION include hypotension, patient positioning and anemia serve as a possible explanation. One possible explanation for ischemia is that patient positioning may lead to venous congestion which causes decreased intraocular pressure and leads to optic nerve ischemia. The posterior optic nerve is supplied by pial branches that originate from the ophthalmic artery, arteries that may not have the capabilities to autoregulate in conditions of severe hypotension. Although PION is important to recognize in its early stages, there is no standardized treatment at this moment. In the future MRI may be of benefit with early identification of patients with PION. Perhaps optimizing control of risk factors, limiting operative time and avoiding intraoperative hypotension may help avoid what can be a devastating disease.

Role of diffusion weighted MR imaging in differentiation Graves’ disease from painless thyroiditis

A Abdel Razek¹
¹Mansoura University, Mansoura, Egypt

Purpose
To assess the role of diffusion-weighted MR imaging in differentiating Graves' disease from painless thyroiditis.

Materials and Methods
Thirty-seven consecutive patients with thyrotoxicosis underwent diffusion MR imaging of the thyroid gland and thyroid function tests. Diffusion-weighted MR images were acquired with a b-factor of 0.250 & 500 sec/mm² using a single shot echo planar imaging. The scanning parameters were: TR= 10000 ms, TE=108ms, bandwidth=125 kHz, slice thickness =4 mm. The apparent diffusion coefficient (ADC) value of the thyroid gland correlated with thyroid function tests. Twenty healthy subjects served as a control underwent the same MR study.

Results
There was significant difference in the ADC value between patients with thyrotoxicosis and volunteers (P=0.003). The mean ADC value of thyroid gland in patients with Graves' disease was 0.66 ±0.22X 10⁻³ mm²/sec in patients with painless thyroiditis was 0.81 ±0.17X 10⁻³ mm²/sec. There was significant difference in the ADC values of patients with Graves' disease and painless thyroiditis (P<0.002). When ADC value of 0.72 X10⁻³ mm²/sec was used as a threshold value for differentiating of Graves' disease from painless thyroiditis, the best result was obtained with an accuracy of 90%, sensitivity 92%, specificity 91%, positive predictive value 85% and negative predictive value of 86%. The mean ADC value correlated with serum free T3 (r =0.85) and TSH (r=0.84).

Conclusions
We concluded that ADC value of thyroid gland can be used for diagnosis of thyrotoxicosis and to differentiate Grave's disease from painless thyroiditis.

Role of diffusion weighted MR imaging in differentiation of Sjogrene disease from IgG4-related dacryoadenitis and sialadenitis

A Abdel Razek¹
¹Mansoura University, Mansoura, Egypt
Purpose
To assess role of diffusion MR imaging in differentiation of Sjögren's disease from IgG4-related dacryoadenitis and sialadenitis.

Materials and Methods
This study was conducted upon 24 consecutive patients (8 male and 14 female aged 15-29 years) with bilateral diffuse lacrimal and or parotid enlargement. They underwent single shot echo planar diffusion-weighted MR imaging of head and neck with b-factors of 0, 500 and 1000 sec/mm2. Apparent diffusion coefficient (ADC) maps were reconstructed. The ADC value of the lacrimal gland was calculated.

Results
The mean ADC value in Sjogren's disease (0.98±0.12X10⁻³ mm²/sec) was significantly lower (P<0.001) than that of IgG4-related dacryoadenitis and sialadenitis (1.12±0.11X10⁻³ mm²/sec). When apparent diffusion coefficient value of 1.02X10⁻³ mm²/sec was used as a threshold value for differentiating Sjogren's disease from IgG4-related dacryoadenitis and sialadenitis, the best results were obtained with an accuracy of 89%, sensitivity of 94%, specificity of 82%, negative predictive value of 91% and positive predictive value of 93%.

Conclusions
Apparent diffusion coefficient value is a noninvasive promising imaging modality that can be used for differentiation of Sjogren's disease from IgG4-related dacryoadenitis and sialadenitis.

Stationary Digital Tomosynthesis for Neuroradiology Applications

Y Lee¹, L Burk², J Lu², J Shan², O Zhou²

¹The University of North Carolina at Chapel Hill, Chapel Hill, NC, ²The University of North Carolina at Chapel Hill, CHAPEL HILL, NC

Purpose
Linear tomography was invented to visualize planes of structures within the body soon after the discovery of x-rays. However, after computed tomography (CT) was invented, linear tomography's use declined. More recently, there has been significant renewed interest in digital x-ray tomosynthesis, which utilizes limited angle acquisition and reconstruction to generate a pseudo 3-D volume. The current clinical applications for x-ray tomosynthesis have focused on breast and chest imaging, however, the physical translation of the x-ray tube has limited both resolution and imaging speed. The carbon nanotube (CNT) based x-ray source enables the creation of completely stationary tomosynthesis systems with both linear and non-linear geometries. This allows faster imaging with no associated focal spot blur. The goal of the study was to explore these novel stationary tomosynthesis systems for neuroradiology applications.

Materials and Methods
A stationary tomosynthesis setup was implemented with prototype linear and non-linear geometry multi-beam CNT based x-ray sources. Additional non-linear geometries were also simulated using physical translation of the CNT x-ray tubes. Images were acquired with a conventional digital flat panel detector and reconstructed with a filtered back-projection based
reconstruction algorithm (Real Time Tomography, Villanova, PA). A pseudo 3-D volume was created for each acquisition, reconstructed to 1 mm slice thicknesses. Imaging was performed on both phantom and cadaveric specimens using body part specific protocols. Specific areas of interest included the face, sinuses, and the cervical, thoracic and lumbar spine. A reader study was performed with board-certified neuroradiologists and trainees to evaluate the utility of the images for visualizing the osseous structures in the areas of interest. Readers were asked to document their confidence in localization of structures and the degree of osseous detail in the tomosynthesis image stack. Readers were also asked to identify the presence of artifacts, and the interpretability of the images in the presence of the artifacts.

Results
Stationary digital tomosynthesis images were successfully acquired of each of the regions of interest. Average scan times were approximately 10 to 15 seconds (linear acquisition) and primarily limited by detector readout times. In-plane image quality was felt to be high, and effective for localization and the evaluation of osseous detail. Spatial localization in the through plane was more limited, as anticipated with the tomosynthesis acquisition approach. Artifacts were greatest when there was significant bone overlap, such as in the sinuses. Wider angles of acquisition were more effective at removing these overlap artifacts, at the expense of requiring a wider angle of x-ray acquisition. Soft tissue evaluation was severely limited, as expected. Radiation dose was measured to be approximately 20% of conventional CT acquisitions.

Conclusions
Stationary digital tomosynthesis has the potential to provide high resolution in-plane imaging for neuroradiology applications. Though conventional CT has advantages in true 3-D imaging and multi-planar reconstruction, the ability to acquire 3-D images using a system with no moving parts has significant potential in mobile, trauma, and battlefield type applications. Furthermore, the potential radiation dose reduction compared to CT would further enhance applications in radiation sensitive populations. Work is ongoing to develop a full clinical prototype system.

**Ultrasound Guided Thyroid Nodule Biopsy and Correlation with Imaging Features**

Z Junwei\(^1\), A Gopinathan\(^1\)

\(^1\)National University Hospital, Singapore, Singapore

Purpose
To evaluate sonographic features predictive of malignancy or benignity in thyroid nodules.

Materials and Methods
From a registry of 559 ultrasound guided fine-needle aspiration biopsies (FNABs) performed at a single tertiary institution between January 2010 and April 2013, 388 thyroid nodules in 325 patients (M:F 61:264; mean age: 52.5 years) which had a pathological diagnosis and pre-biopsy diagnostic ultrasound study were identified. The pre-biopsy ultrasound images were reviewed by a radiologist blinded to the pathological diagnosis. The sonographic features of the thyroid nodules were assessed with respect to their echotexture, shape, margins, size, multiplicity, vascularity, calcifications, extrathyroid extension and cervical lymphadenopathy. A Fisher's
exact test was performed. Sensitivity, specificity, and positive and negative predictive values were obtained.

Results
Malignancy was noted in 7% of the nodules. The presence of microcalcifications (sensitivity, 44.4%; specificity, 98.9%), irregular margins (sensitivity, 59.3%; specificity, 97.8%), marked hypoechogenicity (sensitivity, 38.5%; specificity, 98.5%) and a taller-than-wide shape (sensitivity, 22.2%; specificity, 94.5%) were features consistently seen in malignant nodules while benign nodules were isoechogetic (sensitivity, 56.8%; specificity, 88.5%), had comet tail artifacts (sensitivity, 31.9%; specificity, 96.2%), had a hypoechoic halo (sensitivity, 67.6%; specificity, 88.0%) and were purely or predominantly cystic (sensitivity, 21.6%; specificity, 96.3%). The association between these sonographic features and malignancy or benignity of the nodule was statistically significant (p<0.05). All 5 nodules associated with cervical lymphadenopathy were malignant. The presence of at least one malignant finding had a sensitivity of 85.2%, a specificity of 91.1% and a diagnostic accuracy of 90.7%.

Conclusions
Sonographic features are useful in differentiating between malignant and benign thyroid nodules. High sensitivity, specificity and diagnostic accuracy for malignancy can be achieved using a combination of features.

Adjunctive C-arm CT Imaging with Mechanical Thrombectomy Using Solitaire Stent Retriever for Endovascular Recanalization in Acute Ischemic Stroke.

B Mitchell¹, P Chinnadurai², G Chintalapani³, H Morsi⁴, H Shaltoni⁴, M Mawad⁵
¹Baylor College of Medicine, Houston, TX, ²Siemens Medical Solutions USA Inc., Hoffman Estates, IL, ³Siemens Medical Solutions USA Inc, Hoffman Estates, IL, ⁴St. Luke’s Hospital, Houston, TX, ⁵Baylor College Of Medicine, Houston, TX

Purpose
Rapid treatment of acute stroke with endovascular methods frequently depends on acquiring as much information as possible regarding vessel blockage and distribution of any thrombi in order to effectively deploy retrievable stent thrombectomy devices. We describe the use of C-arm CT in conjunction with mechanical thrombectomy during treatment of acute stroke to aid vascular recanalization efforts.

Materials and Methods
Intra-procedural C-arm Computed Tomography was used in a series of 18 consecutive patients undergoing endovascular treatment to determine areas of maximal stent distortion during thrombectomy for treatment of an acute stroke. Patient outcomes were then analyzed including
extent of reperfusion, post-treatment changes in NIH Stroke Scale, patient survival, and the presence of post-treatment hemorrhage.

Results
Eighteen consecutive cases of acute stroke treatment using Solitaire Retriever devices were included in this study. Intra-procedural C-arm CT allowed for clear visualization of stent distortion in areas of arterial blockage, indicating accurate stent placement. Clot removal with successful recanalization of occluded cerebral arteries was achieved in 15/18 cases (83.3%) with TICI scores of 2B/3 all patients with initial recanalization, using combined C-arm CT and retrievable stent thrombectomy, NIH stroke scale improved on average from 19 pre-treatment, to 11 post-treatment, and 72% of patients survived. Post treatment hemorrhage was observed in 28% of patients (5/18), with 4 of those 5 patients having achieved recanalization during treatment.

Conclusions
Use of C-arm CT may aide the positioning of stroke treatment devices for more rapid treatment and maximally efficient device placement, maximizing the possibility of rapid arterial recanalization following acute embolic stroke. Our data indicates that the severity of strokes can be reduced rapidly by using this method of mechanical thrombectomy.

KEYWORDS: Stents, Stroke, Thrombectomy

Treatment with retrievable stent placement across thrombosed MCA. (A) A-P fluoroscopic view of deployed Solitaire stent device on the first pass across the thrombus. Visualization of the device is poor; arrows indicate approximate location of the stent. (B) C-arm CT of the deployed stent across thrombus – note the narrow diameter of the stent, indicating presence of surrounding thrombus, preventing the stent from full expansion (C) A-P fluoroscopic view of second-pass of the Solitaire device. (D) C-arm CT of the second-pass of the solitaire device - now the stent is able to more fully expand within the artery, although there is still thrombus present. (E, F) 3-D reconstructions of first-pass (gray) and second-pass (red) showing interval expansion of the stent once a large portion of the thrombus had been removed. (G) Retrieved thrombus from the first and second passes in the MCA.
An Analysis of Intraoperative Adverse Events for Interventional Therapy of Intracranial Aneurysms Based on Ruptured Status

S Mangla¹, Y Karim¹, A Eldib¹
¹SUNY Downstate Health Science Center, Brooklyn, NY

Purpose
Interventional therapy has become the primary treatment modality for cerebral aneurysms in most cerebrovascular centers. A growing volume of experience has demonstrated increased capability to successfully treat a larger variety of morphologies and presentations. We analyzed our single operator experience including primary success, retreatment rates, use of adjunct devices, and adverse events with respect to presentation, unruptured cerebral aneurysms (UIAs) vs. SAH/ICH associated aneurysms (SAHa).

Materials and Methods
We performed a retrospective review of clinical records and imaging of a prospectively maintained database of aneurysm therapies performed from 3/01/04 to 6/30/13. Data gathered included presentation (SAHa/UIA), primary success of treatment, retreatment, adjunct devices (stents/balloons), intra-operative adverse events (embolic/hemorrhagic), and immediate clinical outcome (<24 hours).

Results
A total of 131 aneurysms were treated in 107 patients in 123 operations (66 UIA and 65 SAHa). Treatment was successfully achieved in 124/131 (94.7%), and 9/131 (6.9%) represented retreatments or staged operations. Stents were employed in 15/131 (11.5%), and Balloon remodeling in 47/131 (35.9%). In the SAHa group, we experienced 7 (10.8%) intraoperative perforations of the aneurysm with no neurological deficit/change, disabling stroke, or death in 2(3.1%), 2(3.1%), 3(4.6%) patients respectively. Embolic events (including coil migration) were experienced in 2(3.0%) operations: 1(1.5%) with no deficit, 1(1.5%) disabling stroke, 0 deaths. In the SAHa group, overall intraoperative mortality(<24hrs) was experienced in 3(4.6%), with disabling stroke in 3(4.6%). In the UIAs, we experienced 2(3.0%) intraoperative perforations of the aneurysm with no neurological deficit/change, disabling stroke, or death in 2(3.0%), 0(0%), 0(0%) patients respectively (Table). Embolic events (including coil migration) were experienced in 3(4.5%) operations: 1(1.5%) with no deficit, 2(3.0%) disabling stroke, 0 deaths. In the UIAs group, overall intraoperative mortality was 0 with disabling stroke in 2(3.0%).

Conclusions
Cerebral Aneurysms presenting with SAH/ICH are at significantly higher risk of experiencing aneurysm perforation when compared with UIAs. Embolic event rates are similar between the groups. Overall intra-operative disabling morbidity and mortality rates for aneurysm therapy are higher with ruptured presentation (9.2%) vs. (3.0%).

Analysis of radiation dose trends and practices during diagnostic cerebral angiography before and after the implementation of dose reduction strategies

M Pearl¹, T Schneider², E Wyse³
¹The Johns Hopkins University School of Medicine, Baltimore, MD, ²The Johns Hopkins University, Baltimore, MD, ³Johns Hopkins Hospital, Baltimore, MD

Purpose
Despite the increased utilization of noninvasive imaging, cerebral digital subtraction angiography (DSA) remains the gold standard technique for the evaluation of many cerebrovascular disorders. This study analyzes the radiation dose trends and practices during diagnostic cerebral angiography before and after the implementation of radiation dose reduction strategies.

Materials and Methods
This study was approved by our Institutional Review Board. A retrospective review of a single operator's prospectively collected cerebral angiograms from 2010 to 2013 was performed. Inclusion criteria included adult and pediatric patients undergoing a diagnostic cerebral angiogram from January to June 2010 to 2013. Embolization procedures were excluded as well as those patients in whom the radiation dose reports were unavailable. A maximum number of 50 adult cases per year were considered. All angiograms were performed using a biplane angiography system (Artis Zee, Siemens, Germany). Cerebral angiograms and procedure exam protocols were reviewed for patient age, gender, diagnosis, angiography techniques (DSA frame rate, number of exposures, inclusion of aortic arch evaluation, 3D-DSA, or DynaCT), and radiation dose expressed as fluoroscopy time, reference point air kerma (K\(_{a,r}\) in mGy), and kerma-area product (PKA in µGym²).

Results
From January 2010 to June 2013, a total of 231 diagnostic cerebral angiograms were reviewed including 200 adults and 31 children. Adult patients ranged from 19 to 94 years (median 54 years) and included 77 men and 123 women. Pediatric patients ranged from 2 to 18 years (median 10 years) and included 11 boys and 20 girls. The most common diagnoses in adult patients were unruptured intracranial aneurysm (36%) and subarachnoid hemorrhage (18.5%), whereas in children, moyamoya vasculopathy (35.5%) and arteriovenous malformation (22.6%) predominated. The median K\(_{a,r}\) and PKA per adult patient significantly decreased from 2010 (1867 mGy, 21,231 µGym²) to 2013 (653 mGy, 7,860 µGym²), (p < 0.001). The same trend was observed in pediatric patients: 2010 (644 mGy, 6,495 µGym²) and 2013 (138 mGy, 1,465 µGym²). The average DSA frame rate per year decreased for both adults from 3.94 f/s (2010) to 2.04 f/s (2013) and children, 4.22 f/s (2010) to 2.07 f/s (2013). Figure 1. The boxplots show a continuous decline in the median patient radiation doses, expressed as K\(_{a,r}\) (left image) and PKA (right image), since 2010.

Conclusions
Increased radiation awareness and implementation of radiation dose reduction strategies resulted in decreased radiation doses both in adult and pediatric patients. The use of lower and variable DSA frame rates as well as tailored examinations contributed significantly to the reduced radiation doses observed during diagnostic cerebral angiography without a perceived reduction in imaging quality or clinical value.
Anterior Cerebral Artery Embolism as a Complication of Mechanical Thrombectomy of Middle Cerebral Artery Occlusion

J Jacinto¹, I Fragata², A Nunes³, C Ribeiro², J Reis³, J Alcantara¹, A Silva¹  
¹Centro Hospitalar de Lisboa Central, Lisboa, Portugal, ²Centro Hospitalar Lisboa Central, Lisboa, Portugal, ³Centro Hospitalar Lisboa Central, Lisbon, Portugal

Purpose
Mechanical thrombectomy is an effective procedure in acute stroke caused by large vessel occlusions. Clot fragmentation and migration can occur as an adverse event, and potentially be a source of embolism to other arteries. Anterior Cerebral Artery (ACA) embolism after Middle Cerebral Artery (MCA) thrombectomy has been reported and studied. The aim of our study was to assess its frequency and clinical impact in a single centre experience.

Materials and Methods
We analyzed our prospective acute stroke registry and identified 77 patients with isolated M1 occlusions treated by mechanical thrombectomy between May 2009 and December 2012. We reviewed clinical data on admission and after thrombectomy, angiographic images, technical aspects on the thrombectomy procedures, and follow-up imaging to document for ACA infarcts.

Results
11 patients were excluded by insufficient data. A total of 66 patients with M1 thrombectomy
procedures were analyzed. In 77.2% of cases a stent retriever was used. Concerning the total number of patients, the mean TICI score was 2.2. All procedures included proximal occlusion with balloon-guide catheter and distal aspiration. 5 patients (7.6%) had documented embolism to the ipsilateral ACA (one bilateral). ACA recanalization (chemical and/or mechanical) was attempted in all cases, and was successful in 4 with a final TICI score of 2b. On the follow-up imaging, 3 patients (4.5%) had acute ACA infarcts but without significant increase in NIHSS score after the procedure.

Conclusions
ACA embolism is a known complication of MCA thrombectomy. This study reported an incidence of 7.6% of this complication, less when compared to other similar studies. The routine use of proximal occlusion and distal aspiration while performing thrombectomy probably reduced the possibility of clot migration in our series of cases. ACA infarcts on imaging studies occurred in 3 of the 5 patients that had ACA embolism but there was not a significant clinical impact.

Calcium Polyphosphate: A New Radio-opaque Liquid Embolic Agent

E Valliant1, A Momeni2, J Shankar3, R Abraham3, P Colp4, M Filiaggi1

1Applied Oral Sciences, Dalhousie University, Halifax, Nova Scotia, 2Bioengineering, Dalhousie University, Halifax, Nova Scotia, 3Diagnostic Imaging and Interventional Radiology, QEII Health Science Centre, Dalhousie University, Halifax, Nova Scotia, 4Histology, Dalhousie University, Halifax, Nova Scotia

Purpose
Current liquid embolic agents for vascular embolization are not inherently radio-opaque. These materials require the addition of a contrast agent for radio-opacity. Calcium polyphosphate (CPP) is a novel, inherently radio-opaque two-part embolic agent that forms a gel in situ when a sodium polyphosphate solution and a calcium solution are injected simultaneously, with the divalent calcium ions creating crosslinks between the polyphosphate chains. This work examines the in vivo biocompatibility, setting and occlusion ability of this new liquid embolic agent in a rabbit model.

Materials and Methods
Three New Zealand white female rabbits (4-5 kg) were subcutaneously implanted in the back with pre-formed CPP gels, Surgifoam® gelatin sponge controls (soaked for 2 h in 50% iodated contrast), Onyx18® controls (soaked for 2 h in phosphate buffer solution) and sham surgery sites for 1 and 2 weeks. Just before euthanasia, the central artery of each rabbit ear was embolized by 0.25 mL of polyphosphate solution (0.933 mol L−1 PO3, 2.2 mol% Sr, 9 mol% Ba and 3.8 mol% Ca) and an equal volume of 0.33 M CaCl2. The solutions were simultaneously injected through a concentric needle device to model a dual lumen catheter. Formation of gel in the vessel and occlusion was confirmed by x-ray and histology. Tissues were explanted, sectioned while frozen (10 µm), stained with H&E and examined by light microscopy (magnification x40).
Results
Biocompatibility tests showed no signs of adverse reaction, inflammation, swelling or macroscopic changes in the tissue surrounding the subcutaneous implants after 1 and 2 weeks. On histology, a new reaction layer of cells had formed around the implants by 1 week but not in the sham surgery sites (Fig. 1). This layer had a similar morphology for all implants and was thinnest surrounding Onyx®, and thickest surrounding the gelatin sponge (as indicated by arrows). The gelatin sponge also had the greatest resorption at two weeks when cell ingrowth into the porous gelatin matrix was observed. CPP embolic agent successfully occluded the auricular artery in a controlled fashion over several minutes and distal penetration of contiguous small arteries was demonstrated (Fig. 2a). Histological cross-sections of the central artery of the ear confirmed complete cross-sectional filling (d=0.48 mm) (Fig. 2b).

Conclusions
A novel CPP based radio-opaque liquid embolic agent demonstrates initial biocompatibility and forms a gel in vivo which successfully occluded a rabbit auricular artery.

KEYWORDS: Embolization
Carotid Elongation Does not Affect Angiographic Results of Mechanical Thrombectomy in Acute Stroke

U Yilmaz, R Mühl-Benninghaus, A Simgen, W Reith, H Körner
Saarland University Hospital, Homburg, Germany

Purpose
New techniques have substantially raised recanalization rates of mechanical thrombectomy in acute ischemic stroke in the last few years with initial prospective trials reporting good neurological outcomes in up to 58% of the cases. However some recent highly disputed reports questioning the benefit of endovascular therapy have boosted the discussion about the importance of patient-selection. The purpose of this study was to investigate whether an elongation of the carotid artery affects the angiographic outcome of the recanalization procedure in MCA-occlusions.

Materials and Methods
The data of 54 patients with occlusions of the M1-segment who underwent mechanical thrombectomy was included. The lengths of the carotid arteries were measured using preinterventional CT-angiograms. To take individual patient height into account these lengths were divided by the length of the spine from the tip of the dens to the bottom of the th3 vertebral body (referred to as CS-Ratio). Angiographic results were scored according to the mTICI-score.

Results
Recanalization with mTICI ≥ 2b was achieved in 83.3%. The mean CS-Ratio was 1.32 ± 0.13. There was a significant correlation between the CS-Ratio and the age of the patients. There were no significant differences in the CS-Ratios of occlusions that were successfully recanalized and those that were not. Neither were there significant correlations of the CS-Ratio and the length of procedure or the number of deployments of the stentretrievers.

Conclusions
In this retrospective analysis we report that carotid elongation does not affect angiographic results of mechanical thrombectomy in acute stroke.

Clinical Outcome in Acute Embolic Stroke With High Clot Burden: Comparison of Neurothrombectomy and Systemic Thrombolysis

A Rohr, A Binder, J Meyne, C Riedel, R Stingele, O Jansen, G Deuschl
University Clinic Kiel, Kiel, Schleswig-Holstein, DRK Kliniken Berlin Köpenick, Berlin, Berlin-Brandenburg
Purpose
To evaluate the efficacy and safety of neurothrombectomy in the treatment of acute embolic stroke in patients selected by a thrombus length of >= 8 mm using the stent-retriever Trevo Pro device.

Materials and Methods
Forty patients (mean age 66.7±14 years; 27 females) with acute artery occlusion in the anterior circulation with a thrombus length of >= 8 mm as measured on non contrast-enhanced cranial CTs were treated with neurothrombectomy additionally to standard stroke treatment between January 2011 and March 2012 (mean NIHSS on admission 15.3). Twenty-five patients were treated with mechanical thrombectomy alone, the remaining patients were treated with additional i.v.-thrombolysis (bridging concept). We compared the outcome to a historical group of 42 patients (mean age 71.5±11.6; 21 females) with a thrombus length of >= 8 mm that received systemic thrombolytic therapy only (mean duration of symptoms 74.3±27 minutes, mean NIHSS on admission 13.1). Clinical outcome (modified Rankin scale) was assessed on admission, at discharge and at day 90.

Results
Thrombectomy group and control group data on admission did not differ except for time from symptom onset until time of admission (156.2 min vs. 74.4 min; p=0.001). The mean duration from admission to start of angiographic interventions (including time to establish general anaesthesia) was 75.8±37.1 minutes (range 29 to 189 minutes). Artery recanalization (Thrombolysis In Cerebral Infarction Score 2b or 3) was achieved in 33 patients (83%). The mean time from symptom onset to recanalization was 319.9±99 minutes. Treatment-related complications occurred in 3 patients (8%). Mean modified Rankin scale score on admission was 4.6±0.6 (thrombectomy) vs. 4.38±0.8 (control), at discharge 3.00±1.8 vs. 4.7±1.3, (p<0.01) and at day 90 2.6±1.8 vs. 4.8±1.2 (p<0.01), respectively. On Day 90, 7 vs. 24 patients experienced no improvement on the modified Rankin scale. Symptomatic intracranial hemorrhage occurred in 3 vs. 7 patients, 3 vs. 17 patients died within 90 days (thrombectomy vs. control each).

Conclusions
This study in patients with high clot burden found that thrombectomy with the Trevo Pro device has an acceptable risk and was superior to iv-thrombolysis alone. This suggests that stratifying treatment for clot length by 8 mm might be a powerful approach to improve the outcome of mechanical thrombectomy.

KEYWORDS: Stroke, Thrombectomy, Thrombolysis
unruptured intracranial aneurysms from January 2010 to May 2012 in Halifax Infirmary Hospital. The coil protrusion was divided into: mass, loop, tail or no protrusion. These patients were followed up both clinically and by imaging. The use of anti-platelet and any thromboembolic events during the procedure and in the follow up visits were documented.

Results
We had 90 patients and 93 aneurysms. Ruptured aneurysms were 53 (57%) and unruptured aneurysms were 40 (43%). Thirteen aneurysms (14%) of unruptured aneurysms were treated using SILK flow diverter. Anterior circulation aneurysms account for 62.4% and posterior circulation account for 37.6% of total aneurysms. Balloon remodeling was used in 9 patients, stent was used in 4 patients and double microcatheter technique in one patient. Most of the coiling were not protruding into the parent vessel (54.2%). Loop protrusion is seen in 25%, mass protrusion in 18% and tail protrusion in 2.8%. Antiplatelet was prescribed to 36.4 % of patients with coil protrusion. Thromboembolic events were noted in one patient with no protrusion, one patient with loop protrusion on Antiplatelet and in one patient with loop protrusion who did not receive Antiplatelet. Seven patients died within 30 days of coiling, all of them presented with SAH.

Conclusions
There is small risk of thromboembolic events if part of the coiling protrudes into the parent vessel.

Development and Validation of an Endovascular Chemotherapy Filter Device for Removing High-Dose Doxorubicin from the Blood: In Vivo Porcine Study

S Hetts¹, A Patel¹, A Chin², J Yang¹, B Thorne¹, A Losey¹, M Wilson¹
¹UCSF, San Francisco, CA, ²ChemoFilter, Hillsborough, CA

Purpose
A novel disposable endovascular chemotherapy filter (CF) device was developed to remove excess doxorubicin (Dox) from the blood during intra-arterial chemotherapy delivery to prevent systemic toxicities. Previous proof-of-concept established the capacity of the filter to bind Dox in swine serum in vitro. In this study, CF navigation, deployment and in vivo Dox binding was evaluated in the porcine inferior vena cava (IVC).

Materials and Methods
An 18 Fr CF device was constructed with an ion-exchange membrane attached to an expandable 28 mm diameter Nitinol frame. Under X-ray fluoroscopy and contrast venography, the CF was percutaneously introduced via the internal jugular vein and deployed in the porcine infrarenal IVC. 50 mg of Dox (2 mg/ml) was injected over 10 min in the IVC below the CF device. Venous catheters with tips proximal and distal to the CF device in the infrarenal IVC obtained pressures and blood samples for Dox concentrations over 90 min across the CF device membrane.

Results
The CF device was successfully introduced and deployed in the infrarenal IVC in vivo. Visualization under X-ray fluoroscopy verified the proper placement and mechanical expansion
of the Nitinol framework. In a 90 min study, the device was biocompatible, not leading to hemodynamic disturbances: pressure measurements taken throughout the experiment yielded a max gradient of 17 mmHg across the CF membrane. Venography demonstrated non-flow-limiting thrombus associated with the CF device after 90 min of deployment (swine were not heparinized). Significant Dox binding was noted with an 85%, 74%, and 83% decrease in relative pre- versus post-filter Dox concentrations at times 3, 10, and 30 min, respectively after Dox injection.

Conclusions
We developed a biocompatible CF device that can be safely introduced, deployed, and removed from the IVC in vivo. The CF device demonstrated significant Dox binding, and could serve as a platform technology in drug therapy to allow for higher regional doses of drug while limiting systemic toxicity. This technology may be readily adaptable to primary cancers of the head and neck, brain, and spine, with deployment in the relevant vein(s) draining those organs. Future work will modify the filter and its binding capacity to address particular chemotherapeutics of interest for a given diseased organ.

Do Arch and Carotid Characteristics on CT Angiography Predict Delay in Puncture to Device Deployment Time in Acute Ischemic Strokes?

S Mishra¹, M Almekhlafi¹, A Demchuk², M Hill², B Menon², M Goyal³, M Eesa²
¹University of Calgary, Calgary, Alberta, ²Foothills hospital, University of Calgary, Calgary, Alberta, ³Foothills Medical Centre, Calgary, AB

Purpose
Time to successful reperfusion is a significant predictor of a good clinical outcome in acute ischemic stroke. We aimed to identify whether certain anatomical characteristics of the aortic arch and carotid artery on CT Angiography (CTA) predicted delays in the time interval from groin puncture to first device deployment during endovascular stroke treatment.

Materials and Methods
We included patients with clinically-disabling stroke and an anterior circulation proximal occlusion that had CTA and underwent endovascular therapy from January 2011 to February 2013. We explored 10 anatomical characteristics pertaining to the anatomy of descending aorta, aortic arch, cervical, and intracranial carotid arteries (table 1). The time interval from groin puncture to first device deployment (PD time) was the primary end point. We first evaluated the impact of these individual characteristics on delays in PD time and then collectively investigated these characteristics to identify the predictors of PD time delay of 30 mins or more using logistic regression models.

Results
Among 125 patients identified, males were 55.2% and median age was 69 years (inter-quartile range: 16). Median time for puncture to first run was 5 mins (7), puncture to first device deployment was 20 mins (15) and puncture to recanalization was 43 mins (48) (Figure 1). Successful recanalization (TICI 2b or 3) was seen in 78.4 % (98/125) patients. A non-conventional origin of great vessels from the arch (category 1 or 2, table 1) predicted delay in median PD time (p=0.02). The presence of common carotid tortuosity and cervical ICA loops increased PD time. Presence of 2 or more cervical ICA loops increased the time significantly. Other characteristics including types of arch (1 - 3), carotid stenosis or thrombus and intracranial ICA tortuosity did not show significant PD time delays. Logistic regression analysis showed that presence of any one of these characteristics viz. non-conventional origin of great vessels from the arch, tortuosity of common carotid artery and cervical ICA loops increased the odds ratio for PD time delay of more than 30 mins by 2.54 [95% CI: 1.04 to 6.23], p=0.04. However, median PD time in the presence of any of these three characteristics was 21 (23) mins and in the absence of these characteristics was 17 (10) mins. We identified 10 outliers who took more than 50 mins for puncture to device deployment. Factors responsible for this were presence of atypical origin of great vessels, common carotid and cervical ICA tortuosity, age > 65 years, distal occlusions (M2 MCA), unsuccessful recanalization and procedures performed during evening and night hours.

Conclusions
The presence of any of non-conventional origin of great vessels from the arch, common carotid
artery tortuosity and cervical ICA loops predict delay in puncture to device deployment time. Early identification and reporting of these features to the interventional team before the procedure may help mitigate delays. However, its important to realize that these features do not always result in delays subject to operator experience.

Does Maintaining the Patency of the Posterior Communicating Artery Aneurysm after Coiling Increase the Risk of Ischemic Events in the Posterior Circulation?

A Quateen¹, S Patro¹, C Lum², H Lesiuk³, A Sabri², M dos Santos³, R Thornhill⁴, D Iancu³
The Ottawa Hospital, Ottawa, Ontario, University of Ottawa, Ottawa, Ontario, Neuroradiology Section, University of Ottawa, Ottawa, Ontario, University of Ottawa, Ottawa, ON

Purpose
Posterior communicating artery (PComA) aneurysms are common intracranial aneurysms located at the ICA-PComA junction. Endovascular coiling is a widely used option for treatment of ruptured and un-ruptured intracranial aneurysms. When demonstrated patency of ipsilateral, PComA and P1 segment, some operators choose to intentionally occlude the PComA in order to prevent clots from being carried downstream into the ipsilateral posterior circulation. In our institution we generally perform selective coiling of the aneurysm maintaining the patency of the PComA. This retrospective study aims to determine and compare the incidence of ischemic events post coiling in ipsilateral posterior and anterior circulation.

Materials and Methods
We reviewed our database from May 2006 till June 2013 for all consecutive patients with following inclusion criteria: 1) endovascular coiling of PComA aneurysms; 2) patent ipsilateral PComA and P1 segment and 3) MRI with DWI performed within a week after coiling. Two readers, blinded to the endovascular treatment, reviewed the DWI for presence and scoring of the acute ischemic events within the anterior and posterior circulations. The number of foci of restriction of diffusion, defined as DWI hits, was counted as measures of embolic events. The DWI hits were scored from 0 to 5 (0: none, 1: less than five, less than 10 mm in size, 2: more than 5 or larger than 10 mm, 3: one territorial infarct, 4: multiple territorial infarcts, 5: watershed infarcts). We used Cohen Kappa for interobserver agreement and Fisher exact and Chi-square test for statistical analysis of the data.

Results
Thirty eight patients (10 males and 28 females) with 39 aneurysms who had MRI with DWI performed within 96 hours post coiling were included. DWI was found positive for hits in 36% posterior and 72% anterior circulation by the reader 1 and 23% posterior and 74% anterior circulation by the reader 2. There was very good agreement between readers with respect to anterior ischemic events (Kappa = 0.89, 95% CI 0.78-1.00) and substantial agreement between readers with respect to posterior ischemic events (Kappa = 0.78, 95% CI 0.57-0.98). Although not statistically significant, there was a trend towards more acute ischemic events seen within anterior rather than posterior circulation (P=0.06). There was no significant difference in the hits score between posterior and anterior circulations territories for either reader (P=0.23 and P=0.22).

Conclusions
This study did not show an increased number or worse grading of acute ischemic events within the ipsilateral posterior circulation, post coiling of PComA aneurysms, with preservation of the PComA. This finding needs to be validated on a larger group of patients and by longstanding follow up imaging results.

Feasibility and Utility of Intravascular Ultrasound in Cerebral Venous Sinus Stenosis
Purpose
Idiopathic intracranial hypertension (IIH) is a disease of elevated intracranial pressure of unclear etiology. Many symptomatic patients are found to have focal cerebral venous sinus stenosis on noninvasive imaging with impaired cerebral venous drainage. Venous sinus stenting may help reduce this gradient. Intravascular ultrasound (IVUS) can assist with more precise diagnosis and treatment of this disease.

Materials and Methods
This was a prospective, observational cohort study at an urban academic center. Inclusion criteria were as follows: diagnosis of IIH, evidence of venous sinus stenosis on magnetic resonance imaging, and manometric pressure gradient of >10mmHg in the cerebral venous sinuses. Cerebral venography was performed for localization of a focal venous sinus stenosis. IVUS was then performed in the superior sagittal, transverse, and sigmoid sinuses based on the findings on venography with the Volcano Eagle Eye Platinum ST IVUS catheter. The IVUS catheter is mounted on a rapid exchange system with a distal radio-opaque ultrasound probe. The primary endpoint was to (1) confirm the exact location of radiographic stenosis, (2) measure the cross-sectional area of normal and stenotic segments, (3) measure the length of stenosis, and (3) search for the presence of multiple venous channels in the sinuses. These findings were used to choose the appropriate stent dimensions and determine the proximal and distal landing zones for stent delivery.

Results
Nine patients were prospectively studied and treated based on the results of the IVUS. All IVUS catheters were advanced successfully over the rapid exchange system and ultrasonic images/measurements were obtained on all patients without any periprocedural complications. One patient had multiple venous channels in their sinuses. All patients had successful implantation of venous sinus stents based on IVUS measurements.

Conclusions
IVUS is a feasible and efficacious tool in characterization of cerebral venous stenosis and useful in planning for the precise placement of a venous sinus stent.

Feasibility of the transbrachial guide-sheath specifically designed for direct common carotid artery cannulation in carotid artery stenting

S Kasakura¹, T Mori¹, T Iwata¹, Y Miyazaki¹, Y Aoyagi¹, Y Tanno¹
¹Shonan Kamakura General Hospital Stroke Center, Kamakura, Japan

Purpose
Transfemoral approach is a common technique for carotid artery stenting (CAS), and requires guide-wires and/or coaxial catheters for transferal cannulation to CCA. They may be the risk of distal embolism when a high-grade stenosis exists at the CCA. We have used the specifically designed guide-sheath for direct cannulation to CCA without any guide-wire neither coaxial catheter in CAS. The aim of our study is to investigate utility and safety of the specific guide-sheath.

Materials and Methods
Included in our retrospective analysis were patients who underwent CAS for CCA with the transbrachial guide-sheath (6Fr MSK-guide with 0.088 ID, Medikit Co.Ltd, Japan) specifically designed for direct cannulation to CCA, between February 2011 and November 2013 in our institution. Technical success, procedure time, periprocedual complications and 30-day major cardiovascular events (stroke, myocardial infarction, and death) were investigated.

Results
Eight patients were analyzed. Two patients of them underwent transbrachial CAS for right CCA stenosis, and other six for left CCA lesion. In all cases, we were successful in direct cannulation.
to the target CCA with the transbrachial guide-sheath, and performed CAS safely. The median time from the arterial picture to the end of procedure was 44.5 minutes (IQR: 13.5). Neither periprocedural complications nor cardiovascular events within 30 days following CAS occurred.

Conclusions
We successfully and safely performed CAS for CCA stenosis with the transbrachial guide-sheath specifically designed for direct cannulation to the CCA.

LONG TERM FOLLOW UP WITH WEB SINGLE LAYER DEVICE FOR INTRACRANIAL ANEURYSMS

J Chudyk1, A FERRARIO2, P Lylyk2, C BLEISE2, J LUNDQUIST2, R CERATTO2, E Scrivano2
1ENERI, BUENOS AIRES, Argentina, 2ENERI - SAGRADA FAMILIA, BUENOS AIRES, Argentina

Purpose
The endovascular treatment of intracranial aneurysms (IA) presented continuous changes in the last two decades, starting with coils, balloon or stent assisted coiling, and recently with the development of flow diverting devices. The treatment of complex aneurysms such as terminal and bifurcation with wide neck and unfavorable anatomy is challenging. WEB represents an intrasaccular flow diversion device to treat this kind of aneurysms. Our purpose is to report our experience and long term follow up using WEB single layer device (SL)

Materials and Methods
We present 3 IA treated with WEB SL, 1 ruptured, and 2 unruptured. 1 basilar tip, 1 MCA bifurcation and 1 Ophtalmic. Size aneurysms were between 5 and 10mm. Clinical and angiographic follow up were performed at 3, 6 and 12 months and every year after.

Results
Two patients have DSA control at 2 years and 1, at 3 years, all with complete occlusion and modified Rankin Scale of 0. No additional treatment was required. No complications were observed in the periprocedural time or during follow up.
Conclusions
The WEB SL proved to be an alternative for the treatment of bifurcation and terminal aneurysms. Clinical and angiographic controls showed stable results at long term follow up.

MECHANICAL THROMBECTOMY IN ACUTE STROKE

P Lylyk¹, S FRIDMAN¹, E Scrivano¹, J LUNDQUIST¹, J Chudyk², C BLEISE¹, R ROMERO¹
¹ENERI - SAGRADA FAMILIA, BUENOS AIRES, Argentina, ²ENERI, BUENOS AIRES, Argentina

Purpose
Acute ischemic stroke secondary to proximal middle cerebral artery and/or extracranial internal carotid artery (ICA) occlusion has a poor outcome in 35-38% of patients. We assess the safety and efficacy of the Solitaire™ FR device used for mechanical thrombectomy and stenting in ICA/pMCA stroke pts with contraindications for IV-rtPA.

Materials and Methods
47 ICA/pMCA stroke pts treated with the Solitaire™ FR stent without IV-rtPA were found between December 2009 and October 2013. Treatment was performed with a 8-hour window time from onset (or in the case of wake-up strokes, the MRI mismatch and the absence of FLAIR hyperintensities were required).

Results
Mean NIHSS score was 17.7. The principal contraindication for IV-rtPA was time (12 of 17, Wakeup strokes were 41.1%). Vessel occlusions were in the proximal middle cerebral artery (M1, 53%) or in the internal carotid artery (ICA, 48%). Stand alone thrombectomy was performed in 67 % and stent placement in 33 %. Five patients received IA-tPA (doses between 10 and 30mg). Arterial recanalization (TIMI 2/3, TICI 2b/3) was successful in 94.1% . Symptomatic complications were observed 11.8%. 30-Day good clinical outcome (mRS 0/2) was achieved in 41.4 % of the patients, 47% had a moderate outcome (mRS, 3/4), and 11.8 % had a poor outcome or died (mRS, 5/6).

Conclusions
Endovascular Treatment of Acute Stroke of the internal carotid artery or proximal middle cerebral artery with Solitaire™ FR device without intravenous thrombolysis demonstrated a rapid and safe recanalization in patients with contraindications for IV-rtPA.

KEYWORDS: Acute Ischemic Stroke, Thrombectomy

Neurological hemispheric deficits following contrast media exposure after neurointerventional procedures: a stressful and rare complication.

G Fargeix¹, E Pomero¹, C Billon-Grand², F Cattin¹, A Biondi¹
Purpose
Regressive cortical blindness, which can be associated with retrograde amnesia and/or confusion, is a rare and well-described complication of neurotoxicity following contrast media exposure due to a temporary breakdown of the blood-brain barrier (BBB). Nevertheless in the literature, hemispheric focal signs, such as hemiparesis/plegia, aphasia, and hemispatial neglect have been reported in very few cases. We report clinical and imaging data in 5 patients with clinical symptoms due to penetration of contrast medium through the blood-brain barrier (BBB).

Materials and Methods
Five patients developed neurological symptoms following a neuroangiographic procedure (aneurysm endovascular treatment in 3 cases and cerebral angiography in other 2). Clinical finding included: 1 case with right hemiplegia, aphasia and right homonymous hemianopsia; 1 case with right hemiparesis and aphasia; 2 cases with aphasia; 1 case with confusional syndrome. All patients underwent CT-scan and MR study (T2 FLAIR, Diffusion Weighted Images and 3D TOF MRA) after the onset of neurologic symptoms and at follow-up.

Results
In all cases, CT-scan showed local oedema and hyperattenuation of cortex and sulci due to penetration of contrast agent through the blood-brain barrier. MRI confirmed CT findings and showed no acute ischemic lesions. Follow-up imaging studies normalized within 24 to 72 hours associated with complete regression of clinical symptoms.

Conclusions
Development of transient hemispheric signs due to a temporary breakdown of the BBB and neurotoxicity of contrast media is a rare, not well-known and stressful complication of diagnostic and therapeutic angiographic procedures. CT-scan and MRI are mandatory in differentiating this rare entity, precipitated by intracortical contrast leakage, from an ischemic or hemorrhagic stroke needing a prompt and often invasive treatment.

KEYWORDS: Angiography, Contrast Extravasation, Interventional
the solitaire stent. The purpose of this study was to evaluate the safety and efficacy of this new device and persistent anatomic results in the treatment of intracranial wide neck bifurcation aneurysms.

Materials and Methods
Our series include 18 consecutive patients (men age: 53 years) with an unruptured or previously ruptured aneurysm treated using the pCONus device. Sixteen aneurysms were located on the anterior and 2 on the posterior circulation. Four cases were recanalized aneurysms.

Results
Successful deployment of the device was observed in all cases. No hemorrhagic or ischemic complications were observed. One patient had a groin hematoma. After the initial embolization procedure, a 90 to 100% occlusion rate was achieved in all cases but a neck remnant was evident in 3 patients. Follow-up data at 6 months showed good results in all case except in one recanalized aneurysm.

Conclusions
The pCONus device allows a safe coil occlusion of wide neck bifurcation aneurysms. Although more experience and longer follow-up are needed in order to evaluate the pCONus System, this device is an interesting alternative in the treatment of wide neck intracranial aneurysms.

Place of Value of DSA in the diagnostic workup of pulsatile tinnitus.

C Deuschl¹, S Goericke¹, C Gramsch², O Kastrup³, G Lehnerdt⁴, M Oliver⁵, M Forsting¹, M Schlamann¹

¹Institute for Diagnostic and Interventional Radiology and Neuroradiology, University Hospital Essen, Essen, Germany, ²University Clinic Essen, Essen, NRW, ³Clinic for Neurology, University Hospital Essen, Essen, Germany, ⁴Clinic for Otolaryngology, University Hospital Essen, Essen, Germany, ⁵Clinic for Neurosurgery, University Hospital Essen, Essen, Germany

Purpose
Pulsatile tinnitus (PT) is a rare complaint, which can be a symptom of life-threatening disease. It is often caused by vascular conditions, e.g. dural arteriovenous fistula (DAVF), arteriovenous malformation (AVM), tumor or stenosis and might have a treatable cause. The current diagnostic pathway includes neurological examination, cranial MRI and an additional digital subtraction angiography (DSA). The aim of this study was to evaluate the diagnostic impact of DSA in cases of unsuspicous MRI.

Materials and Methods
Retrospectively, 54 consecutive patients with pulsatile tinnitus were evaluated, who were examined in our department between 2002 and 2013. All patients had a diagnostic workup including cranial MRI and DSA. MRI examinations were blinded and retrospectively analyzed in consensus by two experienced neuroradiologists (>10y). The MR examinations were evaluated for each performed sequence separately: time-of-flight angiography (TOF-angio), contrast-enhanced-angiography (ce-angio), T2-Spin echo-sequence (T2), contrast enhanced-T1 spin echo-sequence (ce-T1) and a contrast-enhanced-T1-sequence-with-fat-saturation (ce-T1-fs).
Results
Thirty-seven of the fifty-four patients showed a PT explaining pathology in MRI, which was detected by the readers in 100%. 26 dural arteriovenous fistula (DAVF), four paraganglioma, two arteriovenous malformations (AVM), two carotico-cavernous fistulae, one AV fistula of the vertebral artery, one aneurysm and one stenosis of the internal carotid artery were described. All patients without pathology in MRI did also not show any pathology in DSA.

Conclusions
Our study suggests that MRI is sufficient for the diagnostic workup of pulsatile tinnitus of patients with an inconspicuous MRI if TOF-angio, ce-angio, T2, ce-T1 and ce-T1-fs sequences are performed. DSA is still mandatory for graduation of pathologies e.g. fistula.

Relationship between aneurysm occlusion and flow diverting device oversizing in a rabbit model

R Kadirvel1, S Hodis1, D Dai1, Y Ding1, F Mut2, R Lingineni1, J Cebral2, D Kallmes1
1Mayo Clinic, Rochester, MN, 2George Mason University, Fairfax, VA

Purpose
Flow diverter pore density is considered a prime determinant of device efficacy and is thought to be strongly influenced by proper matching between the device size and parent artery diameter. The objective of this study was to characterize the correlation between device sizing, degree of metal coverage, and the resultant occlusion of aneurysms following flow diverter treatment in a rabbit model.

Materials and Methods
Saccular aneurysms were created in 18 rabbits. Aneurysms were treated with flow diverters (iso-sized to proximal parent artery at the neck, 0.5 mm over-sized, or 1.0 mm over-sized, respectively, n=6 for each group). Eight weeks after implantation, the aneurysm along with the device-implanted vessel was harvested. The neck of the aneurysm covered with the flow diverter struts was photographed. The parent artery diameter to flow diverter diameter was calculated. The metal coverage (amount of metal surface area covered by the device) and pore density (number of pores per unit surface area) at the neck of the aneurysm were calculated and correlated with degree of aneurysm occlusion.

Results
Angiographic results showed there were no statistically significant differences in aneurysm geometry and occlusion among groups. The mean parent artery diameter:flow diverter diameter ratio was higher in the 1.0 mm oversized group compared with other groups. Neither the percentage metal coverage nor the pore density showed statistically significant differences among groups. Logistic regression analysis predicted that the propensity of aneurysm occlusion decreased by 8.8 fold for every millimeter increase in the neck width, irrespective of the size of the device implanted.

Conclusions
Device sizing alone does not predict resultant pore density or metal coverage following flow
diverter implantation. Aneurysm occlusion was not impacted by either metal coverage or pore density, but was inversely correlated with the diameter of the neck.

Relationship of Clot Length to Number of Stent Retrievals, Revascularization Rates, and Functional Outcomes in Endovascular Thrombectomy for Acute Ischemic Stroke

G Jindal¹, D Gandhi², t miller³, j mitchell³, r shivashanksar⁴, b stern³, k yarbrough³

¹univ of maryland, baltimore, MD, ²University of Maryland, Baltimore, MD, ³university of maryland, baltimore, MD, ⁴university of maryland, Baltimore, MD

Purpose
The aim of this report is to study the relationship between intracranial thrombus length and number of stent retrievals, revascularization rates, and functional outcomes in the endovascular treatment of acute ischemic stroke.

Materials and Methods
We prospectively collected data from anterior cerebral circulation endovascular stroke cases performed at our single center institution from April 2012 to September 2013. Thrombus length was measured using either susceptibility weighted MRI, MR angiography, CT angiography, and/or digital subtraction angiography. Demographic and clinical details, the involved vessels, and procedural details, including the number of devices used and number of retrievals utilized for each device, were recorded. Revascularization rates and 90 day functional outcomes were recorded.

Results
Thirty-seven endovascular thrombectomy procedures for acute stroke using stent retriever devices were performed during the 18 month study period. Data regarding length of thrombus in the anterior cerebral circulation was available for 28 patients. There was no significant association (p = 0.9412) between thrombus length and number of stent retrievals. There was a statistically significant direct relationship (p = 0.0458) between clot length and final thrombolysis in cerebral infarction (TICI) score, and a statistically significant inverse relationship (p = 0.0280) between number of retrievals and the final TICI score. No statistically significant relationship existed between clot length and 90 day modified Rankin Scale (p = 0.7208).

Conclusions
Our data suggest no relationship between thrombus length and number of stent retrievals utilized during acute intracranial thrombectomy nor functional neurological outcomes at 90 days. These results do not support a predictive value for thrombus length quantification in the evaluation of stroke.

EP-144  

Risk Factors for Major Recurrence of Intracranial Aneurysms after Endovascular Treatment: A Single-Center Multivariate Survival Analysis

M dos Santos¹, C Lum², D Iancu¹, H Lesiuk¹, A Sabri²

¹Neuroradiology Section, University of Ottawa, Ottawa, Ontario, ²University of Ottawa, Ottawa, Ontario

Purpose
Major recurrence of intracranial aneurysms after endovascular treatment is the most important criterion in considering re-treatment due to the risk of impending hemorrhage. Detecting the risk factors for major recurrence could also help optimize the individual imaging follow up schedule. We investigated the risk factors associated with major recurrence of the coiled intracranial aneurysms according to Digital Subtraction (DSA) or Magnetic Resonance Angiography (MRA).

Materials and Methods
A retrospective analysis of the coiling data prospectively collected from 2003 to 2012 was performed. There were 467 aneurysms in 435 patients (55±12 years old; 74% female).
Aneurysms were acutely ruptured (61%) or unruptured (39%), located in the anterior (74%) and posterior (26%) circulation with ACA/ACOM as the most common site (30%). Mean (±SD) aneurysm dome size was 7.5±3.7 and the neck size was 3.4±1.5. Conventional coiling was performed in 57% of the aneurysms while 33% and 10% of the procedures were assisted by balloon inflation and stent placement, respectively. Major recurrence according to the Raymond-Roy Classification was chosen as the primary outcome in the univariate Cox Proportional Hazards Model followed by multivariate regression analysis of the variables with probability values < 0.1.

Results
Baseline occlusion was complete (class I) in 196(42%), near complete (class II) in 191(41%) and incomplete (class III) in 80(17%) of the aneurysms. Excluding the pre-discharge mortality (10.1%) and the lost to follow-up (7.6%) cases, a total of 1367 angiographic follow-up studies were performed after 1-108 months (Mean: 40.0±28.6; Median: 37), 1-10 times (Mean: 3.6±2.0; Median: 3) in 358(82.3%) patients harboring 384(82.2%) aneurysms. Three aneurysms (0.8%) re-bled after 3, 38 and 81 months without mortality. Major recurrence was detected in 98(21%) aneurysms after 16±18 months. After multivariate analysis of the significant and marginally significant hazard ratios (P<0.1), the significant predictors (P<0.05) of major recurrence included: age>65y (HR: 1.61; P=0.043), male gender (HR: 2.13; P=0.0005), hypercholesterolemia (HR: 1.65; P=0.032), aneurysm neck size≥4mm (HR: 1.79; P=0.015), aneurysm dome size ≥7mm (HR: 2.44; P=0.0004), non-stent-assisted coiling (HR: 2.87; P=0.019), and baseline occlusion class III (HR: 2.18; P=0.008).

Conclusions
When applying our definition of major recurrence post coiling, the angiographic follow-up of patients after endovascular treatment of intracranial aneurysms may be individualized on the patients harboring the above described risk factors.

Saline Push Technique during Pediatric Cerebral Angiography: Contrast Dose Reduction

P Morris1, T Santoro1
1Wake Forest University, Winston Salem, NC

Purpose
The technique of chasing a contrast dose with a bolus of saline is well established in CT and MR imaging. This paper describes an angiographic technique for minimization of contrast dose in children and compromised adults using a saline push technique by either hand injection or by power injector. The efficacy of this technique is supported by a retrospective review of 75 consecutive pediatric diagnostic and interventional endovascular cases during which contrast volumes were recorded and calculated according to body weight.

Materials and Methods
A retrospective review of angiographic data in 75 pediatric patients spanning 6 years was conducted during which time our technique for minimization of contrast dose evolved. During all cases the contrast volume was recorded cumulatively with each administration of contrast.
During the first 3 years of this review period, an "inject and aspirate" technique was used. Contrast was injected by hand in pediatric cases, and at the completion of each run the waste contrast in the dead-space of the catheter system was aspirated until blood was seen reaching close to the aspirating syringe. This aspirated volume was then subtracted from the injected volume to establish the true dose per injection to the patient. During the latter 3 years of this period, a "saline-push" technique was used. The dead-space (2.5mL) of the catheter system was pre-loaded with a precise volume of contrast which was then pushed with a syringe of saline. When necessary the volume of available dead-space was expanded by attaching a side-tubing of up to 8mL in capacity. Contrast doses were reviewed for diagnostic and interventional procedures and evaluated by dose per body weight with particular emphasis on smaller children (<11 years).

Results
All 75 cases of varying complexity and difficulty were completed with an average of 0.86mL of Omnipaque 240/kg body wt, range 0.2 - 2.3ml/kg. For small children <11y (N=27) , the mean dose and range of doses were slightly higher for interventional cases (1.4 mL/kg, range 1.3-2.0) than for diagnostic cases (0.75, 0.2-1.6). Differences in recorded volume of contrast per case and per kg body weight were not statistically significant comparing between the two time periods of this study. However, the saline push technique was considered preferable for several reasons. The technique is cleaner by eliminating the need to aspirate blood mixed with contrast back into the catheter system at the end of each run. Secondly, it permits a more precise dosing of contrast by eliminating operator guesswork in the calculation of aspirated volume of mixed blood and contrast.

Conclusions
The saline-push technique described in this paper is a precise, inexpensive, and technically clean method of minimizing and recording contrast volumes during pediatric cerebral angiography. Intervventional cases of considerable complexity can be completed satisfactorily in small children well within recommended limits of contrast dose per body weight.

The Documentation of a Normal Venous Phase During Spinal Angiography Does Not Rule Out the Presence of a Spinal Cord Vascular Malformation with Perimedullary Drainage. Four Cases Illustrating a Potential Angiographic Pitfall.

M Obrzut1, P Gailloud1
1The Johns Hopkins Hospital, Baltimore, MD

Purpose
It is commonly assumed that the observation of a normal venous phase during spinal angiography rules out the presence of a spinal vascular malformation with perimedullary drainage. This report describes four cases of spinal cord with perimedullary drainage in which a normal venous phase was documented.

Materials and Methods
The lesions reviewed here include one cervical spinal arteriovenous malformation (SAVM), two
spinal epidural arteriovenous fistulas (SEAVFs) (one sacral and one thoracic), and one lumbar spinal dural arteriovenous fistula (SDAVF). Except in the latter instance, the lesions were symptomatic. The MRI studies obtained in the two cases of SEAVFs showed abnormal spinal cord signal. Conservative management was recommended for the cervical SAVM, while the two SEAVFs were treated endovascularly with clinical excellent outcomes.

Results
A "normal" venous phase was documented in each case during the selective injection of the main radiculomedullary contributor (artery of Adamkiewicz). Figure 1 shows an example of SEAVF with a normal venous phase. Figure 1 legend: A shows a left S1 SEAVF (arrowhead), with extensive ascending perimedullary venous drainage. The white arrow indicates the T12 level. B documents a selective injection of the left T12 ISA, which provided the artery of Adamkiewicz (not shown); the perimedullary venous system (arrowheads) is identified during the venous phase.

Conclusions
While it may still be considered a useful angiographic sign, the observation of a normal venous phase during spinal angiography does not allow ruling out a spinal vascular malformation with perimedullary drainage. As a consequence, interrupting a spinal angiogram after the documentation of a normal venous phase carries the risk of overlooking clinically significant lesions.

KEYWORDS: Pitfalls, Spinal Angiography, Spinal Arteriovenous Malformation
The Success of Flow diversion of large and giant sidewall aneurysms may depend on the size of the defect in the parent artery

J Gentic1, T Darsaut2, A Makoyeva3, I Salazkin3, J Raymond4

1CHUM Montreal, Montreal, Quebec, 2University of Alberta Hospital, Mackenzie Health Sciences Centre, Edmonton, Alberta, 3Centre hospitalier de l’Université de Montréal - Notre-Dame hospital, Montreal, Quebec, 4Centre hospitalier de l’Université de Montréal - Notre-Dame hospital, Montreal, QC

Purpose
Flow Diverters (FD) are braided stents designed to occlude aneurysms while preserving flow to jailed arterial branches. We postulated that treatment success depended on the size of the aneurysm neck.

Materials and Methods
Large and giant canine sidewall aneurysms, featuring a branch located immediately opposite the aneurysm, and a small 6-8mm (Group A; n=6) or a large 10-16mm neck (Group B; n=6) were created to study the effects of flow diversion on aneurysm or branch occlusion. Angiographic results after deployment and at 3 months were scored using an ordinal scale. The amount of neointima formation on the segment of the device overlying the aneurysm ostium was determined by postmortem photography.

Results
Group B aneurysms had significantly larger necks (mean 13±2mm) than group A aneurysms (8±1mm; p=0.002). At 3 months, group B aneurysms had significantly worse angiographic outcomes (p=0.002). Aneurysm volumes were also significantly different at 3 months (p=0.002). Group A aneurysms decreased while group B aneurysms increased in volume at 3 months (p=0.004). Neointimal coverage of the FD was more complete in group A compared to group B aneurysms (p=0.002). The most significant correlation was between neointimal coverage and angiographic evolution of aneurysms (p=-0.757; p=0.004). There was a significant correlation between the angiographic evolution of lesions at 3 months and the size of the neck (p=0.620; p=0.03).

Conclusions
The larger the neck, the less likely the same FD is to occlude large or giant experimental aneurysms. LEGEND: Angiographic (A,B) and pathological results (C,D) 3 months after Flow Diversion treatment of narrow (A,C) or wide neck aneurysm (B,D). In C, the neointima fully cover the FD stent whereas in the wide neck aneurysm (D) neointimal coverage is discontinued and permit flow to enter the aneurysm via the transition zone.

Topographic Vascular Mapping of the Right Hepatic Artery Segmental Branches Using C-arm CT with 3D-Reconstruction in Patients Undergoing Transarterial Chemoembolization (TACE) of Hepatic malignant Lesions

J Absharom

Johann Wolfgang Goethe University Hospital, Frankfurt am Main , Germany

Purpose
To create a map for right hepatic artery (RHA) segmental branches using 3D reconstruction of C-arm CT in TACE patients

Materials and Methods
The study was retrospectively performed on 20 patients with primary or secondary hepatic malignancy. C-arm CT was performed during the first TACE session and the images were reconstructed using 3D reconstructed overlaid images using Inspace application of the angiography suite. Segmental arteries of RHA were identified based on segmental liver enhancement when the CT images were overlaid on the 3D reconstructed model of RHA branches. Each segmental branch was evaluated regarding its calibre at origin (CO), detectable length (L), angle of origin (AO) from its main stem

Results
In all 20 patients the anterior segmental artery was the direct continuation of the RHA and it gave origin to the arteries of segments 5 and 8. The mean calibre of artery to segment 5 (A5) at origin was 1.8 + 0.7 mm, its length was 6.2 + 2.01 cm, angle at origin 90.7 + 44.3 while artery to segment 8 (A8) showed 4.7 + 104 mm, 4.8 + 1.7 cm & 0 angle respectively. The posterior segmental artery gave origin to arteries of segment 6 and 7. Artery to segment 6 (A6) showed 2.5+ 1.04 mm, 6.3+ 1.9 cm and 90.5 + 43. Artery to segment 7 (A7) showed 2.8 + 1mm, 5.1+1.6 cm, 0 angle respectively.

Conclusions
Knowing the topographic vascular mapping of the right hepatic artery segmental branches can produce superselective chemoembolization for the hepatic malignant lesions with minimally invasive maximally effective therapy

Transform Balloon for the Treatment of Intracranial Aneurysms, Preliminary Experience

B Bartolini, R Blanc, H Redjem, S Pistocchi, G Ciccio, M Piotin

Fondation A. de Rothschild, Paris, France

Purpose
The technique of balloon remodeling allows the endovascular treatment of wide-neck intracranial aneurysms. For many years the only available devices were Hyperform and Hyperglide (Covidien/ev3, Irvine, CA). Recently, other companies developed newer devices,
single or double lumen. We present our initial experience with the Transform (Stryker Neurovascular, Freemont, CA) balloon-remodeling device for the treatment of intracranial aneurysms.

**Materials and Methods**
We retrospectively analyzed from our prospectively gathered aneurysm database all the aneurysms that were treated with balloon remodeling using Transform balloons from January 2013 to November 2013. We assessed patient demographics, morphologic features of the aneurysms, procedure success, technical and clinical complications.

**Results**
Twenty-three patients harboring 24 intracranial saccular aneurysms were treated during 23 procedures. Clinical findings were: 11 incidental discovery, seven SAH, four compressive symptoms, one recanalization and one intraparenchymal hematoma. Twenty-three aneurysms were in the anterior and one in the posterior circulation. Mean sac and neck size were respectively 6.0 mm (sd:4.6) and 3.7 mm (sd:1.8). Thirteen aneurysms were treated with Transform C and 11 with Transform SC. We collected a peri-procedural thromboembolic event and a coil protrusion, without clinical complications. No early rebleeding occurred.

**Conclusions**
In our small series, the Transform balloon-remodeling device seems to be safe and effective for the treatment of intracranial aneurysms, in ruptured and unruptured cases.

**TREATMENT OF INTRACRANIAL ANEURYSMS USING A FULL RETRIEVAL FLOW DIVERTER P64: BUENOS AIRES EXPERIENCE**

P Lylyk¹, J LUNDQUIST¹, R CERATTO¹, E Scrivano¹, J Chudyk², C BLEISE¹
¹ENERI - SAGRADA FAMILIA, BUENOS AIRES, Argentina, ²ENERI, BUENOS AIRES, Argentina

**Purpose**
Flow diversion is a new approach to the endovascular treatment of intracranial aneurysms which uses a high density mesh stent to induce sac thrombosis. These devices have been designed for the treatment of complex and large size aneurysms. So far, safety and efficacy data published on this approach is scarce.

**Materials and Methods**
Over 18 months (May 2012 to November 2013), standardized clinical and angiographic data were collected on 42 patients with 56 aneurysms (36 women; median age, 60.9 years) treated with PHENOX flow diverter device (p64FMD). 54 (96.4%) aneurysms were in anterior circulation. 42 (75%) aneurysms were small, 10 (17.9%) large and 4 (7.1%) were giant aneurysms. Clinical and angiographic follow up at 3, 6 and 12 months were performed.

**Results**
Technical deployment success was 92.3%. In 38 patients (90.5%) one single device was used. Occlusion rate at 3, 6 and 12 months were 50%, 57% and 100% respectively. One patient (2.4%)
presented intracerebral hematoma 2 months after treatment and died, another patient presented ischemic stroke 5 months after treatment. Morbidity and mortality rate was 4.8%.

Conclusions
This early experience with p64FMD revealed a promising fully retrievable flow diverter device with an acceptable morbi-mortality rate in the short term.

Utility of Dual-Lumen Balloon Catheters for Embolization of Experimental Vascular Malformations with Liquid Agents

J Gentric1, T Darsaut2, A Batista3, I Salazkin3, J Raymond4
1Centre hospitalier de l’Université de Montréal, Notre-Dame hospital, Montreal, Quebec, 2University of Alberta Hospital, Mackenzie Health Sciences Centre, Edmonton, Alberta, 3Centre hospitalier de l’Université de Montréal - Notre-Dame hospital, Montreal, Quebec, 4Centre hospitalier de l’Université de Montréal - Notre-Dame hospital, Montreal, QC

Purpose
Liquid embolic agents (LEA) are increasingly used to treat vascular malformations. In an experimental setting, the performance of dual-lumen balloon catheter was compared to stand-alone injection of LEA in the rete mirabilis.

Materials and Methods
Fourteen controlled injections of LEA were performed using a dual lumen catheter with balloon inflated (n=8), or not (n=6). During embolization, attention was paid to the extent of antegrade filling of the porcine rete, retrograde flow of the embolic agent, and any technical difficulties such as difficulty of catheter withdrawal. Pigs were euthanized immediately following embolization, and the rete mirabilis harvested and fixed prior to pathological and radiological examinations. Angiographic and pathologic rete penetration and the density of liquid embolic within the rete vessels were scored using ordinal grading scales.

Results
Injections of LEA controlled by balloon permitted more complete penetration of porcine rete by LEA compared to stand-alone injections (P<0.05, Mann Whitney U test). Reflux of LEA occurred with greater frequency when a balloon was not used. There was no technical complication related to balloon catheter retrieval.

Conclusions
Dual-lumen catheter-mounted balloons may permit more complete embolization of experimental vascular malformations compared to standard microcatheter techniques. LEGEND: Radiological results of extension of the liquid embolic agent using stand-alone injection (A) and injection using dual-lumen balloon inflation (B).

Achondroplasia in children: Is there a correlation between size of the foramen magnum, jugular veins, emissary veins and degree of ventriculomegaly?

T Bosemani¹, G Orman², B Hergan², K Carson³, T Huisman¹, A Poretti⁴
¹The Johns Hopkins University School of Medicine, Baltimore, MD, ²Johns Hopkins School of Medicine, Baltimore, MD, ³Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, ⁴Johns Hopkins University School of Medicine, Baltimore, MD

Purpose
Achondroplasia is a skeletal dysplasia with diminished growth of the skull base secondary to inhibited enchondral bone formation that leads to narrowing of the foramen magnum and associated stenosis of the jugular foramen, with subsequent ventriculomegaly and prominence of the emissary veins. Progressive hydrocephalus and cervicomedullary compression secondary to a small foramen magnum guide decisions on cerebrospinal fluid (CSF) diversion and/or posterior fossa decompression. Emissary veins in the posterior fossa and prominent meningeal veins along the convexities are usually seen on conventional magnetic resonance imaging (MRI) sequences. In order to test our hypothesis of correlation between severity of ventriculomegaly, narrowed jugular foramen and foramen magnum and emissary vein enlargement, we 1) assessed the size of the foramen magnum and jugular veins, prominence of the emissary veins and degree of ventriculomegaly, in achondroplasia patients and age-matched controls and 2) performed correlation and regression analysis between these parameters.

Materials and Methods
Retrospective review of MRI findings was performed in children with achondroplasia prior to surgery and age-matched controls. Conventional MRI sequences were utilized to measure the surface area of the foramen magnum and the jugular foramina. Ventriculomegaly was measured by dividing the bifrontal width and biparietal diameter. The presence and/or prominence of bilateral occipital, mastoid and condylar emissary veins, bilateral superior ophthalmic veins, bilateral meningeal vessels and occipital sinus were assessed (total score of severity 0-11). In order to remove age as a confounder, median values of foramen magnum, jugular foramina and ventricular size or area were obtained from the control group for 3 age-groups, namely, 0-0.99 year, 1-2.99 years and > 3 years. Ratios for foramen magnum surface area, ventricular size and jugular foramina surface area were calculated for each patient with respect to the median value for age obtained from the controls. Statistical analysis comparing the patients with age-matched controls was done using Wilcoxon signed rank test. In addition, Spearman correlation and multiple regression analysis of the individual parameters was carried out.

Results
16 patients (5 females and 11 males) with achondroplasia and 16 age-matched controls were
included in this retrospective study. Compared to age-matched controls, in children with achondroplasia the surface of the foramen magnum (median 0.50cm², range 0.23cm²-1.37cm² vs. 3.14cm², 1.83cm²-6.68cm², p<0.001) and jugular foramina (median 0.02cm², range 0cm²-0.10cm² vs. 0.21cm², 0.03cm²-0.61cm², p<0.001) were smaller, whereas ventriculomegaly (0.28, 0.24-0.4 vs. 0.26, 0.21-0.28, p<0.001) and enlargement of emissary veins (6, 0-11 vs. 0, p<0.001) were higher. Amongst the patients, Spearman correlation and multiple regression analysis did not reveal correlation for severity between the individual parameters.

Conclusions
Our study confirms significant differences in ventricular size, emissary vein enlargement and surface area of foramen magnum and jugular foramina between children with achondroplasia and age-matched controls. The absence of correlation between the individual parameters in patients suggests a complex dynamic interplay between these parameters which is different for each patient.

Acute Disseminated Encephalomyelitis in Children: A regional experience of 35 Patients

N Mama¹, M Laadhari¹, N Soyeh², I Hasni¹, S Hassayoun¹, S Haddad³, L Boughammoura², S Abroug⁵, K Tili-Graïess¹
¹Sahloul University Hospital, Sousse, Tunisia, ²Farhat-Hached University Hospital, Sousse, Tunisia, ³Fattouma Bouguiba University Hospital, Monastir, Tunisia

Purpose
Acute disseminated encephalomyelitis (ADEM) is an uncommon inflammatory demyelinating disease of the central nervous system (CNS). Magnetic resonance imaging (MRI) is regarded as the diagnostic modality of choice. There are limited series in the literature on acute disseminated encephalomyelitis (ADEM) in children. Moreover, very rare studies of childhood ADEM have been undertaken in Tunisia and African countries. Our objectives are to describe the clinical, laboratory, and neuroimaging features, treatment and outcome of ADEM in Tunisian children and to undertake a systematic review of published ADEM pediatric cohorts in order to find prognostic elements on the initial MRI and to particularly highlight the contribution of advanced techniques (Diffusion and MR spectroscopy).

Materials and Methods
We retrospectively reviewed the medical records and MR images of 35 children diagnosed as ADEM between January 2005 and June 2013. Diagnosis was based on the definition proposed by the International Pediatric Multiple Sclerosis Study Group. All patients were assessed by initial MRI and 28 MRI undergone iterative controls (from 1 to 3). Diffusion was used in 31 patients and MR spectroscopy in 10 patients.

Results
Twenty boys and 15 girls with mean age at disease onset of five years. Eighteen children experienced a prodromal illness. MR imaging showed focal abnormal signal changes mainly in the subcortical white matter of frontal and parietal lobes. Nine patients showed corpus callosum and eight cortical gray matter involvements. A high rate of deep gray matter involvement
including thalami and basal ganglia also was noted. Apparent diffusion coefficient (ADC) values were obtained only in 14 cases with restricted diffusion noted in seven cases. All of the latter have evolved to gliosis. MR spectroscopy (MRS) showed lactates peak in seven cases at the acute phase, associated in four to restricted diffusion. Twenty-three patients recovered completely with normal control MRI. The period of follow up was two months to years with a mean of one year six months. Cases with gliosis were well correlated with neurologic sequellae: lower limb paresis (2), hemiparesis (1), partial epilepsy (3), abnormal behavior (2) and/or speech (2). Death was noted in one case.

Conclusions
The present study demonstrated that ADEM in children is a relatively benign condition. MR imaging usually demonstrates a subcortical white matter and deep gray matter lesions whereas cortical gray matter involvement is rare. Advanced MRI techniques are useful to the prognosis approach.

KEYWORDS: Acute Disseminated Encephalomyelitis, ADEM, Advanced MR Imaging

EP-200

Acute Neurotoxicity Related to High Dose Systemic Methotrexate Chemotherapy

B Harshman¹, A Mahajan²
¹Florida Hospital - Radiology Specialists of Florida, Orlando, FL, ²Yale University School of Medicine, Woodbridge, CT

Purpose
Neurotoxicity with MR changes following methotrexate administration has been documented in the literature, though the mechanism is not completely understood. Acute neurotoxicity following intrathecal chemotherapy has been the subject of several recent publications. The purpose of our study is to present acute changes of neurotoxicity following systemic methotrexate on diffusion-weighted MR imaging (DWI).

Materials and Methods
Retrospective evaluation was performed of charts of patients who developed acute neurologic toxicity after receiving and high dose systemic methotrexate. Imaging findings were reviewed and correlated with duration of treatment and temporal correlation with methotrexate administration was evaluated. A retrospective review was performed of 8 patients who were treated at our institution from April 2009 to March 2012. All patients had an MRI at presentation of acute symptoms, including DWI, and 3 of 8 (38%) underwent at least one follow-up MRI.

Results
Acute DWI changes were found in all 8 patients, primarily in the centrum semiovale, imaged at 1 to 9 weeks following systemic chemotherapy. Complete clinical recovery was demonstrated in 5 patients and the remaining 3 patients had significant improvement with no major deficits. The DWI changes improved on the 3 follow-up exams with eventual fluid-attenuated inversion recovery (FLAIR) changes on 1 exam.

Conclusions
High dose systemic chemotherapy produces similar acute neurotoxicity as does intrathecal administration. Most experience transient stroke-like symptoms with restricted diffusion in the
periventricular and/or subcortical white matter on DWI sequences. The majority made a full
clinical recovery with the MRI changes representing areas of demyelination or focal subcortical
ischemia. Sparing of the gray matter explains the relatively mild and transient nature of
neurological deficits.

EP-187

Adrenoleukodystrophy and the Blood Brain Barrier: Does Disruption of the BBB cause
Cerebral ALD?

R Cusic1, D Nascene2
1University of Minnesota, Saint Paul, MN, 2University of Minnesota, Minneapolis, MN

Purpose
Adrenoleukodystrophy (ALD) is a rare, X-linked disease, with a wide range of neurologic
manifestations and disease courses ranging from (1) no neurologic sequelae, (2) slowly
progressive neurologic involvement, (3) neurologic progression with eventual stabilization, and
(4) rapidly progressive and ultimately fatal course. The University of Minnesota is a large
referral center for ALD. Two very interesting patients presenting with evidence of acute cerebral
infarction subsequently demonstrated rapidly progressive ALD. Alternatively, two patients who
developed posterior reversible encephalopathy (PRES) had stable findings of ALD. This
suggests that ALD progression may be related to breakdown of the blood brain barrier. In this
study we reviewed all referred cases of ALD searching for pathologic processes unrelated to
ALD to evaluate how they affected the progression of ALD.

Materials and Methods
The database of adrenoleukodystrophy patients at the University of Minnesota was
retrospectively reviewed to identify patients with additional, presumably separate and distinct
diseases. The cases were reviewed by consensus by a board and CAQ certified neuroradiologist
and a third year radiology resident. Image findings were matched with clinical information as
available in the electronic medical record. Correlation with ALD progression was determined by
review of the subsequent imaging.

Results
A total of 129 patients with 832 MR scans were reviewed. Two patients presented with acute
arterial cerebral infarction and suffered rapidly progressive ALD spreading from the area of
infarction. Another patient with an infantile cerebral infarction, presumably prior to development
of a functioning immune system, had no apparent significant effect on ALD course despite
multifocal infarcts. One patient presented in an Addisonian crisis with findings of hypoxic
ischemic encephalopathy (HIE) with subsequent marked progression of ALD. Two patients
developed PRES without enhancement, with stable ALD on followup. One patient developed
venous sinus thrombosis without infarct or other effect on ALD course. Two patients developed
subdural hemorrhages, one with associated subarachnoid hemorrhage, and neither appeared to
have significantly altered course of ALD.

Conclusions
By evaluating how ALD is affected by other, unrelated diseases, we can better understand its
pathophysiology. We suggest that the accumulation of abnormal very long chain fatty acids (VLCFA) does not actually cause the typical MRI findings of cerebral ALD, rather it is primarily the immune system reaction that causes the neurologic manifestations. The triggering mechanism responsible for rapid disease progression may be a breakdown of the blood-brain barrier. This is congruent with our findings of rapid disease progression after CVA and HIE and the lack of progression with PRES, intracranial hemorrhage, and venous sinus thrombosis. Interestingly the infant with CVA did not demonstrate the expected ALD progression, possibly due to lack of a well-developed innate immune system.

EP-204

Arterial Spin labeling MRI: a New Imaging Tool for Arteriovenous Malformations Management

F Brunelle1, t Blaublowme2, o Naggara3

1Hospital Necker Enfants Malades, Paris, France, 2hopital necker, Paris, AK, 3Hopital sainte anne, Paris, AK

Purpose
Arterial Spin labeling is a recent perfusion sequence using labeled arterial protons as an endogenous perfusion agent to quantify cerebral blood flow. As cerebral AVM are high flow lesions, we postulated that arterial spin labelling could be useful in AVM diagnosis and follow up.

Materials and Methods
Studies were performed during the last 2 years on a 1.5 Tesla General Electric MRI. Following sequences were acquired: T1 weighted, T2 weighted, MR angiography, and gadolinium injection. We used pulsed continuous Arterial spin labelling in axial scan plane with port label delay of 1025 seconds, with 40 slices of 4mm. All patients had a conventional angiography. 13 patients with a cerebral AVM and PC-ASL imaging were included.

Results
7 patients were recently diagnosed with a brain AVM, 4 patients had been previously treated by surgery or endovascular treatment, 2 patients were followed after radiosurgery. ASL showed hyperperfusion inside the AVM nidus in 100% of the cases. Mean nidal CBF was 143 mL/ (100 min cm3), and nidus size ranged between 0.4 and 12.2cm2. Image fusion between 3DT1Gd and PC-ASL sequences showed precise reproducible co-localization of the nidus. After radiosurgery, CBF decreased in both patients from 200 to 94 and from 151 to 93 mL/ (100 min cm3) after 17 and 14 months respectively,

Conclusions
Arterial spin labelling is a promising tool to diagnose AVM after intra cerebral hemorrhage and to detect residual lesion after treatment. Measurement of CBF and nidus size will quantify objectively the efficacy of radiosurgery and may replace gadolinium injection

KEYWORDS: ASL, AVM, Pediatric Cerebrovascular Disease
ASL Perfusion MR Imaging In Children Presenting With Acute Neurological Deficits: a Useful Tool For Differential Diagnosis

C Billon-Grand¹, A Azizi¹, E Pomero², M Giroud¹, F Cattin², A Biondi²
¹Besançon University Hospital - Franche Comté University School of Medicine, Besancon, France, ²Besancon University Hospital - Franche Comté University School of Medicine, Besancon, France

Purpose
To evaluate brain perfusion during focal neurological deficits using ASL (arterial spin labeling) perfusion MR imaging in children.

Materials and Methods
Seven children aged from 2 to 13 years admitted with acute focal neurological deficits were consecutively enrolled over a 12-months-period. 3 Tesla MRI was performed from 3 to 12 hours after the onset of symptoms using ASL perfusion MR imaging in addition to our standard stroke protocol. A follow-up MRI was performed from 24 hours to 10 days.

Results
Initial MRI DWI was normal in 6 children. One child had punctuated hyperintense lesion on DWI in the left parietal lobe. In all patients, ASL demonstrated a hypoperfusion in the contralateral hemisphere to the deficit in association with venous stagnation in T2* and poor visualization of some distal middle cerebral artery branches on MRI angiography. At 24 hours clinical follow-up, neurologic examination was normal in 6 children. On ASL sequences, a hyperperfusion was observed instead of the initial hypoperfusion. Conventional sequences were normal. Ten days MRI follow-up was still normal, in particular no abnormalities were observed on ASL perfusion MR imaging.

Conclusions
Our preliminary results suggest that ASL perfusion MR imaging is a useful tool in the differential diagnosis in children with focal neurological deficit, in particular in cases of migraine preceded by auras or focal neurological deficits. Variations in cerebral blood flow founded in ASL perfusion MRI imaging seems to support the vascular theory in the physiopathology of migraine headache.

KEYWORDS: Arterial Spin-Labeling, Childhood, Migraine

Brainstem morphology reflects extent of brain damage in Late infantile Krabbe disease.

G Zuccoli¹, S Narayanan², A Panigrahy³, M Poe⁴, M Escolar⁴
¹Childrens Hospital of Pittsburgh of UPMC, Pittsburgh, PA, ²University of Pittsburgh Medical Center, Pittsburgh, PA, ³Children’s Hospital of Pittsburgh of UPMC, Pittsburgh, PA, ⁴Childrens hospital of pittsburgh of UPMC, Pittsburgh, PA
Purpose
The Loes score is based on a point system derived from location and extent of disease and the presence of focal and/or global atrophy. While global scores have been correlated to disease progression, specific training and strong expertise in the field of pediatric neuroimaging is required to avoid interpretation bias. We explored if there were morphological changes typical of early and late infantile forms and if a simpler scoring system could be used to assess disease severity. Based on the knowledge that Krabbe disease is a leukodystrophy with progressive atrophy in areas that are actively demyelinating, we speculated that morphological changes in the midbrain may reflect the severity of neurodegeneration.

Materials and Methods
Two neuroradiologists calculated the Loes score in 28 early infantile and 6 late infantile patients. The affected areas identified by the Loes scores were compared between the early and late infantile patients. A severity score of 0 to 2 based on the severity of midbrain abnormalities as indentified on midsagittal neuroimages was calculated for each exam and correlated to the Loes scoring system.

Results
The total Loes score correlated with the midbrain morphology score (p<.001). Patients scoring a 1 in midbrain morphology averaged 8.7 points higher in Loes score and those with a score of 2 in midbrain morphology scored 17.6 points higher in Loes score. Moderate to severe abnormalities in midbrain morphology were evident in both early and late-infantile patients. A small subset of asymptomatic early infantile patients had scans with normal midbrain morphology findings.

Conclusions
We demonstrate that morphological changes involving the midbrain identify moderate to severe changes in the brain that correlate with the Loes score. This new finding may help detect abnormalities in areas not previously evaluated by the Loes scores and may prove to be a useful and simpler scoring system to follow disease progression in patients at risk or diagnosed with Krabbe disease.

Comparison of Brain Myelination at 1.5 and 3Tesla in Children Under 2 Years of Age

C Saint-Martin1, A Maram2, N Wilson3
1McGill University Health Center, Montreal, Quebec, 2McGill University Health Center, Montreal, Quebec, 3McGill University health Center, Montreal, Quebec

Purpose
To determine whether there is a significant difference between 1.5 and 3Tesla magnets in assessment of myelination of the pediatric brain between 0 and 2 years of age

Materials and Methods
We select 100-200 normal MR Studies of patients from 0 to 2 years of age, divide them into 5 age groups (0-3m), (3-6m), (6-12m), (12-18m), (18-24m). Each group includes 10 to 20 exams done on 1.5Tesla, and 10 to 20 exams done on 3 tesla magnets. Selected regions of interest will be analyzed, including for instance, ventral pons, middle cerebellar peduncles, cerebellar white
matter, internal capsule, optic radiations, corpus callosum and peripheral subcortical white matter. Subjective comparison of their signal intensity will be made with that of cortical ribbon. Patient selection will be based on MRI reports interpreted as normal by pediatric radiologists, including control cases of an ongoing prospective research study. Exclusion criteria include history of hypoxic ischemic injury, epilepsy, follow-up of previously described anomaly, and microcephaly.

Results
We anticipate that this study provides critical information regarding morphological and spatial differences between data acquired using 1.5 Tesla and 3 Tesla protocols at the two scanner field strengths, giving us a better understanding on the pattern of myelination in a growing brain. The data acquired will help create a teaching database of normal pediatric brain development that will always be available to residents and fellows.

Conclusions
The physiological process of brain myelination during the first two years of age has been well described and assessed with the 1.5 tesla magnets. With the increase in number of high-field clinical magnets, it is essential to have access to a database of normal myelination assessed on 3Tesla magnet.

Comparison of Image Deformation Registration Techniques in a Case of Re-Irradiation of Recurrent Pediatric Ependymoma

D Sekar\textsuperscript{1}, N Dholakia\textsuperscript{1}, A Olch\textsuperscript{1}, M Cao\textsuperscript{2}, K Wong\textsuperscript{1}
\textsuperscript{1}Children's Hospital Los Angeles, Los Angeles, CA, \textsuperscript{2}University of California Los Angeles Health System, Los Angeles, CA

Purpose
Re-irradiation of recurrent cancers presents the potential problem of exceeding radiation tolerance of at-risk tissue volumes. This concern is particularly complicated in re-irradiation of pediatric patients, as the gross anatomy is likely to have grown and changed since the initial treatment. As such, the conventionally used rigid fusion of first and second treatment plans for dose summing is inaccurate, as it does not accommodate this degree of change in structure. Instead, deformable registration allows for more accurate matching and dose summing of first and second planning CT scans. We seek to explore the utility of two different deformable registration algorithms, MIM and VelocityAI, in a case of recurrent pediatric ependymoma.

Materials and Methods
The patient is a Caucasian male with recurrent posterior fossa ependymoma, treated first at the 15.5 months and again at six years. The first treatment entailed focal IMRT (59.4 Gy). He was re-irradiated to the left cerebellopontine angle five years later with IMRT (54 Gy with a simultaneous boost to 59.4 Gy). The brain volume at each treatment was 1082.8 cc and 1399.7 cc, respectively, an increase of 29.3%. At the time of treatment we did not have access to deformable image algorithms, so we used rigid registration of first and second planning CT scans for dose summing. In this study, we retrospectively registered the first and second planning CTs.
using MIM 5.6.1 (MIM Software Inc., Cleveland, OH), a constrained, intensity-based deformable registration algorithm, and VelocityAI 3.0 (Velocity Medical Solution, Atlanta, GA), using multi-pass B-spline registration. We then applied each algorithm to the 3D dose grid of the first treatment plan and added the deformed dose grid to the second treatment plan dose grid, producing dose sum maps for evaluation of total dose values. In order to evaluate the risk of radiation toxicity, we calculated the volume receiving 50 Gy (V50) for the spinal cord and the V60 for optic chiasm. To compare differences between the results of the two algorithms, we compared the calculated sums to a reference sum, obtained by manual point dose summation of the original first and second treatment plans.

Results
For both the spinal cord and the optic chiasm, VelocityAI predicted a higher V50 and V60 than did the rigid registration calculation used originally. This result suggests that VelocityAI may reveal potential radiation dose hotspots in regions that were not recognized previously. The elucidation of new hotspots suggest that deformable image registration is more useful than rigid registration in avoiding radiation toxicity. However, it is important to consider that the high degrees of image deformation that may be needed to appropriately match first and second planning CTs must be validated. MIM calculations deviated from reference values for the spinal cord and optic chiasm, but not for other at risk volumes. Although deformable image registration is a promising technique to better sum doses across treatments in children occurring years apart, the differences found in morphing volumetric doses may indicate that further optimization and validation is need for these algorithms.

Conclusions
For both the spinal cord and the optic chiasm, VelocityAI predicts a higher V50 and V60 than does the rigid registration calculation used originally. This result suggests that VelocityAI may reveal potential hotspots of excessive radiation exposure in regions that were not recognized previously. The elucidation of new hotspots suggest that deformable image registration is more useful than rigid registration in avoiding radiation toxicity. However, it is important to consider that the high degrees of image deformation that may be needed to appropriately match first and second planning CTs (separated by enough time to permit significant growth to occur) must be validated. MIM calculations deviated from reference values for the spinal cord and optic chiasm, but not for other at risk volumes. Although deformable image registration is a promising technique to better sum doses across treatments in children occurring years apart, the differences found in morphing volumetric doses may indicate that further optimization and validation is need for these algorithms.

Comparison of Rapid Cranial Magnetic Resonance Imaging to Computed Tomography for Diagnosing Ventricular Shunt Malfunction

M Paldino¹, T Boyle², B Fitz², A Kimia², J Madsen², L Nigrovic²
¹Boston Children’s Hospital, Harvard University, Boston, MA, ²Boston Children's Hospital, Boston, MA
Purpose
Cranial computed tomography (CT), the practice standard for evaluating children with possible ventricular shunt malfunction, exposes them to cumulative ionizing radiation doses associated with significant lifetime malignancy risk. Rapid cranial magnetic resonance imaging (MRI), a new radiation-sparing alternative, has not been compared to CT for diagnosing shunt malfunction. Our goal was to compare the accuracy of rapid cranial MRI to CT for diagnosing ventricular shunt malfunction.

Materials and Methods
We performed a single-center retrospective cohort study of children ≤ 21 years of age with ventricular shunts who underwent either rapid cranial MRI or CT in the emergency department (ED) for possible shunt malfunction. Neuroimaging studies were classified as "normal" (unchanged/decreased ventricle size) or "abnormal" (increased ventricle size). We defined ventricular shunt malfunction as required operative revision to relieve mechanical shunt flow obstruction within 72 hours of initial ED evaluation. We calculated test characteristics for each imaging modality. Our primary analysis tested non-inferiority of the accuracy of rapid cranial MRI to CT for diagnosing shunt malfunction (non-inferiority margin 10%).

Results
We included 657 ED visits for 265 unique patients [median age at visit 10.2 years (interquartile range 6.0-15.6 years)]. Patients underwent CT in 324 (49%) or rapid cranial MRI in 333 (51%) ED visits for evaluation of possible shunt malfunction. Patients had operative revision for shunt malfunction in 95 ED visits (15%). The accuracy of rapid cranial MRI was not inferior to CT scan for the diagnosis of shunt malfunction [80.5% MRI vs. 83.3% CT; risk difference -2.8%; 95% Confidence interval (CI) -8.7%, 3.1%]. The median ED length of stay was longer for visits with a rapid cranial MRI [6.1 hours MRI vs. 5.4 hours CT; difference 0.8 hours; 95% CI 0.4,1.2], in part due to longer times to obtain neuroimaging (1.1 hours MRI vs. 0.7 hours CT; difference 0.4 hours, 95% CI 0.2, 0.6).

Conclusions
Rapid cranial MRI was not inferior to CT for diagnosing ventricular shunt malfunction.

Complications of Cerebral Catheter Angiography in Children: A Review of 316 Cases

N Skipper¹, J Larsen¹, D Connolly¹, R Batty¹
¹Sheffield Teaching Hospitals NHS Foundation Trust, Sheffield, Yorkshire

Purpose
Cerebral catheter angiography is an important tool for the investigation of intracranial vascular lesions and is a requirement before stereotactic radiosurgery (STRS) for arteriovenous malformations (AVMs). Knowledge of complication rates is required for adequate consent but there is limited complication rate data for paediatric angiography available in the literature. There are no published studies with elective STRS patients forming the majority of the study population. This study aims to assess the complication rates associated with paediatric cerebral
catheter angiography at our institution, where most procedures are performed electively prior to STRS.

Materials and Methods
All diagnostic angiograms performed on patients under the age of 17 years between January 2000 and August 2013 were identified using the radiology information system. Data collection was predominantly prospective, using the local angiography database or the data sheets of individual operators; and partially retrospective, using case note review. A total of 323 cases were identified and sufficient data for analysis was available for 316 of these. The following data was collected: age; indication for procedure; diagnosis; operator; complications.

Results
Prospectively collected data was available for 277 cases. Retrospective case note review yielded data for a further 46 cases. Seven cases were excluded as there was no prospective data entry and insufficient information available in the case notes. The age range for the 316 included cases was 2 to 16 years (mean age: 12.0 years). 285 (90.0%) of angiograms were performed in patients having STRS for AVMs. The next largest patient groups were those with parenchymal haemorrhage; 15 patients (4.7%), and vascular tumours; 6 patients (1.9%). There were two complications in total, both in STRS patients. One child (0.3%) had a common femoral artery dissection during the procedure, but remained well at discharge the following day. One child (0.3%) bled from the puncture site post-procedure after haemostasis was thought to have been achieved. This was successfully treated with manual pressure without formation of a significant haematoma or false aneurysm.

Conclusions
In children the complication rates for cerebral catheter angiography are low. This is particularly the case when the procedure is performed electively for STRS. Our results compare favourably with the previously published paediatric data from smaller series.

Desmoplastic Infantile Ganglioglioma (DIG): Imaging features of an uncommon tumour of infancy

D Bhattacharya¹, G Smyth¹, J Turner², E Mckenna²
¹Royal Victoria Hospital Belfast, Belfast, Ireland, ²Ulster Hospital Dundonald, Belfast, Ireland

Purpose
Description of the imaging features of desmoplastic infantile ganglioglioma (DIG), a rare tumor of infancy.

Materials and Methods
We describe two patients; the first was a five-day-old term female infant with a complicated delivery who had a routine antenatal cranial ultrasound scan demonstrating a cystic lesion in the left parietal lobe. The second patient was a six-month-old female infant presenting with seizures; cranial ultrasound showed a large cystic lesion in the left frontal lobe. Computed tomographic (CT) scans showed part solid and part cystic lesions in both patients, with no calcification. Both patients underwent magnetic resonance imaging (MRI) of the brain, with routine T1/T2-
weighted and gradient echo sequences, along with postgadolinium and diffusion-weighted imaging (DWI). Single voxel magnetic resonance spectroscopy (MRS) was performed in one of the patients.

Results
In both cases, a large intra-axial predominantly cystic lesion was seen with a peripheral homogenously enhancing nodular plaque-like solid component, with moderate vasogenic edema. The solid component extended to the dural surface. Diffusion-weighted imaging showed increased diffusion within the cystic portions of the tumor, with some areas of restricted diffusion within the solid components, in both patients. The MRS performed in one patient demonstrated a large lactate peak with low N-acetylaspartate (NAA) and choline. Both patients underwent initial histological confirmation with image-guided biopsy of the lesions, with subsequent definitive total resection of the tumors. Follow-up imaging current at the time of this report showed no recurrence or postsurgical disease progression in either patient.

Conclusions
Desmoplastic infantile ganglioglioma is an uncommon tumor of infancy presenting in the first 18 months of life. Along with a further histologic subtype, Desmoplastic infantile Aastrocytomas, these tumors form part of the larger group of desmoplastic infantile tumors (DIT), believed to have a favorable prognosis. Imaging features usually are consistent with a large cystic supratentorial lesion with an enhancing peripheral solid component extending to the dura. Despite seemingly aggressive appearances, surgical resection is curative in the majority. Our two cases demonstrate the typical imaging features of this tumor and to date both patients have not shown recurrent disease postsurgical resection. Appearances on diffusion-weighted imaging have not, to our knowledge, been described previously. Although the cause of the small areas of diffusion restriction described remains obscure, they may correlate with any aggressive histological appearances.

G Bonaldi1, C Agostinis2, o Manara1
1Ospedale Papa Giovanni XXIII, Bergamo, Italy, 2Ospedale Papa Giovanni XXIII, Alzano L.Ombardo, Italy

Purpose
Spondylolysis, i.e. defect in pars interarticularis of the vertebral neural arch, considered due to chronic stress injury, is a relative rare condition (6%) but identifiable cause of low back pain in children and adolescents. We present our series of 6 adolescent patients affected by spondylolysis and treated conservatively.

Materials and Methods
We diagnosed spondylolysis by means of MR imaging in six young patients (age ranging from 14.5 to 16.8 ys; male:female = 3:3) affected by low back pain. Elapsed time between symptoms onset and evaluation was 1 to 5 months. Back pain was associated with bilateral sciatalgia in one. Two patients were active in sports.

Results
Diagnosis was obtained by non-contrast MRI, showing the typical morphological aspect of defect of the pars interarticularis of the posterior vertebral arch on T1- and T2-weighted sagittal sequences. Spondylolysis was bilateral in all but one case; the interested vertebrae were L5 in four patients and L3 and L4 in one, respectively. The condition was always associated with edema of bone and usually of adjacent soft tissues, demonstrated as hyperintense signal on T2 fat sat sequence. In two cases CT scan was also performed. All patients were treated in a conservative way, by rest and use of a hard brace. Follow up was carried out by means of MR performed every 3-6 months for a period of 12-16 months, till the resolution of edema and demonstration of bone fusion were obtained. Bone repair was confirmed in 2 patients by CT scan, performed with radiation doses as low as possible. In all cases the healing was associated with complete resolution of symptoms.

Conclusions
Our experience shows that diagnosis of spondylolysis in young population with low back pain is feasible not invasively by MRI; the early diagnosis of this condition is important to prevent the occurrence of forward slippage whose treatment could require more aggressive, surgical procedure in the adulthood.

Diffusion tensor imaging of the brainstem in children with achondroplasia

T Bosemani1, G Orman2, K Carson3, A Meoded4, T Huisman6, A Poretti5
1The Johns Hopkins University School of Medicine, Baltimore, MD, 2Johns Hopkins School of Medicine, Baltimore, MD, 3Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, 4The Johns Hopkins School of Medicine, Baltimore, MD, 6Johns Hopkins University School of Medicine, Baltimore, MD
Purpose
Achondroplasia is a skeletal dysplasia and the most common form of disproportionate short stature in children with diminished growth of the skull base that leads to narrowing of the cranio-cervical junction (CCJ) and foramen magnum, which may lead to cervicomedullary compression. Diffusion tensor imaging (DTI) is a magnetic resonance imaging (MRI) technique that allows in vivo evaluation of the microstructure and integrity of white matter tracts. DTI is highly sensitive to detect white matter abnormalities and is a suitable technique to study white matter changes that may result secondary to chronic cervicomedullary compression in achondroplasia. This study aimed to 1) assess the microstructural integrity of the white matter using DTI in the brainstem in comparison to age-matched controls and 2) correlate severity of CCJ narrowing and neurological findings with DTI scalars in children with achondroplasia.

Materials and Methods
The inclusion criteria for this retrospective study were: 1) confirmed diagnosis of achondroplasia (imaging and/or genetic findings), 2) availability of presurgical DTI data without artifacts enabling a high quality DTI post-processing and 3) age at MRI 18 years and younger. DTI data were acquired on a 1.5 T MR-scanner using a balanced pairs of diffusion gradients along 20 non-collinear directions. Measurements from regions of interest sampled in each pontine corticospinal tract (CST), medial lemniscus (ML) and middle cerebellar peduncle (MCP) as well as in the lower brainstem were obtained for fractional anisotropy (FA), mean (MD), axial (AD) and radial (RD) diffusivity. Additionally, a severity score for achondroplasia was assessed by measuring the CCJ narrowing.

Results
8 patients with achondroplasia and 8 age-matched controls were included in this study. Compared to age-matched controls, decrease in FA and increase in MD and RD were found in the lower brainstem of patients. CST's and MCP's showed increase in MD, AD and RD. FA in the lower brainstem negatively correlated with the degree of CCJ narrowing.

Conclusions
Reduction in FA and increase in diffusivities in the lower brainstem may reflect secondary encephalomalacic degeneration and cavitation of the affected white matter tracts as shown by histology. In children with achondroplasia, DTI may serve as a potential biomarker for brainstem white matter injury and aid in the management of these patients.

Emerging left-right asymmetry of white matter brain pathways in humans: Fetal, neonatal, and toddler stages

J Song1, P Mitchell2, J Kolasinski3, P Grant4, R Folkert5, A Galaburda6, E Takahashi7
1Yale University, New Haven, CT, 2Boston Children's Hospital, Boston, MA, 3Athinoula A. Martinos Center for Biomedical Imaging, Charlestown, MA, 4Children’s Hospital Boston, Enders 961, Boston, MA, 5Brigham and Women’s Hospital, Boston, MA, 6Beth Israel Deaconess Medical Center, Boston, MA, 7Boston Children's Hospital, Harvard University, Boston, MA
Purpose
Studies show that cognitive abilities such as language and hand preferences, characteristics unique to the human species, are strongly lateralized in the human brain. However, it is unknown whether asymmetric structural development in the brain influences or is the result of these functional hemispheric asymmetries. Characterizing white matter pathways in developing human brains may provide insight into how asymmetries arise and elucidate a temporal relationship between structure and function. The purpose of this study is to compare the spatio-temporal hemispheric asymmetry of developing white matter pathways using high-angular resolution diffusion imaging tractography in intact human fetal, neonate, and toddler brains.

Materials and Methods
Human ex vivo fetal brain specimens of post-gestational week (W) 17 (n=1) and W20 (n=3) were imaged using a 4.7T Bruker MR system. Premature newborns (W30, W34; n=3), term-birth newborns (W40; n=3), and toddlers (2years; n=1) were imaged in vivo using a 3T Siemens MR system. A 3D diffusion-weighted spin-echo echo-planar imaging (EPI) sequence (61 measurements), TR/TE 1000/40 ms, with b = 8,000 (for ex vivo) and b= 1,000 to 3,000 (for in vivo), small/large delta = 12.0/24.2 ms was performed. Spatial resolution ranged from 400x500x550 μm to 2x2x2 mm depending on the brain size. Tractography pathways were reconstructed using a streamline algorithm with an angle threshold of 40 degrees, and white matter pathways were segmented using TrackVis. Fractional anisotropy (FA), apparent diffusion coefficients (ADC), trajectories and volumes between hemispheres were compared at different developmental time points. A laterality index (LI) for FA, ADC, and volumetric values was calculated (LI= (L-R)/0.5(L+R)). Positive and negative LI values correspond to a left and right-sided preference, respectively. Because ADC values may be affected by the fixation process and b-value, ADC values for brains that were imaged in vivo were standardized against age-equivalent post-mortem brains. This approach facilitated ADC comparisons across in vivo and ex vivo imaged brains. The brains used for standardizing had only one hemisphere and were excluded from asymmetry analyses.

Results
Age-related development of laterality was not observed in a migration stream from the ganglionic eminence nor in a limbic connectional pathway (cingulum bundle or fornix). Among the studied cortico-cortical association pathways (inferior longitudinal fasciculus, inferior fronto-occipital fasciculus, and arcuate fasciculus), only the inferior longitudinal fasciculus showed development of age-related laterality emerging as early as the second trimester. When comparing ages older and younger than 40GW, a leftward asymmetry in the volume of the cingulum bundle in ages older than 40GW emerged. A rightward asymmetry in ADC and a leftward asymmetry in FA emerged in the inferior longitudinal fasciculus in ages older than 40GW.

Conclusions
Regional emergence of fetal brain axonal connectivity appears to proceed from a postero-dorsal to antero-ventral direction with local variations related to the later appearance of gyri and sulci. Hemispheric asymmetry in white matter pathways appears to arise substantially later than asymmetry in related cortical areas. These findings suggest development of hemispheric laterality may be more vulnerable to early life experiences or interventions.

Hippocampal Fractional Anisotropy Changes in a Cortical Dysplasia Animal Model

O Clerk-Lamalice\(^1\), L Tremblay\(^2\), M Dumont\(^1\), L Carmant\(^3\), M Lepage\(^2\), M Descoteaux\(^4\)

\(^1\)Université de Sherbrooke, Sherbrooke, Quebec, Canada, \(^2\)Centre d’Imagerie Moléculaire de Sherbrooke - Université de Sherbrooke, Sherbrooke, Quebec, Canada, \(^3\)Centre de Recherche du CHU Sainte-Justine, Montreal, Quebec, Canada, \(^4\)Sherbrooke Connectivity Imaging Lab – Université de Sherbrooke, Sherbrooke, Quebec, Canada

Purpose
Up to 79% of children with temporal lobe epilepsy (TLE) and mesial temporal sclerosis have cortical dysplasia (CD) (1). To better understand the role between cortical dysplasia and epileptogenesis we studied an animal model combining focal cortical dysplasia induced by cryolesion at postnatal day 1 (P1) and hyperthermia-induced seizures at P10 (2). Previous studies have demonstrated that rat pups with focal cortical dysplasia develop status epilepticus lasting more than 30 minutes when exposed to hyperthermia while controls experienced only brief seizures. This dual pathology animal model causes hippocampal atrophy (3) and increased hyperexcitability in CA1 hippocampal pyramidal cells early on (4). Diffusion tensor imaging (DTI) studies have reported substantial white matter abnormalities in the epileptogenic network of patients with TLE (5) but the link between CD and TLE remains unclear. To our knowledge, DTI has never been applied to study fractional anisotropy (FA) changes in an animal model of cortical dysplasia. Here we use this technique to assess microstructural changes in the hippocampus that could explain increased epileptic activity and seizure propagation in our animal model.

Materials and Methods
Seven male Sprague-Dawley rat pups were divided into two groups: naïve controls (NC, n=2) and freeze-lesion (L, n=5). A freeze lesion was induced on the right frontoparietal cortex at postnatal day 1 (P1) to mimic CD (2). At P8, MR images were acquired on a seven T MR scanner (Varian, Palo Alto, CA) with a 210 mm bore and detection was performed using a rat head coil (Rapid Biomed, Columbus OH). Axial T2-weighted images were obtained to confirm the presence and analyze the location of the cortical dysplasia: TR = 2000 ms, TE = 12 ms, eight echoes, FOV = 25 mm\(^2\), acquisition matrix 256 x 256, slice thickness = 0.7 mm. A six-direction spin echo sequence was used to acquire 2D multislice diffusion-weighted images with the following parameters: TR = 2,000 ms, TE = 35 ms, strength of gradient = 20 G/cm, Δ = 13 ms, δ = 6 ms, FOV = 32 x 32 mm\(^2\), slice thickness = 0.25mm, acquisition matrix 128 x 128, number of acquisitions = 1. Manual delimitation of the hippocampus and frontoparietal cortex was performed with the help of an atlas using Dipy (www.dipy.org) software to calculate FA, mean diffusivity (MD), as well as axial and perpendicular diffusivities (\(\lambda//\), \(\lambda\perp\)). Diffusion tensor imaging metrics statistics in each cerebral region was performed on SPSS (SPSS, Chicago, IL) with a Student’s t-test (p=0.05).

Results
Results demonstrate significantly lower FA in the right dorsal hippocampus (NC=0.32±0.05; L=0.21±0.1; p<0.05) but not on the left side (NC=0.29±0.6; L=0.33±0.02). \(\lambda\perp\) (x10-3mm\(^2\)/sec)
increased but nonsignificantly in the right hippocampus (NC=0.00088±0.00012; L=0.00106±0.00005; p=0.18). Colored FA maps demonstrate important alteration in the fiber orientation of the CD rat pups (Figure 1). On the right cortical lesion side (arrowhead), very few superior-inferior tracts are seen both in the right dorsal hippocampus (short arrow) and thalamus (long arrow) compared to the contralateral side.

Conclusions
Lower FA values are seen in the ipsilateral hippocampus after cortical insult. It has been suggested that FA values in the premature rat brain correlate with microstructural anisotropy (6). Thus, our results could indicate that a superficial cortical lesion can potentially alter the microstructure deep in the developing brain. Previous studies demonstrate that the induction of cortical dysplasia at P1 causes a reorganization of thalamocortical connections (7) but the effects on the limbic system is unknown. We know that rat pups with CD have a lower epileptic threshold and EEG epileptogenic discharges in the hippocampus and amygdala after induction of experimental febrile seizures (2, 8). Further longitudinal studies are required to evaluate if these changes are transient or cause permanent white microstructural reorganization linked to TLE.

Imaging Evaluation of Developmental Anomalies of the External and Middle Ear: What the Surgeon Wants to Know.

S Frost¹, M Maheshwari¹, I Tuna¹, H Segall¹
¹Medical College of Wisconsin and Children's Hospital of Wisconsin, Milwaukee, WI

Purpose
The aim of this exhibit is to provide a review of the developmental anomalies of the external and middle ear. We will discuss the embryologic basis, anatomy, and imaging features of these anomalies with illustrative examples and clinical cases.
Materials and Methods
Developmental abnormalities of the external and middle ear comprise an important group of disorders which are associated with mild to profound hearing loss. We will provide a brief review of external and middle ear embryology and relevant anatomy. We will describe the common developmental abnormalities including external auditory atresia, ossicular maldevelopment spectrums, developmental cholesteatoma, cranial nerve VII dehiscence, stapedial artery variant, dehiscent jugular bulb, etc. We also will discuss various syndromes which are associated with malformation of the external and middle ear structures. The descriptions will focus on common clinical presentation, and classic imaging features with illustrative examples.

Results
Incidence of the congenital external and middle ear anomalies is 1 in 10000 – 20000 live births. Unilateral involvement is more common than bilateral (4:1). Bilateral abnormality is associated more frequently with syndromes. Unilateral versus bilateral nature of the abnormality, auricle and external auditory canal abnormality, course of the facial nerve, status of the oval window, morphology of the stapes and status of inner ear structures are the among the most important features that guide the surgical management in these cases. The complex and compact anatomy of the middle ear can make imaging evaluation difficult and intimidating. While it is important to recognize and characterize pathology it also is critical to provide clinically useful information for the referring physician who is tasked with treating these complex abnormalities.

Conclusions
The objective of this exhibit is to familiarize radiologists with the common developmental abnormalities of the external and middle ear as well as discuss the features and information which the referring otolaryngologist is looking for.

Incidence, Clinical and Radiographic Characteristics of Intracranial Hypertension in Children with Osteopetrosis Undergoing Hematopoietic Stem Cell Transplantation

T Bahr¹, D Nascene², w miller³
¹University of MN Medical School, St. Paul, MN, ²University of Minnesota, Minneapolis, MN, ³university of minnesota, minneapolis, MN

Purpose
Osteopetrosis (OP) is a rare, life-threatening disease caused by abnormal osteoclast function resulting in dense sclerotic bone, cranial nerve impingement, recurrent fractures, osteomyelitis, and hematopoietic failure. Disease presentation and severity vary with genotype. While hematopoietic stem cell transplantation (HSCT) remains the usual treatment, there continue to be numerous complications in the OP population. Intracranial hypertension (IH) has been described in OP, but few case reports exist in the literature. We report the incidence, clinical and radiographic characteristics of IH in OP patients treated with HSCT at our center.
Materials and Methods
Thirty-one OP patients undergoing HSCT at the University of Minnesota from 1978-2013 had medical records and/or neuroimaging available for review.

Results
Ten patients (32%) developed IH at a median age of 11 months. Onset was post-transplant in 3 patients (days +21, +204, and +286) and pre-transplant in 7 (median, day –28). Signs and symptoms included headache, irritability, somnolence, bulging fontanel, proptosis, increased scalp venous markings and sudden vision changes. Three patients had evaluable opening pressures upon lumbar puncture (LP): 1 at 17 cm H2O (3 month-old), and 2 at >55 cmH2O (1 year-old and 15 year-old). For patients with IH, the median age of OP diagnosis was 3 months (range, 0 - 176 months). All 4 patients with genotypic data demonstrated compound heterozygous TCIRG1 mutations. Six patients had evidence of IH at presentation of OP. Neurologic deficits prior to HSCT included hearing loss (3), facial nerve palsy (1), nystagmus (6) and optic nerve atrophy (9). Relative macrocephaly was present in 6 of 7 patients with available anthropometrics. Imaging just prior to intervention for IH was available for up to 5 patients at a median age of 12 months. Four (80%) demonstrated subdural hemorrhage. Three (60%) demonstrated posterior globe concavity. Mean optic nerve sheath diameter was 8.3mm. Mean jugular foramina (pars vasculosa) diameter was 5.4mm. Three patients demonstrated maximal venous engorgement in the posterior superior sagittal sinus (13.4, 12.1, and 11.7mm, transverse dimension). Two patients had maximal dilation in a transverse sinus (10.1 and 12.3mm, A/P dimension). The average maximal third ventricular diameter was 4.9mm.

Interventions for IH occurred in nine patients, including shunting (8), serial LP (2), optic nerve decompression (2), and acetazolamide (1). Transplant occurred at a median age of 12 months. Eight patients experienced respiratory failure and three demonstrated pulmonary hypertension. Five patients died from transplant-related complications and two from disease progression. Three patients survive (3 years, 3 years, and 10 years post-transplant).

Conclusions
Intracranial hypertension appears common in children with osteopetrosis who present for and undergo hematopoietic stem cell transplantation. Ongoing cohort analysis aims to further identify clinico-radiographic features of, and outcomes following intervention for, IH in OP. Ultimately, we hope such analysis will inform rational intervention, perhaps even pre-emptively, for this patient population.

Incidental Hypothalamic Cleavage Anomalies in Children

D Mirsky¹, L Fenton¹, N Stence¹
¹Children's Hospital Colorado, Aurora, CO

Purpose
Structural anomalies of the hypothalamus can either be seen in isolation, as in hypothalamic hamartomas, or can be associated with several midline congenital disorders such as holoprosencephaly spectrum and septo-optic dysplasia. In the literature, hypothalamic anomalies
are almost always associated with symptoms referable to hypothalamic-pituitary dysfunction, seizures, or a midline congenital disorder, with very few asymptomatic patients reported (1-2). Aside from large hypothalamic hamartomas, isolated anomalies of the hypothalamus are difficult to detect by routine MRI, due to its small size and the difficulty in separating the hypothalamus from adjacent structures (3). Using high-resolution isotropic T1 weighted MR imaging, we have observed a number of isolated and apparently incidental hypothalamic structural anomalies. The purpose of our study is to further characterize these anomalies and determine any clinical significance.

Materials and Methods
The Children's Hospital Colorado case file was searched for patients identified with isolated hypothalamic anomalies. Patients with a history of hypothalamic-pituitary dysfunction (including precocious puberty), seizures, hydrocephalus, or neurofibromatosis type I were excluded. These criteria resulted in a study cohort of 8 patients, of equal gender distribution, ranging in age from 18 days to 17 years, mean age 5 years. MR imaging indications for the group included vertigo, concussion, dural venous sinus thrombosis, tongue hypertrophy, and premature birth. Images were reviewed by 2 neuroradiologists for other congenital abnormalities, including lack of midline cleavage, pituitary anomalies and cortical malformations.

Results
In all 8 cases, the hypothalamic anomaly consisted of a band of tissue spanning the anterior recess of the third ventricle (Figure 1a) that appeared nodular on sagittal images (Figure 1b). In all patients, the band of tissue was T2 isointense to gray matter, did not contact the mammillary bodies, and did not extend below the tuber cinereum. On review of the images, no additional structural abnormality was identified, with particular attention to midline structures and for cortical malformations.

Conclusions
This hypothalamic anomaly was observed incidentally through the routine acquisition of high-resolution T1 imaging. No referable symptoms or other congenital anomalies were identified in the study group. As the described anomaly is subtle and only apparent on isotropic T1 imaging, it is likely under recognized. However, as high resolution MRI techniques become more routinely employed, these hypothalamic anomalies or variants are likely to be increasingly identified. Although the underlying etiology is unclear, it may be the result of incomplete hypothalamic cleavage. In the appropriate patient population where related symptoms are absent, the described hypothalamic anomalies are most likely incidental, and should not be misdiagnosed as hypothalamic hamartomas.

Interhypothalamic Adhesion: A Case Series

M Whitehead\textsuperscript{1}, G Vezina\textsuperscript{2}
\textsuperscript{1}Children's National Medical Center, Arlington, VA, \textsuperscript{2}Children's Nat'l Med Ctr., Washington, DC
Purpose
The interhypothalamic adhesion (IHA) is a newly described disease entity. IHA is characterized by an abnormal parenchymal band of tissue connecting the medial margins of the hypothalami across the third ventricle. The purpose of this case series is to describe the imaging findings from 4 additional patients with IHA discovered on brain MR.

Materials and Methods
MR images from 4 separate patients with IHA encountered over a 5 month period at a single academic children's hospital were reviewed. Each study was evaluated by a CAQ holding neuroradiologist. Each patient's electronic medical record was researched for presenting symptoms, past medical history, pertinent physical exam findings, and additional relevant diagnostic tests.

Results
Case Presentations:
Case 1: A 2 month-old former 26 week preterm infant male with a history of a normal head ultrasound presented for a term equivalent brain MR. MR demonstrated an IHA and mild hippocampal under rotation.
Case 2: A 4 year-old male underwent a brain MR for headaches and vomiting. Past medical history was remarkable for Leber congenital amaurosis. Brain MR depicted an IHA, optic pathway atrophy, and old frontal lobe white matter injury.
Case 3: An 11 month-old male with a history of global hypotonia presented for brain MR evaluation. Imaging revealed an IHA as the isolated intracranial abnormality.
Case 4: A 9 year old male with presumed Dandy-Walker malformation continuum underwent brain MR. In addition to cerebellar hypoplasia, a posterior fossa cyst, and periventricular nodular heterotopia, an IHA was discovered.

Conclusions
Interhypothalamic adhesion is a newly described disease entity, first recognized in a patient with cleft palate with additional intracranial findings that raised the possibility of a form fruste holoprosencephaly. We describe associated imaging findings in 4 additional patients with IHA.

Intracerebral Hemorrhage Following Shunting of Neonatal Hydrocephalus: Is it the Vulnerable Venous Vasculature?

D Mirsky, L Fenton, C Wilkinson, N Stence
Children's Hospital Colorado, Aurora, CO

Purpose
Intracerebral hemorrhage following shunting of hydrocephalus is a rare but serious occurrence. While shunt-related complications, including subdural hemorrhage, have been described in both the radiology and neurosurgical literature, there is only a single report detailing parenchymal hemorrhage. The etiology of this potentially fatal complication remains unclear. Based on the subcortical location of the hemorrhages, it is thought that the bleeds are venous in etiology. In the adult population, similar pathology has been described in the setting of rapid decompression of chronic subdural hematomas (CSH). In that clinical context, a variety of differing theories have been postulated as to the etiology of the parenchymal hemorrhages: a) perfusion breakthrough bleeding, b) disrupted cerebral vascular autoregulation, c) vascular damage secondary to mechanical shift of cranial contents, and d) the interplay between intracranial and venous pressures. At the heart of all of these theories lies one common denominator, the vulnerable venous vasculature. We postulate a similar mechanism for parenchymal hemorrhage following shunting of neonatal hydrocephalus.

Materials and Methods
The case file at a tertiary care children's hospital was searched over the last 7 years for neonates with hydrocephalus who developed intracerebral hemorrhage within one week following shunt placement. All available imaging was reviewed. Patients with underlying coagulopathy, infection, or anomalous vasculature were excluded. A literature review of underlying principles and postulated mechanisms for parenchymal hemorrhages following treatment of CSH was performed.

Results
Three infants ranging in age from 4 days to 4 months with subcortical hemorrhages immediately post-shunting of hydrocephalus were identified. Two were female and one was male. In all cases, the subcortical hemorrhages occurred bilaterally involving all cerebral and cerebellar lobes, were unrelated to the drainage catheter sites, and were associated with subdural hematomas. All were associated with a rapid change in ventricular size. We postulate that with increased parenchymal blood flow and altered pressure dynamics following CSF diversion intracerebral veins are vulnerable to rupture. Venous vulnerability is a reflection of disrupted autoregulation, and leads to a type of perfusion breakthrough bleeding.

Conclusions
Intracerebral hemorrhage following shunting of congenital hydrocephalus is likely due to venous vulnerability resulting from the unique environment established by long-standing hydrocephalus leading to altered venous pressure dynamics.

KEYWORDS: Hemorrhage, Hydrocephalus, Shunt
Intraoperative MRI with Diffusion Tensor Imaging (DTI) at 3Tesla for Evaluation of the Extent of Disconnection of White Matter Tracts in Modified Functional Hemispherectomy.

J Nair¹, C Saint-Martin¹, J Farmer¹, J Atkinson¹, J Montes¹
¹McGill University Health Center, Montreal, Quebec, Canada

Purpose
1) To emphasize the role of intra-operative MR imaging (MRI) in the post-surgical outcome of modified functional hemispherectomy performed for seizure control in pediatric epileptic patients. 2) Evaluate the role of DTI in intra-operative MRI, in determining complete disconnection of the white matter tracts for optimal postsurgical results.

Materials and Methods
Ten pediatric patients with recurrent seizures underwent modified functional hemispherectomy for various etiologies of seizure [Congenital Middle Cerebral Artery Infarct with gliosis (n=5), Hemimegalencephaly (n=1), Rasmussen encephalopathy (n=1) Extensive Polymicrogyria (n=1), Cortical Dysplasia (n=1) and Hemorrhagic Encephalitis (n=1)]. All patients had undergone previous MRI examination (including DTI in most cases) and presurgical evaluation including detailed history, neurologic examination and electroencephalogram. All intra-operative MRI scans included 3D T1- and T2-weighted images as well as 32 directional DTI. All cases were all scanned on the same intra-operative 3T MR scanner (Philips Medical Systems, Netherlands). Diffusion tensor images were acquired with SENSE head coil. Each DTI dataset was acquired with a multislice, single shot echo-planar imaging (SENSE factor = 2.5) spin echo sequence. Transverse slices were acquired (parallel to the line connecting the anterior and posterior commissures) covering the whole brain with no slice gap and 2.5 mm isotropic resolution. Diffusion weighting was applied along 32 directions with b value of 1000 s/mm². To improve the signal to noise ratio, additional DTI datasets were acquired and averaged after coregistration. The complete sequence took seven minutes. The images obtained were postprocessed on the Philips Workstation to obtain color maps and also for fiber tracking. The studies were evaluated simultaneously by two fellowship-trained pediatric neuroradiologist blindfolded to the findings of each other.

Results
Two out of the 10 patients had suspected incomplete disconnection on the conventional images which was confirmed further by DTI images. They proceeded for second surgery which then showed complete disconnection on subsequent DTI.

Conclusions
Initial data suggests that addition of DTI sequence to intraoperative MRI, may significantly improve outcome in patients undergoing modified functional hemispherectomy which depends upon complete disconnection of the white matter tracts.

Longitudinal Changes in Diffusion Properties in the White Matter Pathways in Patients with Tuberous Sclerosis Complex

J Song¹, F Baumer², P Mitchell², R Pienaar², M Sahin², P Grant³, E Takahashi⁴
Purpose
The purpose of this study was to identify predictors of longitudinal changes in diffusion properties of white matter tracts of projection, association and commissural fibers in patients diagnosed with Tuberous Sclerosis Complex.

Materials and Methods
Structural and diffusion magnetic resonance imaging was carried out in 17 subjects diagnosed with Tuberous Sclerosis Complex (TSC) (mean age, 7.2 ± 4.4 years, range: 2 – 17.5 years) and with at least 2 scans (mean number of days between the 2 scans 419.4 days ± 105.4 days, range: 309 – 741 days). There were 10 males and 7 females; 5 of whom had autism spectrum disorder (ASD); and 10 of whom had seizure disorder. A coordinate-based tractography atlas was used to guide ROI placement to segment the bilateral internal capsule/corona radiata, bilateral cingulum bundle, and corpus callosum. These ROIs were then co-registered using FLIRT to each subject's second scan. The outcomes were mean change in apparent diffusion coefficient (ADC) and the mean change in fractional anisotropy (FA).

Results
Multiple linear regression analyses showed gender to be a significant predictor of mean change ADC in TSC subjects in the left internal capsule, right and left cingulum bundles, and corpus callosum (Fig 1), adjusting for initial ADC scan measures. Gender also emerged as a significant predictor of mean change in FA in the corpus callosum, adjusting for initial FA scan measure. Adjusting for initial ADC scan measures, seizure disorder emerged as a significant predictor of mean change in ADC in the left internal capsule. ASD did not emerge as a significant predictor in either the mean change in ADC or FA in the studied white matter tract pathways.

Conclusions
Gender and seizure disorder were independent predictors of mean change in ADC or FA in some white matter tract pathways in TSC subjects. White matter microstructural integrity was more affected in males than in females in the left internal capsule, right and left cingulum bundles, and corpus callosum and more affected in TSC subjects with seizure disorder in the left internal capsule than in subjects without seizure disorder.

Magnetic Resonance Imaging of the Pediatric Calvarial and Spinal Bone Marrow

T Kelly¹, J Ledford¹, S Frost¹
¹Medical College of Wisconsin and Children’s Hospital of Wisconsin, Milwaukee, WI

Purpose
The purpose of this educational exhibit is to show how the MR imaging (MRI) signal pattern observed in diseased bone marrow differs from the patterns seen in the normal developing pediatric skull and spine.

Materials and Methods
A focused systematic review of age-related normal MR imaging signal characteristics of the developing axial skeleton is provided. Subsequently examples of the MRI patterns seen in a range of disease processes that involve the calvarium and spine will be shown and categorized as: (1) neoplastic, (2) inflammatory/infectious, (3) genetic/autoimmune (such as the T1 sagittal image of a 14-year-old girl with Blackfan-Diamond anemia shown below), (4) hematologic/vascular, or (5) traumatic/iatrogenic.

Results
MR imaging has long been proven to be the mainstay of bone marrow evaluation because of its excellent tissue contrast differentiation. The normal developing bone marrow undergoes the most rapid change in size, composition and cellularity during the first 25 years of life. In order to facilitate detection of diseased bone marrow, we need to know the MRI appearance of normal bone marrow.

Conclusions
This educational review can facilitate accurate diagnosis of head and spine bone marrow
pathology by providing a fundamental knowledge of the normal MR imaging pattern seen during various stages of development of the pediatric skull and spine. Examples of abnormal bone marrow pathology will be shown.

Mapping the Prenatal Connectivity of the Human Cerebellum and Brainstem Using Diffusion Tensor Tractography

M Cagneaux, C Mitter, P Brugger, D Prayer, G Kasprian

1Department of Pediatric and Fetal Imaging, Hôpital Femme Mère Enfant, Lyon-Bron, France, 2Department of Biomedical Imaging and Image-guided Therapy Medical University of Vienna, Vienna, Austria, 3Centre for Anatomy and Cell Biology, Department of Systematic Anatomy, Medical University of Vienna, Vienna, Austria, 4Department of Biomedical Imaging and Image-guided Therapy, Medical University of Vienna, Vienna, Austria
Purpose
Diffusion tensor based tractography is a non-invasive approach that enables the prenatal visualization of unmyelinated axonal pathways such as the corpus callosum and the corticospinal tract in 3D (1-2). The cerebellum shows a widespread connectivity with various forebrain regions and the spinal cord represented by the superior- (SCP), middle- (MCP) and inferior cerebellar peduncles (ICP). Due to the small dimensions of these pathways in the developing fetal brain, they have not been attempted to be visualized in vivo and in utero. This in utero diffusion tensor imaging (DTI) study aims to depict the connectivity of the normal and abnormal fetal cerebellum in vivo.

Materials and Methods
34 cases (24 normal, 10 brain pathologies, gestational age: 19 gestational weeks (GW) to 36GW) were retrospectively extracted from an existing in utero DTI datasets, after acquisitions with visible fetal movement (>80% of examinations) were excluded. DTI sequences were acquired on a 1.5 T Philips Achieva unit (axial rapid echo planar diffusion tensor sequence; maximum acquisition time 1 min 50 s; 16 gradient encoding directions, b values of 0 and 700 s/mm², reconstructed asymmetric voxel size: 0.94 _ 0.94 _ 3 mm, field of view 230 mm, 408 slices). Tractography was performed using a deterministic approach (threshold: FA=.1, angle change 32°) after defining multiple regions of interest in the area of SCP, MCP, and ICP. Visualization of these structures in adults served as anatomical reference for the tracking procedure (3-4).

Results
The MCP and transverse pontine/corticocerebellar fibers were consistently observed in 18/34 (53%) patients, in association with the SCP in 9/18 (50%) (Figure), ICS in 3/18 (17%) and both in 4/18 (22%). In 5 patients (15%), the transverse pontine trajectories could not be visualized, whereas the MCP (4/5 80%), ICP (2/5 40%) and SCP (5/5 100%) proper were successfully depicted. In 11/34 (32%) patients, cerebellar peduncle pathway identification was not possible, because of a low signal/noise ratio (5/11) (46%) or minor fetal or maternal motion (6/11) (54%).

Conclusions
Despite the small size, low DTI resolution and the random orientation of the fetal head, cerebellar outflow and inflow tracts traveling through the MCP, SCP and ICP were depicted by DTI and tractography in a preselected group of fetuses. Due to the small dimensions of the examined structures, almost complete absence of maternal or fetal motion as well as an optimal signal/noise ratio (coil position) are required to achieve anatomically plausible tractography results.

KEYWORDS: Cerebellum, DTI Tractography, Fetal MR Imaging
Mesial Temporal Lobe Morphology in Intractable Pediatric Epilepsy: So Called Hippocampal Malrotation, Associated Findings, and Utility for Presurgical Lateralization

R Awwad\textsuperscript{1}, H Greiner\textsuperscript{1}, J Vannest\textsuperscript{1}, F Mangano\textsuperscript{1}, J Leach\textsuperscript{1}
\textsuperscript{1}Cincinnati Children’s Hospital Medical Center, Cincinnati, OH

Purpose
Diagnostic criteria for hippocampal malrotation (HIMAL) include: asymmetric rounded hippocampal shape, vertical collateral sulcus, blurring, and low fornix. Relationship to epileptogenesis remains speculative and utility as a lateralizing finding for seizure surgery is unknown. Given normal developmental changes, analysis of HIMAL in a pediatric population is needed to further define this entity and determine potential utility for surgical selection.

Materials and Methods
48 surgically treated children with intractable epilepsy formed the study group excluding tumors, destructive lesions, and gyral malformations involving the temporal lobe. An age, sex, and handedness matched control group (N=48) excluded subjects with a history of neurologic or psychiatric illness (including seizures). Volumetric 1-1.25 mm T1 and T2 FLAIR images were reviewed using MPR perpendicular to the hippocampi blinded to surgical side. Each temporal lobe was evaluated for imaging features associated with HIMAL: rounded hippocampus, blurring, vertical collateral sulcus, wider choroidal fissure, enlarged temporal horn, lower fornix location, hippocampal signal, and findings consistent with hippocampal sclerosis. A mesial temporal score (MTS) was calculated by summing the number of features. Collateral sulcus angle (CSA) was measured on coronal images perpendicular to the hippocampus.

Results
All epilepsy patients had cortical dysplasia (CD) on pathology, mean age:9.6 years (3m-18 y),
M:F 27:21; normal group was statistically identical. Imaging findings included: hippocampal sclerosis (5), findings of CD (20), encephalomalacia (3), non-lesional (23). Only 3 epilepsy (6.2%) and none of the normal subjects exhibited full features of HIMAL, as above (p=0.12). 8/48 (16.7%) epilepsy versus 2/48 (4.6%) normal subjects had both a rounded hippocampus and vertical collateral sulcus (suggesting HIMAL) (p=0.045). All features except lower fornix and rounded hippocampus were more prevalent in the epilepsy group. In normal subjects, all findings except larger temporal horn were more prevalent on the left (low fornix position, p=0.035). In seizure patients all MR imaging findings except larger temporal horn and hippocampal sclerosis were more prevalent on the left (vertical collateral sulcus and lower fornix, p=0.035). No difference in MTS comparing sides was noted in either group. Epilepsy subjects had larger MTS compared with normal (z = -2.95, p = 0.002). 14.6% of epilepsy subjects had a MTS > 3 compared with 1% of normal (p=0.0003). The left CSA was more acute (mean 67.3, 63.9) than the right (mean 74.7, 71.3) in both normal and epilepsy subjects respectively (p<0.0001). Both CSAs were more acute in epilepsy subjects, compared with side matched normal (p=0.04). There was no significant association with surgical side in those with HIMAL or lateralizing CSAs. Lateraling raw MTS had a significant association with surgical side, p=0.03, OR:7.33.

Conclusions
Strictly defined HIMAL occurs rarely in children with intractable epilepsy (6.2%). Using less stringent criteria HIMAL occurs more commonly in surgically treated pediatric epilepsy patients (16.7%) versus normal subjects (4.6%). CSA is more acute, and MTS are larger in epilepsy patients compared with normal subjects. Only raw MTS was significantly lateralizing to the surgical side. Morphologic differences between left and right temporal lobes in normal subjects and epilepsy patients need to be taken into account when evaluating these regions.

Morphologic Differences in Hippocampi of Children with Down Syndrome who Develop Infantile Spasms

A Choudhri\textsuperscript{1}, B Mudigoudar\textsuperscript{1}, J Wheless\textsuperscript{2}
\textsuperscript{1}University of Tennessee Health Science Center, Memphis, TN, \textsuperscript{2}LeBonheur, Memphis, TN

Purpose
The prevalence of epilepsy in children with Down syndrome (DS) is higher than the general population, but lower than in other causes of mental retardation. In patients with epileptic DS, a majority of whom will suffer from infantile spasms (IS), 40\% will have seizure onset within a year of birth. Among mental retardation syndromes, only DS exhibits hippocampal dysfunction. Additionally, studies of DS children, demonstrate that these low hippocampal volumes are not attributed to neurodegenerative changes, but likely are due to developmental differences. We hypothesized that DS with IS patients would have abnormal hippocampal volumes and morphology compared to IS patients without DS.

Materials and Methods
This HIPAA compliant retrospective study was performed after IRB approval. Patients with DS and IS who had MRI of the brain were identified from a chart review, and compared to a
demographic-matched control groups of patients with IS without DS. Hippocampal axis of rotation and volume was evaluated on review of MRI by a neuroradiologist blinded to the diagnosis. Volume loss and axis of rotation were scored in using a 4 point Likert scale (0 normal, 1 mild, 2 moderate, 3 severe). Intrasubject asymmetry in shape, volume and signal intensity was also evaluated.

Results
Six patients had diagnosis of DS with IS (age 1.07 years +/- 0.65, 3M/3F) and six patients had a diagnosis of IS without DS (age 1.05 years +/- 1.00, 3M/3F). Hippocampal volumes were lower in the DS with IS group (p = 0.0046). And hippocampal malrotation was more likely to be present in DS with IS group (p=0.0361) compared to DS without IS.

Conclusions
Children with Down Syndrome and Infantile Spasms have morphologically different hippocampi compared to children with Infantile Spasms without Down Syndrome. These findings may be a demonstration of reported immunohistological evidence of pathologic changes in the GABAergic interneurons in all hippocampal subregions in Down Syndrome patients who suffer from Infantile Spasms.

MRI characterization of Brain tumors in children younger than 2 years old: Correlation with pathology results

P Caro Dominguez1, J Michaud2, E Miller2, J Davila3
1Children's Hospital of Eastern Ontario, Ottawa, Ontario, 2Childrens Hospital of Eastern Ontario, Ottawa, Ontario, 3Children Hospital of Eastern Ontario, Ottawa, Ontario

Purpose
To evaluate the signal intensity (SI) characteristics of brain tumors in children younger than 2 years old, in whom myelination is still in process of development.

Materials and Methods
Brain tumors diagnosed in patients younger than 2 years were retrospectively assessed from January 1998 to November 2013. Two major pediatric institutions were involved in the research. Tumors were classified according the most recent WHO intracranial tumors classification (2007). Two pediatric neuroradiologists and one pediatric radiology fellow retrospectively and independently assessed tumor's T1 and T2 signal intensity qualitatively (hyperintense, hypointense relative to cortex) and quantitatively (measuring the signal intensity ratio [tumor SI / cerebral cortex SI]). The tumor architecture, presence of hemosiderin, ferritin, necrosis, and fibrosis in pathology was correlated with the imaging findings. The study was approved by the local Ethics Boards.

Results
Twenty eight children were enrolled (15 boys: age range 1-24 months; mean 15 months). The brain tumor pathologies included: Thirteen astrocytic tumors; 11 Grade 1 (4 midbrain, 3 suprasellar, 2 infratentorial and 2 supratentorial), 1 malignant suprasellar pilocytic astrocytoma and one glioblastoma multiforme. Five embryonal tumors; medulloblastomas (4; three classic
and one desmoplastic in a child with Gorlin syndrome) and one malignant rhabdoid tumor. Four neuronal and mixed neuronal-glial tumors; 2 gangliogliomas, 1 DNET, and 1 dysplastic cerebellar tissue. Three ependymal tumors, grade 1, grade 2 and anaplastic types respectively. One oligodendroglioma, one choroidal plexus papilloma and one posterior fossa dermoid cyst. Astrocytic, ependymal, embryonal and dermoid cyst had similar signal intensity ratio on T1-weighted and T2-weighted images. Neuronal-glial tumors demonstrated opposite SI. On T1-weighted images, astrocytic, ependymal tumors and dermoid cysts were hypointense (mean SI ratio of 0.81, 0.95 and 0.69 respectively). From all these tumors, only one brainstem glioma was hyperintense. All the glial tumors were hyperintense on T1-weighted sequences (mean SI ratio of 1.18). On T2-weighted images, astrocytic, ependymal tumors and dermoid cysts were hyperintense (mean SI ratio of 1.59, 1.44 and 1.53). Only one suprasellar pylocitic astrocytoma was hypointense on T2-weighted sequences. All glial tumors were hypointense on T2 (mean SI ratio of 0.72).

Conclusions
Brain tumors in the young child are rare but when present often the diagnosis is challenging. Applying the SI of the tumor relative to cortex can add information for characterization of the tumor. In our sample, neuronal-glial tumors had a decrease T1 and an increase T2 ratio; different from the rest of the tumors.

EP-185

MRI Findings in Patients Presenting with (Post)Infectious Acute Cerebellar Ataxia.

T Schneider¹, D Yousem¹, T Huisman¹
¹The Johns Hopkins University, Baltimore, MD, USA

Purpose
The development of acute cerebellar ataxia (ACA) following an infection is extremely rare. Previously published articles regarding imaging features solely refer to single case reports or very small patient populations (n < 4). This study was conducted to determine MRI findings of the largest known population of adult and pediatric patients with the clinical presentation of acute ataxia due to infectious or postinfectious cerebellitis.

Materials and Methods
Patients were identified by searching MRI radiology reports from 2003 – 2013 for the terms „cerebellitis” and „cerebellar ataxia”, and were then matched with the clinical history. Clinical cases submitted from subspecialty collaborating neurologists were also included. Patients with infratentorial as well as supratentorial involvement and cerebellar spread were included. Initial MRI studies of eligible patients were retrospectively reviewed by two neuroradiologists.

Results
During the period studied, 14 patients (7 pediatric and 7 adult patients) presented with infectious or postinfectious acute cerebellar ataxia. Two patients had completely unremarkable imaging. The remaining patients primarily showed cerebellar as well as vermian volume loss, bright signal abnormalities in the cerebellar peduncles, cerebellar hemispheres and / or dentate nucleus and
signs of increased intracranial pressure. Contrast enhancement was observed in cerebellar parenchyma (n = 3) as well as subarachnoid space (n = 3).

Conclusions
The imaging features of acute cerebellar ataxia syndrome vary from non-descript unremarkable findings to fulminant parenchymal inflammation with secondary hydrocephalus. This entity is likely multifactorial and the imaging features have yet to be well-characterized.

KEYWORDS: Cerebellum, Infections
Purpose
To describe changes in DTI, MR perfusion and tumor volumetrics in children and young adults with DIPG undergoing novel primary therapy with Bevacizumab (Bev) and radiotherapy (RT) and identify whether these metrics predict survival.

Materials and Methods
An institutional pilot study of bevacizumab based therapy in newly diagnosed DIPG was performed. MRI analysis (including DTI and DSC perfusion) was performed at 3 time points: baseline, prior to maintenance therapy (PTM, after RT and initial Bev), and at progression. DSC perfusion was processed and maximum normalized cerebral blood volume (mCBV) values within the tumor obtained. Tumor volumetrics were performed at each time point [total tumor volume (TV), enhancement volume (EV)] using a semi-automated technique implemented in BrainLab iPlan 3.0. %TV exhibiting enhancement (%EV) was calculated. DTI data was processed in the same system calculating diffusivity (D), and fractional anisotropy (FA) within the TV. Correlation of imaging metrics with progression free survival (PFS) and total survival (TS) was performed.

Results
8 patients were selected from this pilot clinical study (ages: 3-29 y). Mean PFS was 231 days, mean TS was 313 days. TV decreased markedly in most subjects at PTM (mean 50.7%). A reduction in D at PTM was noted in 7/8 subjects (overall mean change: -21%). Lower baseline D showed a trend towards correlating with TS, but was not significant (p=0.08). At progression D increased in 6 patients. A mixed change in FA was noted at PTM with 5 subjects showing an increase (mean: + 43%) and 3 showing a decrease (mean: -27%). maxCBV decreased (mean change: -30%) at PTM and increased (>20%) in only 3/7 at progression. Tumor enhancement was noted in 5 subjects. (Mean EV and %EV: 5.02 cc and 12.9% respectively). EV decreased in 4/5 at PTM (mean: – 76%) and continued to decrease at progression. Baseline TV, D, FA, EV, %EV and mCBV as well as percent changes of each metric at PTM did not significantly correlate with PFS or TS. No significant tumoral hemorrhage was noted during the treatment course.

Conclusions
During primary treatment of DIPG with Bevacizumab and RT in children there was a decrease in TV in all subjects, and decrease in D, mCBV, and EV in most subjects at the PTM time point. At progression, D increased in most. mCBV, EV, and EV% increased in a minority of cases, potentially related to the anti-angiogenic effects of Bevacizumab. Baseline TV, D, FA, EV, %EV and mCBV as well as percent changes of each metric at PTM did not significantly correlate with PFS or TS.

Multimodal Magnetic Resonance Imaging of Neonatal Encephalopathies.

M Gaha¹, N Mama², W Gamaoun², H Moulahi², N Mahdhaoui³, H Sboui³, K Tlili Graiess²
¹Radiology department Sahloul University Hospital Sousse/Tunisia & CHUM/Québec Canada, Sousse, Tunisia / Montréal, Québec, ²Radiology department Sahloul University Hospital Sousse/Tunisia, Sousse, Tunisia, ³Neonatology department Farhat Hached University Hospital Sousse/Tunisia, Sousse, Tunisia

Purpose
Neonatal brain disorders consist of a wide chapter including brain malformations, hypoxic–ischemic encephalopathy, intracranial infections, perinatal trauma and metabolic encephalopathy. We will focus here on hypoxic–ischemic encephalopathy, intracranial infections (especially materno-fetal infection with or without prolonged and/or premature rupture of membranes) and metabolic encephalopathy, those three conditions being the most frequent so far in our experience. Neonatal stroke is also analyzed. The applications of advanced MRI techniques, such as diffusion-weighted imaging (DWI) and magnetic resonance spectroscopy (MRS) are emphasized.

Materials and Methods
From January 2009 to March 2012, 40 newborns were investigated for neurological impairment without hypoxic-ischemic evident condition, by the neuroradiological staff of medical imaging department in Sahloul University Hospital, Sousse/Tunisia. All the patients underwent a conventional MRI with diffusion and monovoxel Spectroscopy.

Results
MR Imaging including DWI and MRS demonstrated hypoxic-ischemic encephalopathy in 3 cases, infectious disease in 2 cases, inborn errors of metabolism in 13 cases, neonatal focal stroke in 4 cases and isolated cerebral malformation in 2 cases. In 9 cases, various abnormalities were found. MRI was considered as normal in 7 cases.

Conclusions
Neuroimaging in the neonatal period is of great importance to depict parenchyma brain damage. Multimodal MRI is actually considered as a very effective tool in dealing with neonatal encephalopathy especially when a hypoxic-ischemic evident condition is not found. MRI can be performed in the early days of life when the neonate is stable enough and is highly efficient though diffusion images and spectroscopy in brain evaluation.

Neonatal Brain MRI findings; What brings the neonate to MRI suite.

H Tabban¹, M Shah², W Mubarak³, J AlRayahi¹, k salem¹, T salem¹, a Mekhlef¹
¹Hamad Medical Corporation/Hamad General Hospital, Doha, Qatar Doha, ²Hamad General Hospital, Doha, ³Interventional Radiology Fellow, doha, Doha
Purpose
Review of brain MR imaging (MRI) findings in neonates; spectrum of normal, normal variants and pathology.

Materials and Methods
Retrospective study of brain MRIs done in our institute during years 2012 and 2013.

Results
Range of etiology of brain and systematic pathology superimposed on incompletely mature neonatal brain.

Conclusions
Neonatal period is high in morbidity and mortality due to many combined factors, such not fully mature brain, antenatal and perinatal illnesses. Neonatal brain shows variable range of normal and normal variants; myelination and morphology, with superimposed pathology; ischemia, bleeding, sepsis and inborn metabolic disorders.

Patterns of Adrenoleukodystrophy: Influence of Age on Site of Involvement and Incidence of Asymmetry

R Cusic1, w miller2, D Nascene3
1University of Minnesota, Saint Paul, MN, 2University of minnesota, minneapolis, MN,
3University of Minnesota, Minneapolis, MN

Purpose
Adrenoleukodystrophy (ALD) is a rare, X-linked disease, most frequently affecting adrenal cortex, testes and central nervous white matter. When cerebral white matter is involved, disease typically begins in the posterior corpus callosum (CC) and progresses contiguously. Furthermore, the demyelination pattern at presentation is thought to be highly symmetric about the midline sagittal plane, with the progression of disease equally symmetric. In this study, we (1) evaluated for difference in age of presentation of typical versus atypical pattern cerebral ALD, and (2) determined the incidence of asymmetric white matter involvement at any time during the course of disease.

Materials and Methods
All ALD patients (129 patients) referred to the University of Minnesota were evaluated to determine average age of presentation and pattern of cerebral involvement at diagnosis. Patients were excluded if (1) they demonstrated no radiographic evidence of cerebral disease, or (2) known previous diagnosis of ALD without sufficient prior images at onset of cerebral disease.

Age at presentation was defined by first abnormal brain MRI within the University of Minnesota electronic records. Typical presentation was defined as posterior pattern of demyelination, beginning in the splenium of the CC with or without contiguous progression into surrounding white matter and/or into the brainstem. Atypical presentation was defined as disease originating from the genu corpus callosum, internal capsule, or any other atypical location. Presence of
asymmetry was noted either at the time of presentation or, for patients with more than 1 evaluable scan, at any time point during the course of disease.

Results
A total of 129 male subjects with 832 MR scans were evaluated. Based on the exclusion criteria described, 118 patients were included in the study. 64 patients (54.2%) presented typically, while 54 (45.8%) presented atypically. The median age of typical presentation pattern was 7 years, 7 months (range, 3y, 11m – 22y, 2m), while that of atypical presentation pattern was 9 years, 5 months (range, 4y, 0m – 37y, 6m) (p = 0.0004). Among patients with atypical presentation pattern, 20 demonstrated disease emanating from the genu of the CC (median age of presentation 10y, 1m) while 36 showed independent corticospinal tract involvement (median age of presentation 9y, 8m). At presentation, 17 patients (16%) demonstrated asymmetric disease as their only abnormality. A total of 53 patients (44.9%) demonstrated asymmetry at any time point.

Conclusions
Cerebral adrenoleukodystrophy has several different presentations, with the typical one originating posteriorly from the splenium of the corpus callosum and extending into the surrounding white matter and into the brainstem. The typical presentation is more common in a younger subset of patients, with atypical presentation occurring in an older population. This suggests different locations of selective vulnerability through childhood development. Asymmetric disease involvement was surprisingly common, seen in 44.9% of patients. To our knowledge, aside from one case report, this has never been reported. However, despite asymmetry at presentation or during follow-up, many of the patients with asymmetric disease demonstrated more symmetric disease with further follow up.

Pediatric spinal cord diffusion tensor imaging: a feasible study?

G Orman¹, T Huisman², I Izbudak³
¹Johns Hopkins School of Medicine, Baltimore, MD, ²The Johns Hopkins University School of Medicine, Baltimore, MD, ³Johns Hopkins University, Baltimore, MD

Purpose
Diffusion tensor imaging (DTI) of the spinal cord (SC) is technically limited by several reasons including small volume of the SC and low signal to noise ratio. In pediatric SC DTI application, the possibility of increased motion artifact makes obtaining accurate and reproducible DTI parametrics even more difficult. But, it could be still feasible and might give additional valuable information. Our purpose is to show our preliminary SC DTI results in different patient groups.

Materials and Methods
Pediatric SC DTI studies of patients with clinically confirmed pathology of the SC or central nervous system were prospectively evaluated for the study. Patients were divided into 5 groups according to their clinical history and conventional magnetic resonance imaging (MRI) findings. Region of interest (ROI) were placed manually by a radiologist in the sagittal plane at 7 intervertebral disc levels at the cervical SC (CSC) and 3 intervertebral disc levels at the thoracolumbar SC (TLSC). Fractional anisotropy (FA) and mean diffusivity (MD) values were
obtained for each level. The CSC group FA and MD values were compared with our previous normal CSC DTI database. TLSC values were evaluated independently.

Results
A total of 26 DTI studies of the 20 CSC MRI and 6 TLSC DTI were included in the study (One patient had both CSC and TLSC DTI). The mean age of the children was 6.64 (between 0.17 and 16) years. There were 11 girls and 14 boys in the study. The patients were divided as 1) Group 1: Hypoxia to the brain (3 patients), 2) Group 2: Craniocervical junction malformations (9 patients), 3) Group 3: Vertebral pathologies (4 patients) 4) Group 4: Head trauma (4 patients) 5) Group 5: Thoracolumbar DTI group (6 patients). Different groups were showing different FA and MD changes. One of the interesting findings was lower FA and higher MD at all CSC levels in a patient in group 1, who had chronic ischemic changes in his brain MRI due to hypoxic brain injury following cardiopulmonary arrest nine months ago. Our results also showed that, cranial malformations which cause compression at the level of craniocervical junction might cause lower FA and higher MD values in the upper CSC level. We had 6 TLSC DTI patients and we found variable FA-MD changes in patients with different pathologies.

Conclusions
Our preliminary data showed pediatric SC DTI is feasible at both CSC and TLSC levels and may give additional microstructural information by utilizing quantitative data which may be useful for clinical evaluation or follow-up of patients. DTI may also bring new insights in diseases such as Chiari 1 malformation or hypoxic brain injury in which conventional MRI may show normal cord. Further studies are needed in different disease groups with larger patient populations.

Pituitary Gland Enlargement in Sanfilippo Syndrome

D Nascene¹, Z Beatty¹, A McKinney²

¹University of Minnesota, Minneapolis, MN, ²University of Minnesota and Hennepin County Medical Centers, Roseville, MN
Purpose
CNS imaging findings in Sanfilippo syndrome (MPS III) are not well characterized. The purpose of this study is to confirm our initial hypothesis of pituitary gland enlargement in patients with Sanfilippo syndrome during routine MRI observed at our institution.

Materials and Methods
Patients with a clinical diagnosis of Sanfilippo syndrome and at least one brain MRI from 2007 onward were initially considered for inclusion from our PACS system. This yielded 15 patients that ranged in age from 2-19. For comparison to controls, a maximum age of 7 was chosen to avoid the potential for confounding pubertal changes. 3 patients were above age requirements and were excluded from statistical comparison. Controls with normal brain MRI were extracted from our PACS system and matched for age and sex, as both have been shown to correlate with differences in pituitary size. 11 children with a clinical diagnosis of Hurler syndrome (MPS I) met initial inclusion criteria of prior brain MRI from 2007 onward. 2 were excluded from statistical comparison for exceeding 7 years of age. Pituitary volumes were estimated using the prolate ellipsoid volume calculation method \( \pi/6 \times L \times W \times H \). The hyperintense foci on T1 imaging representing the posterior pituitary was measured separately and together with the rest of the gland to achieve whole, anterior, and posterior pituitary volume estimates. Pituitary shape was assessed by assignment of an Elster's grade. (Grade 1 = markedly concave, grade 2 = mildly concave, grade 3 = flat, grade 4 = mildly convex, and grade 5 = markedly convex.) Many patients in the Sanfilippo group had multiple studies with a maximum range of 26 months. Pituitary growth over these intervals was analyzed for longitudinal trends.

Results
12 patients with Sanfilippo syndrome, 11 patients with Hurler syndrome and 11 normal controls were included. Anterior, posterior, and whole pituitary volume, as well as Elster grade were all significantly greater in patients with Sanfilippo syndrome than in healthy controls and in patients with Hurler syndrome (all p values less than 0.05). Mean pituitary volumes were 530 mm\(^3\) in Sanfillipo patients, 310 mm\(^3\) in Hurler syndrome, and 217 mm\(^3\) in controls.

Conclusions
The results show a significant increase in anterior, posterior, and whole pituitary volume, as well as Elster grade in the patients with Sanfilippo syndrome when compared to both normal controls and patients with Hurler syndrome.

KEYWORDS: Metabolic, Pituitary Gland
Purpose
Imaging diagnosis of retinal hemorrhage in pediatric abusive head trauma (AHT) can be of important clinical value in very ill children in whom immediate ophthalmologic evaluation with dilated fundus exam is not feasible. Based on the preliminary evidence that trauma-induced breakdown of the blood-brain barrier with subsequent diffusion of inflammatory cells and cytokines can alter the biochemical profile of the vitreous humor (Morescalchi, Duse et al. 2013), we speculated that the vitreous humor will demonstrate altered diffusivity in the presence of trauma-induced retinal hemorrhage with associated inflammatory response. The study therefore evaluated the potential utility of measuring apparent diffusion coefficient (ADC) of the vitreous humor to detect diffusivity changes in the vitreous compartment.

Materials and Methods
The study was approved by our Institutional Review Board as part of a larger study related to the identification and evaluation of children at risk for AHT. A total of 16 brain MR imaging (MRIs) from March 1, 2011 to June 1, 2012 obtained at Children's Hospital of Pittsburgh of UPMC from
children with retinal hemorrhage and a clinical diagnosis of AHT were retrospectively evaluated. As controls, 22 negative brain MRIs obtained from patients of similar age with varying clinical indications for the exam including seizure, nonspecific neurologic complaints, developmental delay, ingestion, and nontrauma neurologic insults were studied. None of the controls obtained dilated fundus exam as there was no clinical indication. Apparent diffusion coefficient values of the right and left eye were obtained of both cases and controls to evaluate for potential correlation to the presence or absence of retinal hemorrhage on dilated fundus exam. Region of interest (ROI) with an area of 2-3 cm² was drawn in the right and left eye directly on the Stentor workstation. For internal control, ROI with an area of approximately 1 cm² was drawn of the frontal horn of right lateral ventricle.

Results
The median age was 4.6 months (quartiles: 2.6, 7.4) in the control group and 5.5 months (quartiles: 4.3, 18) in the trauma group with no statistically significant different between them (p = 0.10). The percent of subjects that were female was 46% in the control group and 38% in the retinal hemorrhage group with no statistically significant difference between groups (p = 0.60). Additionally, there was no statistically significant correlation between ADC values and age (R² = 0.2, p = 0.44) or sex (p = 0.29). The median ADC value was 3.0 (quartiles: 2.9, 3.2) in the control group and 3.0 (quartiles: 2.9, 3.1) in the retinal hemorrhage group (p = 0.55). Similarly, there was no statistically significant difference in normalized ADC values between the control and retinal hemorrhage groups (-0.13 and -0.08 respectively, p = 0.55). The areas under the receiver operating curve for the determination of the presence of retinal hemorrhage based on ADC values and normalized ADC values were 0.56 and 0.44, respectively.

Conclusions
Apparent diffusion coefficient has not shown to be a sensitive imaging biomarker for detecting changes in molecular diffusivity within the vitreous compartment in children with retinal hemorrhage associated with AHT. More recently, Bodanapally et al. (Bodanapally, Kathirkamanathan et al. 2013) found that trauma-related diffusivity changes in the posterior segment of the optic nerve differentiated patients with traumatic optic neuropathy from those without (p<0.05). It may be that the degree of ocular trauma is better evaluated with optic nerve diffusivity than vitreal compartment diffusivity. Alternatively, high resolution susceptibility MRI can be instituted to better delineate the presence of retinal hemorrhage as confirmed previously by our group (Zuccoli, Panigrahy et al. 2013). Continued efforts will be needed to develop a sensitive imaging biomarker for ocular manifestations of AHT in children.

Pre-Operative Quantitative Diffusion Tensor Tractography to Determine Language Laterality in Pediatric Epilepsy.

P Muthusami¹, F Wang¹, W Logan¹, M Shroff¹
¹The Hospital for Sick Children, Toronto, Ontario, Canada

Purpose
Language functions often are affected in epilepsy patients. Surgical candidates require detailed neuropsychological assessment to determine language functional status and hemispheric laterality. Functional MR imaging (fMRI) is the currently accepted gold standard in adults to determine hemispheric dominance; however, in children the application and interpretation is not straightforward, often leading to failed or indeterminate exams. Diffusion tensor tractography (DTT), on the contrary, is easier to perform and does not require active patient participation. The purpose of this study was to assess if DTT-derived metrics can reliably determine hemispheric language laterality preoperatively in pediatric epilepsy patients.
Materials and Methods
Seven consecutive pediatric epilepsy patients, who were determined to be surgical candidates, underwent blood oxygen level dependent (BOLD) fMRI in a 3 T magnet as part of their routine presurgical work up. Diffusion tensor imaging was performed in the same sitting. Diffusion tensor imaging data and fMRI data were postprocessed separately by two readers blinded to the findings of the other. Tractography was performed using standard software (DTI Studio) and DTI metrics including number of tracts, number of voxels, tract length and tract density were calculated. This was followed by calculation of laterality indices (LI) from each of these metrics. A composite DTI-LI was generated to represent hemispheric language laterality from DTI. These LIs subsequently were compared to BOLD fMRI-determined language laterality.

Results
There was correlation in six of the seven cases (85.71%) between DTI-LI and fMRI lateralization. The sensitivity and specificity were 83.3% and 100% respectively, while the positive and negative predictive values were 100% and 50% respectively. However, no correlations were found between classically used clinical features (duration and frequency of seizures) with strength of lateralization or the total number of fiber tracts.

Conclusions
These preliminary data show that DTT-derived metrics hold promise in determining hemispheric language laterality in pediatric epilepsy patients. This could potentially play a role in pediatric epilepsy cases where fMRI is not feasible, not interpretable or indeterminate.

Relationship of Syrinx Size and Tonsillar Descent to Spinal Deformity in Chiari I Malformation with Associated Syringomyelia

A Radmanesh1, J Godzik2, J Shimony3, D Limbrick2
1Mallinckrodt Institute of Radiology, St Louis, MO, 2Washington University in St Louis, St Louis, MO, 3Washington Univ School of Medicine, St. Louis, MO

Purpose
Chiari Type I Malformation (CIM) is a developmental abnormality often associated with a spinal syrinx. Syringomyelia in CIM patients is known to be associated with scoliosis. However, the influence of specific radiographic features on the prevalence of scoliosis remains unclear. The primary purpose of this study is to assess the relationship between maximum syrinx diameter and the presence of scoliosis in patients with CIM-associated syringomyelia. A secondary purpose was to explore the role of CVJ characteristics as additional risk factors for scoliosis.

Materials and Methods
A retrospective review was performed of children with CIM and syringomyelia who were evaluated at a tertiary local academic institution from 2000 to 2012. Syrinx morphology and craniovertebral junction (CVJ) parameters were evaluated by magnetic resonance imaging (MRI), while the presence of scoliosis was determined using standard radiographic criteria. Multiple logistic regression was used to analyze radiological features that were associated with scoliosis.
Results
Ninety-two subjects with CIM and syringomyelia were identified. Mean age was 10.5±5 years. A total of 35/92 (38%) patients were found to have spine deformity, of whom 23/35 (66%) were referred primarily for deformity and 12/35 (34%) were diagnosed with deformity during workup for other symptoms. Multiple regression analysis identified larger maximum syrinx diameter (>6mm) (OR 12.1, CI95% 3.63 - 40.57, p < 0.001), and moderate (5-12 mm) rather than severe (>12mm) tonsillar herniation (OR 7.64, CI95%2.3 - 25.31, p = 0.001) as significant predictors of spine deformity when controlling for age, gender, and syrinx location.

Conclusions
The current study further elucidates the association between CIM and deformity by defining specific radiographic characteristics associated with the presence of scoliosis. Specifically, patients with larger maximum syrinx diameter (>6mm) are at increased risk of scoliosis at presentation.

EP-206 6:30AM - 9:00PM
Screening Cranial MRI and MR Angiography in Sickle Cell Anemia: A Frequency and Cost Evaluation Study

D Russell1, J Loewen1, C Brown2, M Quarmyne2, J Kang1, Y Zhao1, N Desai1
1Emory University, Atlanta, GA, 2Children's Healthcare of Atlanta, Atlanta, GA

Purpose
A devastating complication of sickle cell anemia (SCA) is overt clinical stroke. Overt clinical stroke incidence may be reduced with institution of chronic transfusion therapy after consecutive abnormal transcranial doppler (TCD) examinations. Patients with abnormal TCDs and/or prior overt stroke, many of whom are placed on chronic transfusion therapy, regularly undergo MRI/MRA to screen for vasculopathy and silent cerebral infarctions. Currently, however, there exists no evidence based recommendations for the appropriateness of screening MRI/MRA. Such screening, regardless, is commonly performed on an empiric basis at annual or biennial frequencies, contributing to significant medical risk (due to the need for sedation in young children) and cost. The purpose of this study is to assess the cost and efficacy of screening frequency for MRI/MRA detected abnormalities with regard to temporal progression of infarct and arterial stenosis in a large group of SCA patients.

Materials and Methods
IRB approval was obtained. At a large tertiary referral children's hospital, a retrospective review of MRI/ MRA reports of SCA linked to a database containing patients currently undergoing chronic transfusion therapy for either abnormal TCD (primary prophylaxis) or previous overt clinical stroke (secondary prophylaxis) was evaluated noting the presence of chronic white matter disease, basal ganglia and large territory infarcts, vessel stenosis and progression of such findings between exams. Exclusion criteria included blood dyscrasia other than SCA and patients older than 21 years. Data were analyzed for both descriptive and inference-based statistics along with a hypothetical cost basis analysis.
Results
595 MRI/MRA reports in 140 patients were reviewed with the population having undergone a mean of 4.25 (SD=2.639) MRI/MRA exams occurring on average 18.054 months apart (SD=11.429). Assuming a unit cost of $2000/exam, the total cost in this group was $1,191,000. The higher the patient's age and higher number of transfusions the patient had received, the more likely they had received a higher number of MRI exams (p< 0.001). While 40 out of 140 (29%) patients had progression of stenosis and 19 out of 140 (14%) had progression of infarcts, neither the presence of progression of stenosis or progression of infarcts had a significant relationship with the number of months between examinations (p=0.271 and p=0.654, respectively) based on a two-sample t-test.

Conclusions
In a group of SCA patients undergoing chronic transfusion therapy, MRI/MRA documented progression of stenosis and infarcts correlated poorly with examination frequency with current empiric practices while resulting in significant cost impact, raising the critical issues of possible overutilization or misutilization. Prospective trials assessing individualized clinical and radiological criteria, to include distinction between patients undergoing chronic transfusion for primary versus secondary prophylaxis, are needed to procure evidenced based MRI/MRA screening guidelines in patients with SCA.

Tecto-cerebellar dysraphism with occipital encephalocele is part of the Joubert syndrome spectrum

A Poretti1, K Rostasy2, X Wei3, E Lance4, C Fauth2, J Koch2, W Hader6, L Jamal4, E Valente7, T Huisman5, E Boltshauser9
1Johns Hopkins University School of Medicine, Baltimore, MD, 2Medical University, Innsbruck, Austria, 3University of Calgary and Alberta Children’s Hospital, Calgary, AB, Canada, 4Kennedy Krieger Institute, Baltimore, MD, 5University Hospital, Salzburg, Austria, 6University of Calgary, Calgary, AB, Canada, 7Mendel Laboratory, IRCCS Casa Sollievo della Sofferenza Institute, Roma, Lazio, Italy, 8The Johns Hopkins University School of Medicine, Baltimore, MD, 9University Children’s Hospital, Zürich, Switzerland

Purpose
Tectocerebellar dysraphia with occipital encephalocele (TCDOE) describes vermian hypogenesis with tectal malformation and occipital encephalocele. Based on conventional MR imaging (MRI) and diffusion tensor Imaging (DTI) findings, we recently suggested that TCDOE may be part of the Joubert syndrome (JS) spectrum. We report on clinical, neuroimaging (conventional and DTI) and genetic findings in four children with TCDOE.

Materials and Methods
Conventional MR images were evaluated for infra- and supratentorial abnormalities. Color-coded fractional anisotropy (FA) maps were evaluated for presence of the midbrain decussation of the superior cerebellar peduncles (SCP). Data about neurological findings and outcome were
collected from clinical history and follow-up examinations. Genetic analysis was performed in three patients.

Results
Four children were included (2 females). All patients presented at birth because of an occipital encephalocele. At last follow up, only two patients were alive. Two children died at the age of 18 months and 10 years. Data on neurocognitive development were available for three children at 4 months, 6 years and 17 years, respectively. Truncal hypotonia was present in all patients. Two patients had intellectual disability (severe in one patient and mild in the other one), the youngest patient impaired global development. Ataxia, spasticity of all extremities, anarthria, ptosis, neonatal breathing abnormalities, facial dysmorphic features and choroidal colobomas were present in one patient. In all patients, MRI demonstrated hypoplasia of the cerebellar vermis, tectal beaking, and elongation, thickening, and horizontal orientation of the SCP with a deepened interpeduncular fossa forming a molar tooth sign (MTS). Additionally, in all patients there was congenital ventriculomegaly that required a ventriculo-peritoneal shunt in three children. Finally, in one patient, subependymal heterotopia and focal cortical dysplasia were noted. Diffusion tensor imaging data were available for three children and showed absence of the SCP decussation in all. Genetic analysis revealed a homozygous deletion leading to a frameshift and premature stop codon in exon 6 of the TMEM237 gene (one of the 23 JS genes known so far) in one patient. Whole exome sequencing did not reveal causative mutations in the two other patients.

Conclusions
The presence of MTS in all, absence of the SCP decussation on DTI in three, and a homozygous mutation within the TMEM237 gene in one patient confirm our first hypothesis that TCDOE may not be a nosological entity, but rather represents a structural manifestation within the JS spectrum.

E Bonfante¹, M Koenig², R Adejumo¹, R Riascos³
¹University of Texas Medical School at Houston, Houston, TX, ²University of Texas Medical School at Houston, Houston, TX, ³University of Texas Medical Branch, Galveston, TX

Purpose
To review the clinical presentation and neuroimaging findings of patients with genetically confirmed Leigh syndrome.

Materials and Methods
We reviewed the clinical and imaging findings of the 15 genetically confirmed Leigh syndrome patients followed at the University of Texas Houston Leigh clinic.

Results
Of our 15 genetically confirmed Leigh syndrome patients, 9 were male and 6 were female. The age of first symptom onset was birth in 6 (40%), less than two years in 4 (26%), and more than three years in 5 (33%). The most frequent presenting symptoms were hypotonia (n=11, 73%),
developmental regression (n=11, 73%), hypertonia (n=4, 26%), and ataxia (n=4, 26%). Genetic studies showed mitochondrial DNA mutations in 11 and nuclear mutations in 4. MR findings included lesions in the brainstem in 7 patients (46%), basal ganglia in 12 (80%), thalami in 3 (20%), cerebellar white matter in 2 (13%), and global atrophy in 2 (13%). The lesions in the brainstem were most frequent in the midbrain and medulla oblongata. Increased number of original lesions was seen in 4 of the 7 patients with follow up studies, evolution of the initial lesion was seen in 4, and regression of the original lesions was seen in a single patient. No cerebral white matter or cortical lesions were found in any of the 15 patients.

Conclusions
Leigh syndrome is a devastating neurodegenerative disorder characterized on neuroimaging by focal, bilateral symmetric lesions in the basal ganglia and brainstem. Historically it is described as presenting in infancy with death by 2 years. The availability of genetic testing has enabled us to recognize clinical and genetic heterogeneity in this devastating disease. Diverging from the classic descriptions, we found a significant proportion of patients presenting after the third year of life (33%). In concordance with the literature, we found that Leigh syndrome does not have predilection for cerebral white matter or cortical involvement¹⁻³. Children follow a similar pattern of bilateral, symmetric basal ganglia or brainstem changes. The presence of white matter or cortical lesions in a child with regressive neurologic disease should prompt investigation for other etiologies, besides Leigh syndrome. Lesions in Leigh syndrome evolve over time. The lack of visible lesions should not necessarily exclude the diagnosis of Leigh syndrome. If the diagnosis is highly suspected, repeat imaging may be indicated. In summary, it is crucial for neuroradiologists to include Leigh syndrome in the differential of any child presenting with bilateral, symmetric basal ganglia or brainstem lesions.

KEYWORDS: Mitochondrial Disease, MR Imaging Brain, Neurodegenerative
Comparing Preliminary and Final Neuroradiology Reports: What are the Factors that Determine the Differences?

L Babiarz\(^1\), M Cohen\(^1\), M Carone\(^2\), G Sevinc\(^1\), P Nagy\(^1\), J Lewin\(^1\), D Yousem\(^1\)

\(^1\)Johns Hopkins Hospital, Baltimore, MD, \(^2\)University of California, Berkeley, Berkeley, CA

Purpose
Trainees' initial interpretations of neuroradiological studies are typically reviewed and finalized by neuroradiologists on staff. In this study we set out to identify the factors that determine the
degree to which the preliminary neuroradiology reports are modified compared to the finalized reports.

Materials and Methods
Study protocol was approved by our internal review board (IRB). All neuroradiology reports composed by a trainee and finalized by faculty between November 2012 and October 2013 were analyzed. The character length of the preliminary and final reports was determined, and the percent character change (PCC) between the preliminary and final reports, defined as 100 x total number of single character changes / total number of characters in the initial report, was calculated. Additional data including exam time (day vs. night), critical finding (CF) flag, trainee training level (R1, R2, R3, R4, and fellow), faculty experience level (junior, intermediate, senior), imaging modality (CT vs. MRI), and native vs. non-native English speaker status of the interpreter were collected. Univariable and multivariable linear regression models were employed to evaluate the marginal and joint association between PCC and the factors considered. Model parameters were estimated using generalized estimating equations accounting for the possible correlation between data on reports written by the same trainee and/or faculty.

Results
34,661 reports, including 21,204 (61.2%) CT and 13,457 (38.8%) MRI, were reviewed. 20,123 (58.1%) were performed during the daytime and 14,538 (41.9%) were at night. 4,091 (11.8%) were flagged with a CF. 21,998 (63.5%) were read by fellows, 2,322 (6.7%) by R1s, 4,429 (12.8%) by R2s, 3,663 (10.6%) by R3s, and 2,249 (6.5%) by R4s. 3,920 (11.3%) were read by junior, 12,885 (37.2%) by intermediate, and 17,856 (51.5%) by senior faculty. Of the 58 trainees, 12 were non-native English speakers, and of the 18 faculty, 10 were non-native English speakers. The average PCC was 14.8% (min=0%, 1st quartile=0.3% median=6.6%, 3rd quartile=21.1%, max=701.8.2%) for all reports. The distribution of all reports by PCC is depicted in Table 1. Multivariable analysis revealed that PCC was on average increased for CF flagged reports (+4.8%; p<0.0001), MRI exams (+3.7%; p<0.0001) and in reports involving non-native trainees (+4.0%, p=0.0248). Compared to R1 trainees, reports written by R2 (-5.5%; p=0.0017), R3 (-6.0%; p=0.0015), R4 (-8.2%; 0.0003) and fellows (-8.9%; p<0.0001) had decreased PCC on average. While junior and intermediate faculty were associated with similar average PCC (p=0.8589), on average, reports edited by senior faculty had a lower PCC (-6.88%, p<0.0001). The association between average PCC and either of exam time and native vs. non-native speaker status of the involved faculty was not statistically significant (p=0.6098 and 0.3516, respectively).

Conclusions
Our review of 12 months of neuroradiological reports showed that having a CF in the report, trainee training level, faculty experience level, imaging modality, and native vs. non-native English speaker status of the trainee are associated with the degree to which the preliminary reports are modified compared to final reports, and that exam time and speaker status of the faculty are not. We believe that understanding the factors that influence the extent of report revisions could facilitate and improve the quality of report generation.

Effectiveness of Direct Physician-to-Physician Marketing When Compared with Physician-to-Patient Consultations on Imaging Volumes in Outpatient Imaging

L Grignon¹, M Keiper²

¹University of Nebraska Medical Center, Omaha, NE, ²University of Nebraska Medcial Center, Omaha, NE

Purpose
The purpose of this study is to compare the effectiveness of direct radiologist-to-physician marketing with physician-to-patient consultations in maximizing imaging volumes in outpatient imaging.

Materials and Methods
Monthly cross sectional imaging referral volumes from target referring clinicians and cross-sectional imaging volumes for individual patients were tracked to determine the effect of direct physician-to-physician marketing when compared with the effect of physician-to-patient consultations on imaging volumes. From January to December 2009, baseline monthly physician referral data were obtained from 19 referring clinicians while a non-physician radiology sales representative visited the referring clinicians’ office every two weeks to establish a baseline referral volume. From January to June 2010, the same radiology sales representative visited the referring clinician offices every two weeks but was accompanied by a neuroradiologist once a month to assess the effect of direct radiologist involvement in marketing to referring clinicians. Direct radiologist to patient consultations on cross-sectional imaging studies were also performed for a 6 month period from January 2009 to June 2009. Imaging volumes from these patients were tracked from the point of consultation through June 2010 and compared with a representative control sample of patients who did not elect to have a personal consultation with a radiologist.

Results
Cross-sectional imaging referral volumes after direct physician-to-physician marketing were
approximately 2.5 times greater during the 6-month period when compared with the imaging volumes achieved by utilizing the sales representative alone (p< 0.0001) The increase in cross-sectional imaging volumes with physician to physician marketing was also significantly greater than the increase in cross-sectional imaging volumes derived from patients who participated in one-on-one physician consultations, even though these patients demonstrated a modest increase in utilization of imaging services when compared with baseline controls.

Conclusions
Direct physician-to-physician marketing is a highly effective tool in rapidly increasing cross-sectional imaging volumes and is significantly more effective than direct radiologist to patient consultations in increasing referral volumes in outpatient imaging.

Expectations of Medical Student Neuroradiology Education: A Survey of Practicing Neuroradiologists and Neurologists

F Chokshi¹, S Galgano², A Prater³, E Ebert⁴, J Khan³, M Mullins³
¹Emory University School of Medicine, Marietta, GA, ²University of Alabama Birmingham, Birmingham, AL, ³Emory University School of Medicine, Atlanta, GA, ⁴Metrowest Medical Center, Framingham, MA

Purpose
Currently, neuroradiology education for medical students does not have established guidelines. The purpose of this study is to determine which neuroradiological diseases neuroradiologists and neurologists feel are important for a medical student (MS) to competently recognize by the end of medical school. This information may be used to formulate national guidelines.

Materials and Methods
Members of the American Society of Neuroradiology (ASNR) and the American Academy of Neurology (AAN) were surveyed. Respondents were presented 32 diseases with neuroimaging findings, and asked which ones a MS should be expected to diagnose by the end of medical school. Using a 50% response threshold per disease entity, results were tabulated into three groups: diagnoses that 1) greater than 50% of neuroradiologists and neurologists felt MS should know radiographically by rotation completion; 2) less than 50% of respondents in both groups felt were important for MS to identify; and 3) both groups disagree are important for MS to identify.

Results
Most ASNR and AAN respondents thought MS should be able to diagnose intraparenchymal hemorrhage (ASNR 80.4%, AAN 84.3%; p=0.346) and subarachnoid hemorrhage (ASNR 74%, AAN 78%; p=0.394). Both groups (>50%) thought subdural hematoma, acute ischemic stroke, epidural hematoma, and spinal cord compression are important to diagnose. Conditions such as spine fractures, non-acute stroke, AVM, and ENT pathology showed varied results between both groups (Table 1).

Conclusions
Varying degrees of similarity and disparity exist between the expectations of neuroradiologists
and neurologists regarding MS neuroradiology education, presenting a positive opportunity for greater consensus, dialogue, and joint curriculum formation.

Improving Quality of Patient Care by Minimizing Potential Risk: Decreasing Non-Contrast Head Computed Tomography Radiation Dose

R Smyth1, M Graves2, A Corey1
1Emory University School of Medicine, Atlanta, GA, 2Grady Memorial Hospital, Atlanta, GA

Purpose
At our facility, we perform approximately 800 non-contrast head computed tomography (CT) exams each month. Prior to this intervention, computed tomography (CT) technologists used a wide variety of personally installed non-contrast head CT (NCHCT) protocols to complete these examinations. As a result, many patients received radiation doses higher than the dose required to generate quality diagnostic images, and significant dose variability existed. The goals of this investigation were: (1) to evaluate the effect of standardizing NCHCT protocols on average radiation dose and on dose variability; and (2) to ensure no NCHCT was performed with a CT dose index volume (CTDIcon) greater than 70mGy.

Materials and Methods
All previously installed protocols for adult axial NCHCT's were erased from each of the six CT scanners and were replaced with standardized protocols. These updated protocols were based upon the recommendations of the American Association of Physicists in Medicine and vendor technical support. This investigation examined individual scan doses (CTDIcon) of a 100 patient sample from three time points: a baseline pre-intervention month, the month immediately following the intervention month, and three months post-intervention. A random order generator within Microsoft Excel was used to organize the patients scanned during each of the index

2374
months and the first 100 patients from each month who met inclusion criteria were included in analysis. The difference in mean CTDIvol between the pre-intervention month and the post-intervention months were analyzed by a two sample t-test. The difference in CTDIvol variance within the pre-intervention month and within the post-intervention months was analyzed using an F-test.

Results

All axial NCHCTs performed on adults as a discrete encounter were eligible for inclusion. If any portion of the exam had to be repeated due to technical error or patient motion, or the study was non-diagnostic, the patient was excluded. The average CTDIvol for a NCHCT performed during the pre-intervention month was 63.1mGy (SD: 10.5). The averages for the two post-intervention months were 48.6mGY (SD: 6.1) and 51.3mGy (SD: 7.6), a reduction of 23% and 19% in average radiation dose. The difference in CTDIvol between the pre-intervention month and each of the post-intervention months was statistically significant (both P<0.0001). The difference in variance within the pre-intervention month and each of the post-intervention months was also significantly different (P<0.0001 and P<0.0016). Finally, not a single exam performed in the post-intervention months had a CTDIvol greater than 70mGy, whereas before the intervention 33 of 100 of exams delivered a CTDIvol above 70mGy.

Conclusions

Study results demonstrate that standardization of head CT protocols significantly reduces the average patient radiation dose, reduces dose variability, and eliminates outlier techniques with excessive CTDIvol. These reductions were achieved while maintaining quality diagnostic imaging. The standardization of protocols was a meaningful step on a population level in achieving lower radiation exposure and on an individual level by preventing any one exam from delivering excessive radiation. This method of protocol update can be applied to other types of CT examinations performed at our institution.

Model for Calculating Effective Doses for CT-guided Spine Biopsies

K Shpilberg¹, A Doshi¹, S Esses¹, R Subramaniam¹, B Delman¹
¹Mount Sinai Hospital, New York, NY

Purpose

Effective dose is a radiation exposure measurement that takes into account biologic sensitivity of different organs to radiation. It is a single parameter that reflects relative risk of detrimental biologic effects from nonuniform partial-body exposure to ionizing radiation in terms of a whole-body exposure. Characterizing radiation exposure as effective dose and comparing the value to other radiation risks is the best way to convey to the patient and referring clinician the relative potential for harm from a diagnostic imaging exam or image-guided procedure. We designed a model for determining effective dose conversion coefficients and, thereby, calculating effective doses for CT-guided spine biopsies. Then, we used our model to compare effective doses in patients who underwent CT-guided spine biopsies utilizing low-dose and regular-dose protocols.
Materials and Methods
We determined effective dose conversion coefficients for cervical, thoracic, lumbar and sacral spine by adjusting the scan range to different spine levels on the phantom provided in the ImpACT software package. The range for the cervical spine extended from z of 68.5 to z of 81, for the thoracic spine from z of 36.5 to z of 68.5, for the lumbar spine from z of 15.5 to z of 36.5 and for the sacrum from z of 1 to z of 15.5 (see images). ICRP 103 organ weighting scheme (2007) was used. Coefficients for cervical, thoracic, lumbar and sacral spine were calculated by dividing the effective dose (mSv) by the dose length product (DLP, mGy-cm). The four coefficients then were plotted in Excel with a polynomial trendline and an equation was generated, from which effective dose conversion coefficients (mSv/mGy-cm) centered on each vertebral level were calculated. Coefficients appropriate to the vertebral level biopsied were then multiplied by total DLP for each patient in order to calculate effective doses for 64 patients who underwent CT-guided spine biopsies as part of an IRB-approved retrospective study. Effective doses of patients who underwent CT-guided spine biopsies using low-dose and regular-dose protocols were compared using unpaired t-test.

Results
Effective dose conversion coefficients were determined to be 0.01095 mSv/mGy-cm for the cervical spine (centered on C4), 0.02037 mSv/mGy-cm for the thoracic spine (centered on T6), 0.0177 mSv/mGy-cm for the lumbar spine (centered on L3) and 0.0129 mSv/mGy-cm for the sacrum (centered on T2). An equation was generated after plotting the data on Excel and applying a polynomial trendline (y = 0.0017x^3 - 0.016x^2 + 0.0458x - 0.0205; see images). A distinct x-value was assigned to each vertebral level and plugged into the equation in order to calculate an effective dose conversion coefficient for each level (y-value; see Table). There was a statistically significant difference in effective doses between the low-dose and regular-dose protocol CT-guided spine biopsy groups (12.70 ± 1.193 mSv, N=31 and 28.90 ± 2.300 mSv, N=33 respectively; p< 0.0001).

Conclusions
Effective dose is the best measure of cancer risk to a whole organism due to ionizing radiation delivered nonuniformly to parts of the body. Therefore, it is very important to calculate effective doses for diagnostic imaging exams and image-guided procedures. We illustrated one method for determining effective dose conversion coefficients for each vertebral level in order to calculate effective doses in CT-guided spine biopsies.

MRI of the Internal Auditory Canals (IAC): What is the diagnostic yield in general practice?

A Knobel¹, G Panagopoulos¹, D Shatzkes¹

¹Lenox Hill Hospital, New York, NY
Purpose
Contrast-enhanced MRI of the IAC is commonly ordered in patients with a variety of symptoms referable to the seventh or eighth cranial nerves, including hearing loss, dizziness and facial palsy. The goal of this study was to assess the diagnostic yield of MRI of the IAC in a community hospital setting and to determine which variables, if any, impact this yield.

Materials and Methods
This retrospective study underwent IRB review and was deemed exempt from informed consent. A search of examination codes corresponding to MRI of the IAC for the 5 year period from 4/08 to 4/13 yielded 239 studies, of which 25 were excluded for known diagnosis of vestibular schwannoma, prior surgery in the area of examination, or age of patient less than 18 years old. Clinical information and reports available within the radiology information system were analyzed for indication, specialty of ordering physician and imaging diagnosis. Studies were categorized as negative, positive relevant to the presenting indication and positive irrelevant to the presenting indication (i.e. incidental). Statistical analysis was performed using the Fisher's exact test with a p-value less than 0.05 designated to indicate statistical significance.

Results
Out of 214 MRI IAC studies, six yielded a new diagnosis of vestibular schwannoma (3%). Moreover, there were 14 additional positive relevant diagnoses other than schwannoma (6%) and 8 positive diagnoses deemed irrelevant to the reported clinical indication (3.6%). When indications and referring physician specialty were analyzed, no statistically significant difference in diagnostic yield was identified.

Conclusions
In our practice setting, MRI of the IAC, when ordered in the absence of known disease, proved to be a low yield examination, with no change in diagnostic yield based on exam indication or specialty of ordering physician. Improved patient selection for this study may result in greater yield and cost-effectiveness.

Online Patient Resources – The Readability of Neuroradiology-Based Education Materials

D Hansberry¹, N Agarwal¹, S Baker¹, S Gonzales¹
¹Rutgers, New Jersey Medical School, Newark, NJ

Purpose
The Internet is a frequently accessed resource for both patients and their families when encountering healthcare-related issues. As such, many professional medical societies have created online resources specifically for patients. Our goal is to evaluate these resources on the American Society of Neuroradiology (ASNR) website for their level of readability.

Materials and Methods
Online patient education resources were downloaded from the ASNR website, http://www.asnr.org/patientinfo/, as well as the patient education material available on the Society of NeuroInterventional Surgery (SNIS) website and analyzed for their level of readability using 10 quantitative readability scales, including the Flesch Reading Ease, Flesch-Kincaid Grade Level, Simple Measure of Gobbledygook, Coleman-Liau Index, Gunning Fog Index, New Dale-Chall, FORCAST Formula, Fry Graph, Raygor Reading Estimate, and the New Fog Count.

Results
The 20 different patient education resources were written between the 10.3 and 16.9 grade level. Only one patient resource was written below the 11th grade level and collectively, they were written at the 13.9 grade level. There was no statistical difference between the level of readability of the patient education materials found on the ASNR and SNIS websites.

Conclusions
All the patient education resources found on the ASNR and SNIS website are cast at a level well above the 3rd to 7th grade level that is recommended by the National Institutes of Health (NIH) and the American Medical Association (AMA). Revision of this textual information will increase the number of online viewers who can fully benefit from these resources and thus improve patient understanding of neuroradiology-related diseases, diagnoses, and treatments.

Radiation Exposure During Vertebroplasty

A Borowski¹, S Ali¹, J Beauchamp¹, A Jain¹, A Kolar¹
¹Providence Health Center, Waco, TX

Purpose
Radiation exposure and patient safety are being evaluated, tracked and recorded, according to new state and federal mandates. Texas, through our Department of State Health Services
(DSHS), recently enacted regulations to "establish guidelines for radiation reporting, training personnel, and establishing acceptable dose thresholds for various diagnostic and therapeutic procedures". We practice at a 250 bed, community-based Catholic hospital in Central Texas, and have a high volume Spine Intervention and Pain Management Service at our facility. We decided to proactively start evaluating these parameters for our procedures, and percutaneous vertebroplasty was the first of these to be selected for evaluation.

Materials and Methods
Starting on January 1, 2013, we began recording all patient demographics and procedure measures associated with every single-level percutaneous vertebroplasty performed. All patients were treated in the same Interventional suite (SIEMENS Neurostar), using similar equipment (COOK, Osteo-Site 13G Bone Biopsy needle kits) and the same bone cement (Stryker VertaPlex HV), for each therapy. No multilevel fracture patients were included, and no patients treated with mechanical assistance (curetting) or balloon augmentation (kyphoplasty) were included.

Results
Data were collected on 101 patients by the end of July, 2013. As expected, the majority of the patients were women (71%), and most fractures were in the mid-thoracic region (15% at T8/T9) and at the thoraco-lumbar junction (61% at T12-L3). Patients ranged in size from a 91 pound 90-year-old, to an almost 400 pound 41-year-old. Average cement volume in the thoracic spine was 3.8 cc/level, and in the lumbar spine it was 6.3 cc/level. Physician surgical time averaged 17.3 minutes for a thoracic level, and 16.7 minutes when treating a lumbar fracture. With thoracic fractures, fluoroscopic time averaged 6.3 minutes, total patient dose was 366.6 mGy, and average skin-entry dose was 3845.4 mcGy/sq-meter. Lumbar spine parameters were 5.1 minutes for average fluoroscopic time, total patient dose at 619.8 mGy, and an average skin-entry dose of 5677.1 mcGy/sq-meter.

Conclusions
We found that the procedures in the lumbar spine can be performed slightly faster, and with less fluoroscopic time for our patients; but compared to the thoracic spine, the total body dose per level was almost 60% higher, and the skin-entry dose was almost 70% higher per level. We hope that this source of data can help act as a reference point for similar type spinal interventions in the future. Our next step is to start reviewing outcome measures with this cohort of patients (evaluating pain relief and improvement in life-style, at one week, one month and one year after surgery), and to start tracking similar information for our other high-volume procedures.

KEYWORDS: Radiation Exposure, Vertebral Augmentation
Purpose
The aim of the project was to increase communication compliance between the Neuroradiology section and clinical services regarding non-contrast head CT findings in patients presenting with acute stroke who are being considered for tPA (tissue plasminogen activator). Practice guidelines established by the American Stroke Association (ASA) state, "For patients who are candidates for treatment with tPA, the goal is to complete the CT examination within 25 minutes of arrival at the ED, with the study interpreted within an additional 20 minutes (door-to-interpretation time of 45 minutes)." (1, 2) Initial baseline communication compliance collected by the Radiology Department quality committee from one year prior to the initiation of this project was available as a baseline measurement. Our goal was to increase compliance to greater than 90%.

Materials and Methods
We performed a group practice quality improvement project that included Neuroradiology faculty, clinical instructors, ACGME-accredited fellows and residents as well as administrative staff. The assessed metric was communication time in minutes, measured from the time of examination completion to the time of communication as dictated in the radiology report. Baseline communication compliance was collected from October 2011 through October 2012. The initial baseline denominator was based on a random sampling of all patients who were discharged from the hospital with a diagnosis of stroke. We then performed a root cause analysis and identified several systems based practice gaps. We implemented several changes to the workflow regarding stroke patients including 1) Designating a separate exam type titled "Stroke Code Head CT" to be ordered only in those patients presenting with acute stroke, 2) Placing a "stroke code pager" in the reading room to alert the radiology team when a "stroke code" was activated, 3) Limiting the auditing metric to include only those acute stroke patients in whom tPA was being considered. After implementing these changes we measured the communication compliance in all patients who underwent a "Stroke Code Head CT" from November 2012 - August 2013.

Results
Baseline communication compliance regarding head CT examinations in stroke patients measured 53%. We measured post implementation communication compliance in 272 patients in whom "Stroke Code CT" examinations were ordered for 8 months. The average compliance after the changes were implemented measured 92%.

Conclusions
Patients presenting to the hospital with symptoms of acute stroke have a narrow time window for making treatment decisions. This practice quality improvement project streamlined the ordering and interpretation of head CT examinations in patients presenting to our hospital system with
acute stroke, leading to greater compliance with ASA door-to-interpretation time guidelines and contributing to more expeditious delivery of care in patients who need it most.

Adult-derived mesenchymal stem cells and stromal vascular fraction from adipose tissue as a therapeutic treatment for osteoarthritis

H Mahmood1, J Feller2, S May2, C Hancock1
1Desert Medical Imaging, Palm Springs, CA, 2Desert Medical Imaging, Indian Wells, CA

Purpose
Autologous adult-derived mesenchymal stem cells (MSCs) of the stromal vascular fraction (SVF) found in adipose tissue serve to function as a clinical therapy for inflammation and granulation scar type tissue regions in and about facet joints. The more recent advent of obtaining MSC’s from adipose tissue, as opposed to more commonly using bone marrow, has several advantages including a greater concentration of stem cells per tissue, less degeneration in number of stem cells due to age, and greater modulation of immune response from endothelial progenitor and T regulatory cells found in adipose SVF. Furthermore, adipose SVF give rise to cells that express MSC surface markers and therefore share the same regenerative properties and diverse differentiation capabilities. This potential MSC/SVF treatment and efficacy is observed in an IRB-approved clinical study for patients that have been indicated to have reactive osteoarthritis.

Materials and Methods
Standard MRI spine imaging was performed without and with contrast providing for specific interrogation of potential reactive facet arthropathy. Inflammatory facet joint levels were identified and reported as potential sites for therapeutic intervention. Tissue was surgically extracted from abdominal fat via liposuction and the stromal vascular fraction was isolated from the adipose and collagen via centrifugation and collagenase. The unaltered SVF cells were infused in an autologous serum and were redeployed to sites of inflammation on the same day. Intra-articular facet joint injections were performed via CT image-guidance at the cervical level or lumbar level to ensure precise placement and for stem cells to act locally. Patients were scored according to the Oswestry Disability Index indicating level of pain and functional disability in the neck and back. Patients took the Oswestry questionnaire at variable intervals according to clinical practice to assess long-term therapeutic effect. Patients are scored according to the Oswestry Disability Index indicating level of pain and functional disability in neck, shoulders, back, or hips. Patients took Oswestry Questionnaire at regular evaluations every three months to assess long-term therapeutic effect.
Results
Forty-seven patients at baseline presented with an average Oswestry score of 10 due to lumbar spine osteoarthritis and were injected at inflamed levels as determined by postcontrast MRI analysis on T1 Fat Suppression sequencing. Numbers of patients 10, 11, 7, 2, 5, 1, and 1 were re-evaluated at 1, 3, 6, 9, 12, 15, and 18 months respectively. Average Oswestry follow-up scores were 9, 13, 13, 24, 5, 12, and 20 for the aforementioned returning patient numbers at the respective time intervals. Nineteen patients at baseline presented with an average Oswestry score of 18 due to cervical spine osteoarthritis and were injected at inflamed levels as determined by postcontrast MRI analysis on T1 Fat Suppression sequencing. Numbers of patients 4, 1, and 1 were re-evaluated at 1, 3, and 12 months respectively. Average Oswestry follow-up scores were 16, 15, and 0 for the aforementioned returning patient numbers at the respective time intervals. No adverse events were encountered.

Conclusions
Autologous adipose-derived mesenchymal stem cells and stromal vascular fraction may prove to be beneficial in attenuating degenerative osteoarthritis inflammation in facet joints. Preparation and same-day administration of SVF follows a protocol that is effective in minimizing ex-vivo manipulation and contamination. Results from this clinical study show that this new technique in regenerative medicine has the potential to reduce pain in patients with degenerative arthritis. Further rigorous clinical trials will be necessary to measure the efficacy of this treatment.

Carcinoma Cells Type Identification Based on the Texture Analysis

A Chaddad\textsuperscript{1}, R Colen\textsuperscript{2}, P Zinn\textsuperscript{2}
\textsuperscript{1}University of Texas MD Anderson Cancer Center, Houston, TX, \textsuperscript{2}MD Anderson Cancer Center, Houston, TX

Purpose
The robust recognition and classification of cancer cells can enhance work efficiency while identifying new inter-relationships among biological features. Texture analysis was chosen and the Haralick's features based on Gray Level Co-occurrence Matrix (GLCM) were applied for grade cancer cell discrimination. A critical characteristics study was employed using the five Haralick features, namely, Contrast, Entropy, Energy, Correlation and Homogeneity. These features capture useful information about the patterns that emerge in the texture of considered images. The proposed work is based on the values of the Haralick's coefficients used as a primary component to distinguish between different grades of cells namely, Stroma, Benign Hyperplasia (BH - benign condition), Intraepithelial Neoplasia (IN) that is a precursor state for cancer and Carcinoma (Ca) that corresponds to abnormal tissue proliferation (Cancer).

Materials and Methods
Optical microscopy provides multispectral biopsy images with the wavelength between 500 and 650 nm. The multi-spectral images are then analyzed at low, medium and high wavelength. Four categories of grade cells were applied, GLCM were calculated for each texture image using four distances $d = \{1, 2, 3, 4\}$ and phase = \{0; 45°; 90°; 135°\}. Texture features were computed using
the GLCM matrix. In each category of grade cells, we selected the dominant feature which is used for making the grade cells discrimination.

Results

512 bio-images from the optical microscopy were analyzed. Each grade of cells contains 128 images. Simulation result showed that the Energy feature is a dominant for BH cells identification with 0% error and by the Contrast feature we can identify the Carcinoma cells type with 0% error. These results mainly appear on the middle frequencies range.

Conclusions

Texture features extracted from four grades of cell using GLCM matrix, were successfully demonstrated that the Contrast feature allows discriminating the image characterized by a malignant cancer grade of Ca which was a difficult task previously. This is important as these features can be subsequently used to correlate between the underlying genomic composition of the tumor.

EP-226

Comparison of Rapid MRI Lumbar Spine Protocol to Full MRI Lumbar Spine Protocol for Evaluation of Lumbar Spondylosis
Purpose
More than 80% of the population will experience an episode of LBP at some time during their lives. The condition is also costly, with total costs estimated to be between $100 and $200 billion annually, two-thirds of which are due to decreased wages and productivity. The average cost of a lumbar spine MRI is over $2,000. Reducing scan time without compromising diagnostic accuracy can reduce costs while benefiting patients. We will compare the effectiveness of a full lumbar spine MRI for spondylosis with a rapid protocol using 3-D T2 SPACE (Sampling Perfection with application-optimized Contrast with different flip-angle evolutions).

Materials and Methods
75 consecutive patients imaged for low back pain and radiculopathy using the full protocol were included in this IRB-approved study. The full protocol consists of standard fast spin echo (FSE) sagittal T1 and T2 weighted sequences and axial T2 weighted sequence as well as the rapid 3-D T2 SPACE sequence acquired in the sagittal plane. Scan time for the standard sequences is approximately 30 minutes versus approximately 5 minutes for the 3-D T2 SPACE. Several months after a final report was generated using the full protocol, the 3-D T2 SPACE sequences were retrospectively reviewed in isolation by 2 attending neuroradiologist who were blinded to the final reports. Each reader had the ability to manipulate the images into orthogonal planes on a 3-D workstation. At each disc space between L1 and S1 the following data was recorded: the presence or absence of disc herniations, synovial cysts and neural foraminal compromise in the central and lateral regions. Sensitivity and specificity of the rapid protocol was then compared to the final reads on the full study. Exclusion criteria included history of infection, trauma, cauda equina, tethered cord, metastatic disease.

Results
We will present data on the sensitivity and specificity of the rapid sequence for evaluation of low back pain and radiculopathy using the full protocol as the standard of care. We will also provide a cost effectiveness analysis using this shorter protocol during a typical workday.

Conclusions
We hypothesize that there is no significant difference in interpretation of lumbar spine degenerative changes between the rapid study and full study. This could allow institutions to save scanner time and reduce cost without compromising patient care.

KEYWORDS: Degenerative
Purpose
Computed tomography angiography (CTA) of the neck commonly is used as a first-line modality for screening for cervical arterial injury in victims presenting with a seatbelt sign following a motor vehicle accident. We present here a retrospective analysis of all CTA neck studies performed on victims of motor vehicle accidents at our Level I Trauma Center between 2001-2010 to determine whether the seatbelt sign has a direct correlation with cervical arterial injury.

Materials and Methods
Clinical histories and imaging results were analyzed retrospectively for all CTA studies performed on trauma victims from 2001-2010 using our center's PACS and electronic medical record. A total of 831 studies were evaluated. Of these, 397 studies were performed on victims involved in motor vehicle accidents and had unequivocal conclusions on imaging. These 397 studies were analyzed to determine if there was a significant correlation between the seatbelt sign and cervical arterial injury.

Results
Of 397 victims of motor vehicle accidents, a cervical arterial injury was found in four of 309 patients (1.3%) with a seatbelt sign compared to four of 88 patients (4.5%) without a seatbelt sign (p = 0.08). Of the four arterial injuries in patients with a seatbelt sign, one patient had no associated osseous injury or predisposition to arterial injury. Of the other three patients, one had adjacent cervical spine fractures, one had fibromuscular dysplasia and a carotid dissection, and one had a variant origin of the left vertebral artery from the aortic arch and rib fractures adjacent to the arterial injury.

Conclusions
Presence of a seatbelt sign has no significant correlation with cervical arterial injury.

Enhancing the Sensitivity of Nuclear Cisternography in Diagnosing Cerebrospinal Fluid Leaks

D Black¹, F Diehn¹, C Hunt¹, V Lehman¹, K Schwartz¹, P Luetmer², C Wood¹, R Carter¹, K Thielen¹, J Swanson¹, M O'Connor¹, R Witte¹
¹Mayo Clinic, Rochester, MN, ²placeholder, blank, blank

Purpose
In the evaluation of patients with possible cerebrospinal fluid leaks, we have noticed inconsistency and variability in the interpretation of Indium-111 DTPA cisternograms which conflict with the clinical diagnosis. Hence we sought to create a more objective method to evaluate the radiotracer kinetics in this patient population. The purpose of this study was to assess whether the sensitivity of Indium-111 nuclear cisternography in diagnosing cerebrospinal fluid leaks could be improved by dividing each planar image into multiple regions of interest and displaying the total radioisotope counts in each segment graphically over time in conjunction with traditional planar images.

Materials and Methods
We developed a relatively simple program which divides the planar images from our unchanged
In-111 cisternograms into seven regions of interest and plots the total radioisotope counts from each region on a graph wherein the counts are the ordinate and time is the abscissa. Nineteen sequential patients who had recently undergone cisternography for possible cerebrospinal fluid leak were enrolled after obtaining internal review board approval. Six blinded board certified radiologists reviewed the cisternograms, the graphs, and the combination of the cisternogram and associated graph and categorized each image as "leak" or "no leak." The readers were instructed to use their knowledge of spinal fluid circulation and resorption to interpret the graphs. Two unblinded authors reviewed the medical records and the final clinical diagnosis was compared with our readers' interpretations.

Results
The diagnostic sensitivity and specificity for CSF leaks was 63% and 83%, respectively, using planar images alone, 78% and 80% using the graphical depiction alone, and 55% and 61% using both the planar images and graphical representation simultaneously (p-values were 0.09 for sensitivity and 0.03 for specificity).

Conclusions
The sensitivity for the three methods ranged from as low as 55% to as high as 78%. While this degree of variability would be indicative of a clinically relevant variation in performance, the differences did not reach statistical significance with the available sample size. These initial findings suggest that adding a semi-quantitative graphical representation of the data already acquired during conventional nuclear cisternography may be beneficial but further study is required. Unexpectedly, the combination of planar and graphical data appeared to have the lowest sensitivity and this may reflect a negative bias of the planar data on the final interpretation.

KEYWORDS: Cerebrospinal Fluid, Leak

Increased Tc-99m Bone Tracer Activity in the Costovertebral and Costotransverse Joints on SPECT/CT: Does it Predict Pain and Response to Percutaneous Treatment?
Purpose
Pain related to the costovertebral and costotransverse joints is likely an underrecognized and potentially significant cause of thoracic back pain. With use of combined SPECT and CT, demonstration of Tc-99m bone tracer activity at these articulations is not rare. Overall, the relationship of radiotracer activity to pain and the ability to predict response to percutaneous intervention seems to vary at different joints throughout the axial skeleton. Therefore, evaluation of the potential significance of Tc-99m bone tracer activity at the costovertebral and costotransverse joints is desirable. We evaluated whether Tc-99m bone tracer activity at the costovertebral and costotransverse joints corresponded to clinical pain and if percutaneous injection of these joints correlated with improvement in thoracic back pain.

Materials and Methods
After obtaining IRB approval, a retrospective review was performed of all Tc-99m SPECT/CT reports completed at our institution from March 2008 to February 2013 to evaluate for examinations with Tc-99m bone tracer activity in the costovertebral or costotransverse joints as reported by the interpreting nuclear medicine radiologist. A chart review was performed to determine the presence of corresponding clinical pain as determined by the physician ordering the exam (typically a pain specialist), whether percutaneous injection was performed, and the patient's response to the injection.

Results
A total of 442 SPECT/CT examinations were identified. Increased Tc-99m bone tracer activity at costovertebral or costotransverse joints was reported on 31 examinations. Of these, 20 patients had corresponding clinical pain and eight (3 male and 5 female, average age 43, ranging from 17-76) proceeded to percutaneous injection of the costovertebral or costotransverse joint(s) that demonstrated increased activity. A total of 11 joints were injected by either an interventional radiologist or other interventional pain physician. All injections included a combination of local anesthetic and steroid and were performed under CT or fluoroscopic guidance. Clinical follow up between one and 12 weeks postinjection revealed that 0 (0%) patients had complete pain relief, one (13%) had near-complete pain relief, two (25%) had partial pain relief, and five (63%) had no pain relief.

Conclusions
There is little to no prior report in the English literature of the utility of Tc-99m bone tracer activity for direction of percutaneous treatment of costotransverse or costovertebral joints. Based on the present study, costovertebral and costotransverse joints with increased Tc-99m bone tracer activity on SPECT/CT examinations exhibit variability in terms of associated clinical pain and also response to percutaneous steroid injection, often with no reported pain relief. However, future prospective investigation with a larger number of patients is desirable to firmly establish the significance of costovertebral and costotransverse joint Tc-99m bone tracer activity.

MR Imaging of the Brachial Plexus with and without Blood-suppression Pulse at 3T.

M Odashima¹, T Inaoka¹, N Kitamura¹, S Kasuya¹, R Kasai¹, H Kudo¹, T Nakatsuka¹, M Tozawa¹, H Nakazawa¹, M Sogawa¹, H Terada¹
¹Toho University Sakura Medical Center, Sakura, Chiba, Japan

Purpose
To compare MR images of the brachial plexus with and without blood suppression pulse at 3 T.

Materials and Methods
Four asymptomatic males (mean age: 26 years) were enrolled. All MR imaging (MRIs) were performed by using Siemens Magnetom Skyra 3 T and neck plus body coils. At the brachial plexus, STIR images using 3D FSE SPACE sequence with and without blood suppression pulses were obtained in coronal plane. Slice thickness was 0.8mm. The signal intensities of the cervical nerves, ganglia, veins, and muscles on the STIR coronal maximum intensity projection images with and without blood suppression pulses were measured, and the contrast ratios (cervical nerve-vein, ganglia-vein, and muscle-vein) on the images with and without blood suppression pulses were compared.

Results
With blood suppression pulse, average percentages of the decreased signal intensities were 8.1%, 16.6%, 26.7%, and 18.9% in the cervical nerves, ganglia, veins, and muscle, respectively. The contrast ratios of cervical nerve vein and ganglia vein were significantly higher in coronal STIR images with blood suppression pulse than those in coronal STIR images without blood suppression pulse (p< .05)

Conclusions
3D FSE SPACE STIR images with blood suppression pulse may show a better visualization of the brachial plexus in comparison with those without blood suppression pulse.

Percutaneous Rupture of Lumbar Facet Synovial Cysts: What Factors Predict Success?

D Pastel¹, S Cambron²
¹Dartmouth-Hitchcock Medical Center, Lebanon, NH, ²Dartmouth Hitchcock Medical Center, Lebanon, NH

Purpose
Lumbar facet synovial cysts (LFSCs) most commonly arise in the setting of degenerative spondylosis and are a cause of back pain and radiculopathy (1-4). Treatment options include percutaneous rupture and surgical removal. We previously reported that T2 hyperintense and intermediate signal intensity LFSCs are easier to rupture and less likely to need surgery (5). Cyst size and location did not affect percutaneous rupture or surgical rates. The purpose of this follow-up analysis is to identify additionalsurgeries performed within our study group and identify other features that may predict outcome in patients undergoing percutaneous LFSC rupture.
Materials and Methods
We retrospectively reviewed the clinical outcome and imaging of 110 patients with 113 LFSCs who underwent attempted CT-guided synovial cyst rupture as primary treatment for symptomatic LFSCs. The rates of successful cyst rupture and need for subsequent surgery were recorded. Follow-up ranged from 7-93 months after the last attempted percutaneous rupture. This study will update the follow-up period by 18 months and report any additional surgeries performed within our study group. The following data will also be collected as they relate to percutaneous rupture success and need for subsequent surgery: BMI, narcotic use, previous back surgery, cyst wall calcification, facet effusion size, and spondylolisthesis.

Results
As previously reported, LFSC rupture was technically successful in 87% of all cases, with the highest success rates found in cyst of high and intermediate signal intensity. We reported lowest post-procedure surgical rates (29%) in patients with high signal intensity cysts. As discussed above, we will record additional surgeries performed since we first reported our data and analyze additional factors they may predict success.

Conclusions
Most patients with symptomatic LFSCs can avoid surgery with percutaneous rupture (5). Patients with T2-hyperintense synovial cysts are most likely to benefit from nonsurgical intervention (5). This study will identify additional features as described above that may predict outcome in patients undergoing percutaneous LFSC rupture. Information such as this can be valuable when selecting and counseling patients on their treatment options for symptomatic LFSCs.

EP-219

Percutaneous Treatment of Lumbar Disc Herniation with Gelified Ethanol: a Preliminary Study

M Runge

University Hospital, Besançon, France

Purpose
Evaluate the safety and efficacy of disk nucleolysis using gelified ethanol in the percutaneous treatment of herniated lumbar disk (HLD).

Materials and Methods
From March 2010 to July 2013, 42 consecutive patients (22 male, 20 female) aged 22-80 years (mean age 45.1) with a symptomatic HLD were included in this study and treated with gelified ethanol nucleolysis. Symptomatic levels (L3-L4: 3, L4-L5: 19, L5-S1: 20) were identified by clinical examination, computed tomography or MR imaging (MRI). In most cases, the clinical abnormalities corresponded to the lumber disk level. All procedures were performed in ambulatory condition under local anesthesia and under fluoroscopic guidance. Injection dose of radiopaque gelified ethanol was 1 ml. Three months after nucleolysis, a clinical exam and a MRI exam were performed to appreciate the follow up of HLD and to evaluate the signal changes of the surrounding endplates.
Results
Very good results with total disappearance of radicular pain were obtained in 54.8% of cases (24/42). Good results with a significant reduction of symptoms and medications were obtained in 33.3% (14/42) and bad results with the persistence of radicular pain and recourse to surgery in 11.9% (5/42). Two patients underwent diskolysis in more than one level (2 levels). No difference was observed in the results in comparison to those treated at a single level. There was no complication in any of our patients. Short term follow up (3-4 months) with MRI exam showed in all patients with very good and good clinical results a complete HLD disappearance in 16.7% of cases, a minimal reduction of hernia volume (less than a quarter of hernia size) in 21.4% and no changes in 61.9%. No changes were observed in the intervertebral space height and in the bone marrow signal intensity of the surrounding endplates.

Conclusions
This preliminary study shows the efficacy and the inocuity of nucleolysis with gelified ethanol in the treatment of any kind of HLD

Spontaneous Intracranial Hypotension Secondary to New Use of a Rowing Machine? A Case Report

E Yang¹, M Barbarisi¹, M Benstock¹
¹Main Line Health Bryn Mawr Hospital, Bryn Mawr, PA

Purpose
To report a case of spontaneous intracranial hypotension in a female with no significant history except for first time use of the rowing machine at the gym. Case Report: A 29-year-old previously healthy woman presented with spontaneous onset of generalized headache, associated with nausea and vomiting, that prompted transportation to Bryn Mawr Hospital Emergency Department. The headache was consistently exacerbated by sitting or standing and improved while lying down. She had no recent history of infection or trauma, however did report first time use of the rowing machine at the gym. The patient had no neurological symptoms and a normal neurologic exam. Lab tests revealed an elevated WBC count of 12.2. CT brain performed was normal. When her symptoms did not improve she had a failed lumbar puncture attempted by Neurology.

Materials and Methods
An MR imaging (MRI) brain w/w/o contrast revealed diffuse pachymeningeal enhancement, with additional finding of edema involving the deep musculature of the upper dorsal cervical spine. Initial noncontrast MRI of the cervical and thoracolumbar spine revealed mildly prominent T1 hypointensity and T2 hyperintensity in the ventral extradural space extending from C2-T1, which maintains hyperintensity on the STIR sequence. Additional findings included a prominent dural venous plexus. These findings were most in keeping with spontaneous intracranial hypotension/CSF leak. Next a nuclear medicine cisternogram was performed in attempts to localize the site of CSF leakage. Initial 30 minute and one hour imaging revealed no abnormality. Delayed 3, 4.5 and 21 hour images revealed radiotracer activity outside the
expected confines of the thecal sac bilaterally, just below the level of the cervicothoracic junction. CT myelogram showed leakage of contrast along bilateral neuroforamina at C7-T1 and T1-T2, as well as along C1-C2 posteriorly. The patient's symptoms improved on purely conservative treatment including bedrest and oral hydration and was discharged home after several days.

Results
Spontaneous intracranial hypotension is a clinical syndrome of reduced CSF volume secondary to spontaneous leakage of CSF through small defects in the meninges. This condition affects women more frequently than men, and is associated with connective tissue disorders such as Marfan syndrome, Ehlers-Danlos syndrome, and ADPKD. Spontaneous intracranial hypotension is a well known clinical entity; however it is commonly under-diagnosed. Generally CSF leaks do not cause local symptoms and thus remain undetected unless specifically looked for in a patient suspected of having SIH. The main symptom is an orthostatic headache that worsens when upright and improves when recumbent. More often that not, there is history of a failed lumbar puncture attempt, a "dry tap," which would be expected in the setting of decreased CSF pressure. The exact cause of spontaneous spinal CSF leaks is unknown, but generally an underlying structural weakness in the spinal meninges is suspected. This, coupled with a seemingly insignificant traumatic/inciting event, can cause defects within the dura that allow CSF to leak into the epidural space. Many cases of SIH resolve spontaneously on their own, and treatment options for those seeking medical treatment are usually conservative.

Conclusions
Brain MRI characteristic features of SIH include: 1) pachymeningeal enhancement, 2) subdural fluid collections, 3) dural venous engorgement, 4) pituitary hyperemia, 5) sagging of the brain. Many of the MRI findings of SIH can be explained by the compensatory changes related to the loss of CSF volume. The Monroe-Kellie rule states that in an intact calvarium, the sum of the volumes of intracranial blood, CSF, and cerebral tissue must remain constant. Cerebrospinal fluid volume loss from the spine can be compensated for by an increase in the vascular component, which accounts for engorgement of venous structures, pachymeningeal enhancement, and pituitary hyperemia. Spinal myelogram with intrathecal contrast is currently the study of choice for identifying the location and extent of the CSF leak. The volume of CSF leak is variable. The vast majority of CSF leaks are found at the cervicothoracic junction or along the thoracic spine. It is not uncommon to demonstrate multiple sites of leakage. It is important to note that retrospinal collections of contrast at the level of C1-C2 should not be mistaken for the actual site of a CSF leak. Delayed imaging also may be necessary to visualize intermittent or slow leaks, and immediate imaging following injection of contrast may be necessary to identify the site of a fast high-volume leak. Radionuclide cisternogram also may be used to diagnose CSF leak; however it is limited in evaluating exact site of leakage, which may be obscure in up to one third of patients. Findings include early accumulation of radiotracer in the kidneys and bladder, slow ascent along the spinal canal, and a scarcity of activity overlying the cerebral hemispheres.

A Case of Acute Cervical Myelopathy in a Myasthenic Patient

C Legault¹, D Gendron², L Jacques², D Tampieri³, M Cortes⁴, D Melanson²
¹McGill University, Montreal, Quebec, ²Montreal Neurological Institute, Montreal, Quebec, ³Montreal Neurological Hospital, Montreal, Quebec, ⁴Montreal Neurological Institute and Hospital, Montreal, Quebec

Purpose
Intramedullary abscess is a very rare entity with around 120 cases reported in the literature since its first description by Hart in 1830. This is a case report of 77-year-old female patient with myasthenia gravis on corticosteroid immunosuppressive treatment presenting with acute cervical pain that was diagnosed as an Nocardia cervical intramedullary abscess. The purpose of this poster is to review the rare pathology that is intramedullary abscess and the diagnostic challenge such a case represents and also to discuss the use of diffusion-weighted image technique which was critical in the diagnosis and management of the case, a technique that has been reported in three cases of spinal abscesses in the literature.

Materials and Methods
The material used for this case report was a complete chart review of the clinical, laboratory and radiological investigations of the patient. The method is a case review of this patient that was admitted to our institution. The patient was a 77-year-old female that presented to the emergency room with a two-weeks history of severe cervical pain accompanied by profound left-sided weakness. Three months prior, she had been diagnosed with myasthenia gravis after an episode of ptosis and respiratory failure. In the emergency department, her initial neurological examination was consistent with left upper extremity radiculopathy at C5-C8 with concomitant myelopathy. On MRI, patient was found to have an intramedullary ring enhancing, longitudinally extending lesion with surrounding edema. The differential diagnosis included a primary neoplasm of the spine with a cystic component, a metastasis or an abscess. Her primary investigations were negative, including neoplastic, infectious and inflammatory work up, a full body PET scan and an analysis of cerebrospinal fluid. Upon repeating the neuroimaging, there was presence of diffusion restriction in the core of the intramedullary cervical lesion on spinal diffusion-weighted images. This was highly suspicious for an intramedullary abscess. In light of this finding, a posterior myelotomy was performed which confirmed the radiological diagnosis with the presence of an isolated intramedullary Nocardia abscess on the cultures obtained from the intramedullar fluid collection.

Results
The diagnosis of spinal cord abscess, suspected on the MRI of spinal, mainly after the use of the diffusion technique, was confirmed by the cultures obtained in the cystic cavity after the myelotomy, showing Nocardia species. The patient did well after months of antibiotics and was able to go to a rehab facility, able to ambulate with a walker and assistance at the time of discharge. She was treated with a total of six months of parenteral broad spectrum antibiotics followed by four months of oral antibiotics. Her multiple repeat spine MRI showed an almost complete normalization of the spinal cord with only mild residual myelomalecia.
Conclusions
In this case, the diagnosis of spinal cord abscess was made after clinical input and effort of a multidisciplinary team including neurology, neuroradiology and neurosurgery. The use of advanced neuroradiologic technique, mainly diffusion-weighted images of the spine, were crucial in the clinical care. Intramedullary abscesses, being a rare pathology, always represent a clinical challenge to physician in both the diagnostic and treatment. In this case, the patient had a good outcome as the etiology of her myelopathy was recognized and treated promptly.

A step towards absolute blood volume mapping using steady state ferumoxytol MRI in glioblastoma patients

C Varallyay\textsuperscript{1}, E Neuwelt\textsuperscript{1}
\textsuperscript{1}Oregon Health and Science University, Portland, OR
Purpose
Cerebral blood volume (CBV) values in brain tumors usually are normalized to normal appearing white matter (NAWM) and expressed as relative CBV (rCBV). The selection of NAWM as well as its potential disease involvement makes this technique less objective. In this study we are proposing the use of steady state CBV mapping using ferumoxytol, a blood pool contrast agent, and normalization of the CBV maps to intravascular ferumoxytol concentration.

Materials and Methods
Forty-two patients with CNS pathologies underwent MR imaging using 510 mg ferumoxytol administered in three consecutive bolus injections in doses of 75 mg, 150 mg and then 285 mg. At baseline as well as following each injection T2*-weighted echo planar gradient echo images were acquired and steady state CBV maps were created by calculating the changes of transverse relaxation rates (deltaR2*) to baseline. The relationship between deltaR2* and injected doses were tested in normal appearing brain areas (white matter, thalamus and putamen). Doses were expressed as mg Fe/kg body weight and also as mg Fe/L total circulating blood volume (TBV, obtained using the Nadler’s formula), the latter one indicating intravascular ferumoxytol concentration [Fe]. We calculated rCBV as well as CBV expressed as deltaR2*/[Fe] in the normal appearing brain areas and in enhancing tumors and hotspots (in patients with glioblastoma) for each injection.

Results
The dose range of ferumoxytol was 0.54 to 10.29 mg/kg. This resulted an intravascular [Fe] between 9.81 and 151.42 mg/L. A good linear relationship was found between deltaR2* and injected ferumoxytol dose in each of the normal brain areas. In white matter, thalamus and putamen the coefficient of determination (R2) was higher when [Fe] was used (R2: 0.878, 0.875 and 0.88 respectively), compared to the dose expressed as mg/kg, resulting R2 of 0.832, 0.803 and 0.83 respectively. Figure 1 shows the comparison of rCBV and deltaR2*/[Fe]. (Error bars indicate 95% CI). DeltaR2*/[Fe] values show better consistency between doses.

Conclusions
The good linear relationship between deltaR2* and [Fe] is promising for quantifying ferumoxytol CBV mapping in brain tumors. The deltaR2*/[Fe] maps could eliminate the need of NAWM selection, which would make CBV mapping more objective and consistent, this technique also would allow the assessment of the white matter. Steady state CBV mapping using ferumoxytol has the potential of absolute CBV assessment, which would be beneficial in longitudinal studies, and would allow comparison of CBV between patients.

**Purpose**

Our goal is to decompose a subject's resting-state fMRI spatiotemporal signal into independent components that are anatomically and functionally representative of known resting-state networks (RSNs) and then accurately classify each component as belonging to one out of seven RSNs as defined by a template previously compiled by Allen et al. The overall goal is to create a clinically oriented, automated component classification method using resting-state fMRI that could complement or substitute task fMRI for patient diagnostic and presurgical procedures.

**Materials and Methods**

Resting-state fMRI scans from 23 patients (17 epilepsy, six vascular/tumor, 10 male, mean age = 39 years) were acquired on GE MR750 3 T and GE MR450 1.5 T scanners with a gradient echo
EPI sequence (28 slices, 150 volumes, 2s TR, 30ms TE, 3.75×3.75×5 mm). Data were preprocessed, consistent with Allen et al's study, using AFNI and FSL which included slice-timing correction, motion correction, transformation into standard MNI space (3×3×3 mm), and spatial smoothing (Gaussian 10 mm FWHM). The patients had no gross structural abnormalities and the resultant registration was satisfactory. Data were decomposed into functional networks using individual, spatial independent component analysis (ICA), a MVPA technique, implemented in the GIFT toolbox (Figure 1). Components for the visual, sensorimotor, default mode, and auditory networks were identified visually. Each resultant component was spatially correlated with 28 ICs of the template and a ranking by correlation was used for the classification step (using MATLAB). The most correlated component was chosen to represent the subject's component, and its network membership was inherited. The metric used for measuring classification performance was a matching rate to the researcher's network identification.

Results
The analysis of the patient data set revealed clear and adequate functional components. For the components which the researcher identified as the visual network, the classifier achieved 88.7% agreement (of 62 visually identified network components, the classifier matched 55, p-value < 1 × 10-16 (binomial test)). For the sensorimotor network, the classifier was in 57.9% agreement (38 visually identified components, 22 classifier matched, p-value < 1 × 10-6). For the default-mode network, the classifier was in 48.9% agreement (139 visually identified components, 68 classifier matched, p-value < 1 × 10-16). For the auditory network, the classifier was in 65.2% agreement (46 visually identified components, 30 classifier matched, p-value < 1 × 10-16).

Conclusions
The automated classifier showed promising performance [significantly better than random guessing (roughly 1 out of 7, ~15%)] for the visual, sensorimotor, default-mode and auditory networks of clinical patients. Further development and validation will be done to make this method available as a clinical software tool for automated functional network component extraction and classification.

Automatic Vascular Territory Mapping for Quantification of Cerebral Ischemia

N Chatterjee\textsuperscript{1}, S Ansari\textsuperscript{2}, P Vakil\textsuperscript{1}, T Carroll\textsuperscript{1}, M Hurley\textsuperscript{3}

\textsuperscript{1}Northwestern University, Chicago, IL, \textsuperscript{2}Northwestern University Feinberg School, Chicago, IL, \textsuperscript{3}Northwestern Feinberg School of Medicine, Chicago, IL

Purpose

MR perfusion imaging has emerged as an important tool in the evaluation of cerebral ischemia. While it is relatively straightforward to visually inspect images of cerebral blood flow and blood volume to look for relative deficits, quantifying these results can be difficult. One commonly used approach is to manually draw ROIs and extract average values from these ROIs. However, because these ROIs are drawn manually, often with prior knowledge of clinical history, this approach can introduce bias in the measurement. Similarly, when tracking longitudinal changes in a single person, it is difficult to draw identical ROIs. Also, because they are drawn by hand one at a time and correct placement of ROIs requires familiarity with cerebrovascular anatomy, manual ROI drawing can be a time intensive process. Both shortcomings are especially noticeable when conducting research because it is critical to avoid bias and studies can involve large numbers of patients. A more automated approach that has been used recently is quantifying...
the volume of tissue above a specific Tmax threshold. However, this approach does not take advantage of incorporating information about underlying cerebrovascular anatomy. For example, a lesion localized entirely to the MCA territory may be interpreted differently than one spanning both the MCA and ACA territories, but a single number specifying lesion size would ignore this difference. To attempt to address these concerns, we propose an automated approach to evaluating regional ischemia based on automatic drawing of vascular territory ROIs.

Materials and Methods
Twenty-three patients with ischemic stroke were identified by retrospective chart review. Maps of cerebral blood flow were reconstructed offline using automatic AIF selection (1) and SVD deconvolution. These images then were read independently by two neuroradiologists blinded to the patients' history, who rated the perfusion in each vascular territory as hyperperfused, normal, mildly hypoperfused, or severely hypoperfused. Ischemic regions were defined as those that were mildly or severely hypoperfused. In this cohort, 18 MCA (six inferior division, one superior division, 11 both), five ACA, and one PCA ischemic regions were identified. Twenty-one of these ischemic territories were verified by MR or x-ray angiography of the corresponding vessel. Additionally, 10 healthy volunteers were scanned with identical DSC perfusion scans (2). All volunteers and patients received anatomical imaging for reference. A single vascular territory ROI template map including superior and inferior MCA divisions, the ACA, and PCA territories was drawn by a neuroradiologist on a canonical image in MNI space. Cerebellar ROIs were omitted due to inadequate coverage in volunteers and patients. The template ROI map then was used to automatically generate subject specific vascular territory maps. For each patient, the anatomical reference image was coregistered to the patient's perfusion image and normalized to MNI space (SPM 8). The normalization parameters then were used to transform the vascular territory template into subject specific vascular territory ROIs. For each ROI, an asymmetry index was calculated by dividing by the contralateral ROI (for healthy volunteers, asymmetry was instead defined as left/right). The theoretical normal asymmetry index in an ROI is one with lower indices indicating greater relative perfusion deficits.

Results
Mean values in affected regions in patients, unaffected regions in patients, and volunteers are shown Table 1. Due to an insufficient number of patients with PCA ischemia, the PCA was excluded from analysis. Perfusion deficits were greatest in patients with confirmed stroke and smallest in healthy volunteers. In the ACA and both MCA territories, asymmetry index was decreased significantly (meaning increased asymmetry) in affected regions compared to unaffected regions (p<.001 for MCA territories, p<.05 ACA) or volunteers (p<.001 all territories).

Conclusions
Using a completely automated process, we calculated quantitative measures of regional perfusion deficits in different vascular territories. In the ACA and both major territories of the MCA, these measures showed significantly decreased perfusion when the territory was identified by neuroradiologists as being hypoperfused. This agreement between the automated and manual approaches suggests that this method may be feasible for rapid, automated, and unbiased analysis of MR perfusion images.

Purpose
Parenchymal hemorrhages including micro-hemorrhages are a known finding in traumatic brain injury and frequently accompany diffuse axonal injury. As a result, their detection is important, especially as a prognosticator. These hemorrhages are detected best by MR imaging (MRI) sequences optimized in assessing the susceptibility difference between blood products and neighboring tissue. A commonly used sequence is the T2* gradient recalled echo (GRE) sequence which allows detection via the "blooming" effect of blood products. Increasingly, studies have looked into methods such as susceptibility-weighted imaging (SWI), as well as scanning with higher magnetic field strength, to improve detection of hemorrhages. We however attempted to evaluate a much more common sequence done in all our patients, namely the diffusion-weighted sequence. This echo planar sequence is a routine sequence in most centers and is extremely fast. The B0 part of this sequence (routinely obtained and utilized in determination of the apparent diffusion coefficient) is often referred to as "poor man's version of susceptibility". Our aim was to compare this routine B0 sequence with the T2* GRE sequence in detection of parenchymal hemorrhages in patients with trauma. Our hypothesis was that the routine B0 sequence detected many of the hemorrhages.

Materials and Methods
The study was approved by our institution's Human Investigation Committee. MR imaging brain studies performed for trauma at our institution, from January 1, 2010 to October 4, 2013 were reviewed for the presence of intraparenchymal hemorrhages. Fifteen consecutive post-traumatic brain MRI studies were selected that had diagnostic T2* GRE and diffusion-weighted images (DWI) and demonstrated intraparenchymal hemorrhages. An additional 15 patients scanned in the same time frame and with similar scanning technique (1.5 T) with MRI images not demonstrating parenchymal hemorrhages were used as controls. The B0 map images and T2* sequences were separated from the rest of the study and were anonymized and randomized. In order to prevent bias, the randomized B0 images of the 15 patients and 15 controls were first reviewed by a CAQ neuroradiologist with over eight years of experience. The images were reviewed to identify if hemorrhage was present and the number and sites of hemorrhage. Confidence of the reviewer also was recorded (questionable lesions marked separately from definite lesions). In a similar fashion the T2* images of the 30 study patients also were reviewed.
The data then were analyzed by a bio-statistician. The original studies including other relevant sequences also were reviewed.

Results
The B0 was a fairly good surrogate test for the presence of hemorrhage. Using the T2* sequence as the "gold standard", the sensitivity to detect hemorrhage on the B0 map was 80% with a p-value of 0.352 and the specificity was 93% with a p-value of <0.0001. The positive predictive value was 92% with a p-value of 0.0034 and the negative predictive value was 82% with a p-value of 0.0127. The accuracy was 87% with a p-value of<0.0001. However, the B0 underestimated both the number and location of hemorrhagic lesions and only on three of the cases was the correct number of hemorrhages seen on the B0 map. In particular, the B0 map was poor in detecting hemorrhages in the corpus callosum and brain stem.

Conclusions
In conclusion, while the B0 map is sensitive in detecting hemorrhages, it underestimates both the number and locations of hemorrhages. The B0 map was limited especially in detecting hemorrhages in the corpus callosum and midbrain, which are both important sites in grading diffuse axonal injury. This is understandable as other studies have demonstrated that even T2* GRE imaging is deficient as compared to 3D SWI in detection of hemorrhages of the corpus callosum. Distortion and less prominent "blooming" artifacts made detection of hemorrhages more difficult on the B0 EPI sequence. Therefore, while the B0 sequence does detect hemorrhage, it cannot replace the T2* sequence in accurate staging and evaluation of hemorrhage in trauma.

Can Permeability Imaging be Another Predictor to Assess Leptomeningeal Collateral Flow in Patients with Severe Intracranial Arterial Stenosis: A Pilot Study.

H Chen1, X Lou2, B Wu1, G Zhu1, z Su3, X Xu4
1Military General Hospital of Beijing PLA, Beijing, China, 2Military General Hospital, Beijing, China, 3GE Healthcare, Beijing, CO, 4GE Healthcare, Shanghai, China

Purpose
Leptomeningeal collaterals are anastomotic vessels, which provide cerebral blood flow if primary collateral flow is insufficient. At present, digital subtraction angiography (DSA) remains the method that can best measure collateral extents, but it is relatively time-consuming, invasive, and costly. Leptomeningeal anastomotic vessels due to chronic hypoperfusion are accompanied with new vessel formation as transferal anastomoses. These immature vessels are more likely absent of vessel stabilization and have incomplete blood-brain barrier (BBB). Permeability imaging could be a promising tool to investigate leptomeningeal collaterals indirectly.

Materials and Methods
Seven adult patients with severe intracranial arterial stenosis or occlusion were included. All patients underwent a complete MR stroke imaging workup. MR imaging (MRI) included these sequences: conventional sequences, ASL, and DCE T1. Ktrans maps from DCE T1 were derived according to the method described in detail by Johnson et al (5). All patients also received CTA
and DSA. Collateral flow assessments on DSA, Ktrans maps, ASL, CTA-SI were evaluated using a grading system at 15 anatomical sites based on regional vascular territories. Statistical analyses on the diagnostic information of Ktrans maps, ASL, and CTA-SI comparing with DSA respectively were performed using contingency test. McNemar-Bowker test and Kappa coefficient were calculated from a $\chi^2$ statistics with SPSS.

Results
Of seven patients, three presented with unilateral MCA stenosis or occlusions, two with unilateral distal internal carotid artery stenosis or occlusions, and two with multiple intracranial arterial stenosis. A reasonable contingency was found between DSA and Ktrans maps if all 15 sites included (Contingency coefficient, Kappa=0.502, estimated P<0.001). When 10 sites (A1-2; M1-6; P1-2), but without perforating territories, were included, better contingency was found after separation between cortical and perforating arteries (Kappa=0.766, estimated P<0.001). The contingencies between CTA-SI and DSA were not good on all 15 sites (Kappa=0.413, estimated P<0.001) and 10 sites (Kappa=0.329, estimated P<0.001). Our results showed the worst contingencies between ASL and DSA. One case example was used to illustrate our result.

Conclusions
Collaterals can provide alternate routes for circulation, both acutely and progressively when an artery is occluded pathologically. It preserves perfusion and stabilizes cerebral blood flow in acute occlusion and chronic atherosclerosis. But no ideal or specific imaging modality is available for demonstration and accurate measurement of leptomeningeal collateral flow. Angiogenesis is a complex triggered by hypoxia that consists of the sprouting of new blood vessels from pre-existing vascular structures. It is correlated with the development of leptomeningeal anastomosis and can be detected by permeability imaging. In our study, we investigate the consistencies of the results in DSA, CTA-SI, ASL, and Ktrans maps. We find Ktrans maps have the best consistency with the collateral score in DSA, especially those patients who have multiple occlusion sites and complex collateral flow. Higher Ktrans signs may indicate better collateral flow. More specifically, Ktrans maps seem more sensitive to LMF. Further studies are needed to investigate its validity in a large registry of patients.

Purpose
Ultrasound-based characterization of carotid plaque composition has high accuracy compared to histopathology and recently has been studied as a potential tool to predict ischemic events in carotid atherosclerotic disease. Echolucency (EL) and plaque heterogeneity (PH) are two commonly studied characteristics of plaque morphology. We've initiated a systematic review and meta-analysis to summarize the association between these two plaque characteristics and future ischemic events in patients with carotid atherosclerotic disease.

Materials and Methods
We performed a comprehensive literature search evaluating the association of ultrasound-based characterization of carotid plaque composition with stroke. The included studies were prospective or retrospective studies examining EL and PH with mean follow-up of at least one year assessing for development of ipsilateral ischemic event [stroke or transient ischemic attack (TIA)]. Pooled hazard ratios (HR) for EL and PH as predictors of future stroke/TIA will be determined.

Results
Of the 4250 manuscripts screened five have met eligibility for systematic review including a total of 3276 patients. Four of the manuscripts studied EL and three studied PH. All but one study are prospective. Either (or both) EL and PH was associated with higher rates of downstream ischemic events in all of the eligible studies included to date.

Conclusions
The presence of EL and PH in carotid plaque increases the risk of future ipsilateral ischemic event in patients with carotid atherosclerotic disease. Dedicated imaging to characterize plaque composition may offer information beyond luminal stenosis to further risk stratify patients with carotid atherosclerotic disease.

Cerebral venous thrombosis as a rare cause of subarachnoid hemorrhage: case report and literature review

N Sahin1, A Solak1, B Genc1, N Bilgic1
1Sifa University School of Medicine, Izmir, Turkey

Purpose
The clinical diagnosis of cerebral venous thrombosis (CVT) can be difficult because of a wide spectrum of clinical presentations and variable etiologies. The diagnosis of CVT is complicated further when patients initially present with subarachnoid hemorrhage (SAH). Our objective is to discuss the role of imaging for diagnostic work-up of SAH in the setting of CVT with the literature of documented cases and to summarize the possible pathophysiologic mechanisms.

Materials and Methods
We performed a literature review of the presentation of CVT with SAH. In addition, we reported a 48-year-old woman presenting with SAH as the first manifestation of superior sagittal sinus thrombosis.
Results
In a review of 38 articles with a total of 73 cases, the distribution of SAH associated with CVT was different from that of SAH with arterial origin, which usually was seen at the cerebral convexities sparing the skull base and basal cisterns. The most commonly involved sinus was superior sagittal sinus and usually associated with SAH at the frontoparietal convexity, interhemispheric fissure, and sylvian fissure. Subarachnoid hemorrhage usually was adjacent to the thrombosed venous structures. Therefore, the most possible explanation seems to be the rupture of dilated cortical veins due to extension of thrombosis and subsequent venous hypertension. Nonenhanced CT was effective for the diagnosis of SAH in 91% of the cases and for the diagnosis of CVT in only 32%. Hemorrhagic infarct, edema, and parenchymal hemorrhage were the most commonly associated findings that were detected in 33 (45%) of the 73 patients.

Conclusions
Cerebral venous thrombosis presenting with SAH is rare. Because the clinical management of this presentation is quite different from that of arterial SAH, CVT should be considered especially when SAH is limited to cerebral convexities and imaging with MRI and MR venography should be included in the diagnostic workup of SAH.

Purpose
Primary lateral sclerosis (PLS) is a form of motor neuron disease characterized by progressive spasticity and weakening of voluntary muscles caused by the relatively selective degeneration of corticospinal neurons. Resting state functional magnetic resonance imaging (RS-fMRI) and diffusion tensor imaging (DTI) are methods for assessing functional and structural brain networks. To assess whether PLS patients demonstrate increased or decreased connectivity, RS-fMRI and DTI studies were obtained on a group of PLS patients and compared to age-matched healthy controls.

Materials and Methods
Fourteen healthy controls and 19 PLS patients (16 with RS-fMRI and 19 with DTI studies) were included in this study. Network analysis was conducted in two ways. First, functional connectivity was calculated for each voxel by extracting its time series and then correlating it with all other voxels' time series. The individual maps were averaged within each group and compared using t-tests. The results then were cluster size corrected for multiple comparisons (p<0.005) and regions surviving correction then were used as individual seeds to find other functionally connected areas in order to generate a functionally connected brain network, eg., data-driven approach. Region x region correlation matrices were then calculated for patients and healthy controls and were compared using a t-test to assess connectivity differences. The second, structural DTI connectome, where 108 cortical nodes were defined with the AAL template and edges were defined with probabilistic tractography. The resulted connectivity matrices, were compared between groups with network-based-statistics (NBS), which can detect interconnected sub-network as a whole.

Results
Primary lateral sclerosis patients had increased functional connectivity in both motor and extra-motor brain regions compared to healthy controls. A total of 12 distinct regions were found that contributed to this increase in connectivity. These areas then were sorted into three separate clusters of regions using a k-means clustering algorithm. The most prominent cluster contributing to the increases in functional connectivity included the right and left cerebellum as well as the right middle temporal and superior frontal gyri. Areas from this cluster showed a significant increase in connectivity with regions from the other clusters including bilateral premotor cortex and supplementary motor areas, right putamen, and the middle cingulate gyrus. Network-based-statistics identified three structural networks with higher connectivity in PLS patients compared to controls (p<0.05). The first network included fronto-parieto-cerebellar regions. The second, right interhemispheric, included frontal/precentral-cerebellar regions, and the third, included posterior-parietal-cerebellar regions.

Conclusions
In PLS patients, changes in functional and structural connectivity occur among brain regions outside the motor cortex, such as the cerebellum, putamen, fronto-parietal and temporal gyri, that often are overlooked in motor neuron disease. We observed a good correspondence between the structural and functional networks. Increased connectivity in these regions may suggest plasticity
in which other motor regions are now accounting for functions previously attributed to the primary motor cortex. Alternatively, the increased connectivity may be due to widespread reduced intra/inter-hemispheric inhibition due to the degeneration of inhibitory interneurons.

Combined evaluation using noncontrast CT ASPECTS and CT angiography collaterals improves clinical detection of large DWI infarcts

F Mehrkhani1, S Kamalian1, S Kamalian1, L Morais1, M Lev1, A Yoo1
1Massachusetts General Hospital, Boston, MA

Purpose
Diffusion-weighted imaging (DWI) is the most accurate technique for delineating acute infarct core. Large DWI infarct volume (>70 cc) is associated with poor outcome despite treatment, and has been used as a treatment exclusion criterion. CT is more widely available than MRI, but suffers from poor sensitivity for infarct detection. We sought to determine whether a combined approach using noncontrast CT (NCCT) and CT angiography (CTA) improves prediction of large DWI infarcts.

Materials and Methods
In a single-center, retrospective study, we identified consecutive acute ischemic stroke patients with anterior circulation proximal artery occlusions who underwent both CT and MRI. Patients were categorized into two groups based on DWI lesion volume (≤ versus >70 cc). Because patient exclusion from treatment requires high certainty for the presence of a large infarct, we utilized thresholds previously reported to have high (>95%) specificity for DWI infarct volume >70cc for NCCT ASPECTS (scores 0-4) and CTA collateral evaluation (malignant collateral profile: absent collaterals in >50% of MCA M2 division territory). We determined the test characteristics of these prespecified thresholds in this dataset, and evaluated whether these thresholds in combination would improve the diagnostic yield for identifying patients with large infarcts.

Results
Fifty-five patients satisfied study criteria. The mean patient age was 66.9 ±15.2 years. Fifty-four percent of patients were male and 41.8% of strokes were right-sided. The median NIH Stroke Scale (NIHSS) was 14 (IQR 6-18). Eighteen of 55 patients (32.7%) were treated with intravenous (IV) tissue plasminogen activator (tPA) alone, 14 with intra-arterial (IA) with or without IV tPA, and 23 (41.8%) without any treatment. At three months the median modified Rankin Scale (mRS) was four(0-6). Thirty-two of 55 (58.1%) patients had good outcome (mRS>2). The median NCCT ASPECTS was eight (2-10). Of the 55 patients eight (14.5%) had ASPECTS 0-4. The median CTA collateral score was two (1-3); nine cases (16.4%) were categorized as CS=0. In combined approach, 12 (21.8%) patients belonged to collateral score =0 or ASPECTS =0-4. They had larger admission DWI infarct volumes and worse outcomes (3-month mRS) (P<0.001, P=0.002 respectively), whereas there were no significant differences in age, sex, side of infarct, treatment and the time between ictus and CTA. Fifteen (27.2%) patients had a baseline DWI infarct volume >70 cc. Of the 15 patients with large DWI infarcts, seven
were missed using each threshold alone, while only four were missed using the combined thresholds. ROC analysis demonstrated high specificity of the CTA malignant collateral profile (97.5%) and ASPECTS 0-4 (100%) for determining DWI lesion volume >70 cc, but both of these methods suffered from poor sensitivity (both 53.3%). In the combined approach, the sensitivity improved significantly to 73.3%, while maintaining a high specificity (97.5%). The area under the curve (accuracy) of the combined methods increased dramatically to 0.854 (P<0.001).

Conclusions
Combining NCCT and CTA collateral evaluation improves the sensitivity for identifying patients with large DWI infarcts while preserving the high specificity required for treatment exclusion.

Comparison of Quantitative versus Qualitative Evaluation of MR Perfusion Images in Acute Stroke
Purpose
Stroke is a leading cause of morbidity and mortality world over. Qualitative evaluation of MR perfusion to demonstrate salvageable ischemic penumbra has been used to guide clinicians in deciding interventional management options beyond iv TPA. However, the role of "penumbra imaging" in management of stroke is an area of current debate. This study aims to compare the quantitative mismatch measurement vis-a-vis visual qualitative interpretation by radiologists and thus ascertain the reliability of qualitative interpretation.

Materials and Methods
This IRB approved, retrospective study will analyze data from 200 consecutive patients presenting with clinical diagnosis of stroke to our radiology department over a period of five years (2008-2013) with available emergent MRI including perfusion-weighted imaging (PWI). Only patients with a clinical diagnosis of acute ischemic stroke after excluding patients with hemorrhage are included in the study. Perfusion-weighted imaging sequences were reanalyzed for the purpose of this study using the FDA approved Olea software. Imaging was done in clinical 1.5 and 3 T scanners including T1- and T2-weighted spin echo, FLAIR, gradient echo, and EPI DWI (b values of 0 and 1,000) and dynamic susceptibility PWI sequences. Stroke volume was measured on diffusion-weighted imaging with a cut-off ADC value of 0.6 mm²/s. For measuring perfusion abnormality, a Tmax value of 6 sec was considered as lower limit of normal. A significant quantitative diffusion-perfusion mismatch was defined as mismatch ratio (ratio of perfusion abnormality volume to lesion volume on ADC) of > 1.5. The results were compared with visual qualitative dichotomized interpretation of the Tmax and ADC color maps into either significant mismatch or no mismatch. The quantitative mismatch calculation was used as gold standard with a cutoff value of 1.5.

Results
In our initial evaluation of 50 patients, four patients were excluded because of poor quality motion degraded study. Out of the 46 patients (24 females and 22 males; mean age: 72.4 years; range 29-97 years) with acceptable imaging quality, the following results were obtained: 1. Twenty-three patients (50%) were interpreted to have qualitatively positive mismatch. 2. Twenty-two patients (47.8%) were interpreted to have quantitatively positive mismatch (mismatch ratio >1.5). 3. Four patients out of 23 patients with qualitative mismatch did not have significant quantitative mismatch. (False positives = 17.39%). 4. Five patients out of 23 patients with no significant qualitative mismatch were indeed found to have quantitative mismatch. (False negatives = 21.74%).

Conclusions
Initial results suggest that qualitative interpretation leads to false positive interpretation of mismatch in approximately 1 of 6 cases. Also qualitative interpretation missed almost 1 of 5 cases of quantitatively significant mismatch. We wish to further evaluate our data of 200 patients to attain statistical significance to our preliminary results and to determine the clinical relevance of this discrepancy between qualitative and quantitative evaluation of PWI. On the basis of initial results, we propose that quantitative interpretation should be undertaken to reduce false positive as well as false negative results.
Comparison of Whole Brain Perfusion Computed Tomography Performed on 320-Detector Row CT with Diffusion-Weighted Imaging for Evaluation of Acute Infarct.

M Gul1, A Chaudhry2, V Grechushkin3, C Kim3, J Dunkin3
1Winthrop University Hospital, Mineola, NY, 2Stony Brook University Medical Center, Westbury, NY, 3Stony Brook University Medical Center, Stony Brook, NY

Purpose
We aim to compare sensitivity of acute infarct as detected on 320-detector row whole-brain perfusion CT with diffusion-weighted magnetic resonance imaging (DWI). To our knowledge, this is the first study done comparing 320-detector row brain perfusion CT to conventional DWI.

Materials and Methods
In this retrospective study, 149 patients with symptoms suggestive of acute stroke were evaluated using whole brain perfusion CT and DWI. All patients underwent 320-detector row dynamic volume CT angiogram with slice thickness of 0.5 mm and gantry rotation time of 350ms. Cerebral blood flow thresholds were used to delineate the ischemic lesion, penumbra, and infarct. Magnetic resonance imaging (MRI) studies were performed within 48 hours symptoms onset and results were correlated with perfusion CT.

Results
Eighty of the 149 (54%) patients were found to have either an ischemic or hemorrhagic infarct. Sixty-nine of 149 (46%) patients had ischemic infarct as confirmed by DWI and 65 of 149 (44%) were detected on perfusion CT. Forty percent were transcortical infarcts all of which were seen on both DWI and perfusion CT. Nine of 149 (6%) were lacunar infarcts, which were all detected on DWI. However, only five of nine (56%) lacunar infarcts were seen on both perfusion CT. Perfusion CT had sensitivity of 94% for detection of all ischemic infarcts (including lacunar). Sensitivity of transcortical infarct detection was 100% and sensitivity for lacunar infarcts was 56%. Eleven of the 149 (7%) patients had hemorrhagic infarct. Ten of these 11 (91%) patients showed associated perfusion CT defect. Eight of the 149 (5%) patients did not have any significant DWI abnormalities noted; however, these patients had perfusion CT defects noted which corresponded to patients' symptoms.

Conclusions
Detection of acute transcortical infarct on dynamic volume whole brain CT perfusion images is equivalent to DWI with sensitivity of 100% and negative predictive value of 100%. The detection of lacunar infarcts is lower with sensitivity of 56%. Additionally, perfusion CT appears to detect perfusion defects which do not have correlative DWI abnormality. These findings are suggestive of vascular insufficiency to the brain analogous to that seen in unstable angina where decreased tissue perfusion leads to symptoms and perhaps can be a sign of impending stroke.

Correlation of Abnormal Diffusion Properties with Regional Volume Reduction: In Temporal Lobe Epilepsy with Unilateral Hippocampal Sclerosis

S Lim\textsuperscript{1}, S Han\textsuperscript{1}, Y Son\textsuperscript{2}

\textsuperscript{1}St. Vincent’s Hospital, The Catholic University of Korea, Suwon, Kyung-gi-Do, Korea, \textsuperscript{2}The Catholic University of Korea, Seoul, Korea

Purpose
The most commonly described pathology in temporal lobe epilepsy (TLE) is hippocampal atrophy. However, there is evidence for more widespread damage in the mesial temporal lobe and the limbic network involving the amygdala, the entorhinal cortex, the fornix and the thalamus. In patients with TLE with hippocampal sclerosis (HS), analysis of diffusion tensor imaging (DTI) data provides some indirect radiologic evidence of microstructural changes. We investigated whether the volume changes in mesial TLE could be correlate with water diffusion abnormalities by means of voxel-based DTI analysis.
Materials and Methods
The study population included 19 patients (13 women and 6 men; mean age, 34.1 ± 10.3 years, range 15–48 years) with mTLE (left TLE/right TLE, 12:7) who were undergoing video-EEG monitoring for presurgical evaluation at the epilepsy monitoring unit of St. Mary's Hospital of Korea. The identification of the epileptogenic focus was based on seizure semiology and prolonged ictal and interictal vEEG in all patients. These patients had evidence of unilateral hippocampal sclerosis (TLE-HS) based on the qualitative MR imaging (MRI) assessment of hippocampal atrophy on T1-weighted images and a high signal on T2-weighted or FLAIR images. All patients had been seizure free for ≥24 h before the MRI. The age at onset of epilepsy is 17.1 ± 10.7 years and the duration of epilepsy is 17.0 ± 10.4 years. MR scanning was performed using a 1.5 T magnet. Axial T2-weighted and coronal FLAIR images, and diffusion-tensor images also were acquired.

Results
No brain area showed abnormal diffusion properties correlation with regional volume reduction in right TLE patients. No significant region correlated between diffusion property change and the regional volume change of entorhinal cortex and fornix in left and right TLE patients. Brain area showed reduced FA value correlation with decreased amygdala, hippocampal and thalamic volume in left mTLE. These areas were left cingulate gyrus.

Conclusions
Our results demonstrate that water diffusion abnormalities of left cingulate gyrus is correlated with the left amygdala, hippocampal, and thalamic atrophy in the left mTLE. The present data show that volume loss in left mTLE is associated with a widespread limbic systems atrophy. These findings are helpful to better understand the functional deficit and reorganization often found in temporal lobe epilepsy and also will provide a basis to assess neural plasticity in the limbic system for those patients who will undergo curative temporal lobe surgery.

Decrease of Hounsfield Units on CTA in Acute Stroke as a Possible Predictor of Final Brain Infarct: A Retrospective Quantitative Study

M Moon¹, J Gadde¹, A Liu¹, K Anzilotti¹, X Liu¹
¹Christiana Care Health System, Newark, DE

Purpose
A subtle decrease of attenuation on unenhanced CT (NCT) in acute stroke is considered an early sign of acute infarct, but often can be subtle to be well seen. The decrease in attenuation on CT angiography (CTA) is usually more conspicuous, probably reflecting the combination of early cytotoxic edema and decreased capillary filling in the affected area (1). We theorize that the degree of decreased Hounsfield unit (HU) in the affected area may predict final brain tissue infarct.

Materials and Methods
Fifty-three consecutive subjects who had acute occlusion of M1 segment of the middle cerebral artery (MCA) on CTA from 2009 to 2013 were included in the study. Final infarct area was determined on diffusion-weighted MR images (DWI) obtained within 10 days of initial CTA. The final infarct area was measured on a slice with the largest infarct area on DWI, which was used as a reference to determine the corresponding slice and areas of interest on the initial NCT and CTA exams (2). The area of infarct was traced using the free-hand drawing tool on both the infarcted and the contralateral side of the brain to obtain average HU. The Hounsfield unit also was calculated in a noninfarcted area of both MCA territories as a control.

Results
The mean HU decrease in the area of infarct compared to the contralateral side was 6.13 +/- 3.45 (14.6%) for CTA, and 1.76 +/- 1.49 (4.9%) for NCT, statistically significant for both (P < 0.01) (Figure 1). There is a significantly higher percentage of HU decrease on CTA as compared to NCT (P < 0.001), while no significant difference of HU is present for the control areas in both MCA territories (P = 0.45).

Conclusions
Both the NCT and CTA demonstrate significant decrease in mean HU in the areas of final infarct as compared to the contralateral side. CT angiography has significantly higher sensitivity when compared to NCT. A significant relative decrease of HU on CTA (approximately 15%) may serve as a measurable parameter to predict final infarct, which could provide additional useful information for the management of acute stroke.

KEYWORDS: CTA, Hounsfield, Stroke
Purpose
Common diagnostic modalities for intracranial and extracranial dissecting aneurysms include digital subtraction angiography (DSA) as a gold standard, computed tomography (CT), CT angiography (CTA), magnetic resonance Imaging (MRI) and MR angiography (MRA). It was suggested that the diagnosis of arterial dissections is likely to increase in the next future due to more available and sensitive neuroimaging techniques. The assessment of the incidence as well as the diagnostic and treatment modalities available for dissecting aneurysms is therefore advised. In this study, particular attention is given to high resolution CTA as a newly available diagnostic technique compared to other commonly used radiological modalities.

Materials and Methods
We retrospectively reviewed the charts of all patients referred or diagnosed with aneurysm at the Department of Neuroradiology of the Montreal Neurological Institute and Hospital from 1997 to 2013 in order to select cases presenting with intracranial and extracranial dissecting aneurysms.
We systematically recorded demographic, clinical, radiological and treatment data for each patient.

Results
We identified 28 (3.3%) cases of intracranial and extracranial dissecting aneurysms among 832 cases of aneurysms from 1997 to 2011. The annual incidence of dissecting aneurysms went from four cases or less from 1997 to 2009 to seven cases in 2010 (p < 0.0005). There were respectively five, one and two new cases in 2011, 2012 and 2013. In 2010-2013, the major proportion of diagnoses were made with new generation CTA (8/15; 53.3%) followed by DSA (5/15; 33.3%). Stenosis, vascular irregularity, thrombotic occlusion, saccular dilation, double lumen and calcifications are common morphologic features of dissecting aneurysms that were depicted clearly with CTA. With regards to treatment, a total of 20 (20/34; 58.8%) patients with dissecting aneurysms were treated surgically. These include three (3/10; 30.0%) of the subjects diagnosed with CTA and 17 (17/24; 70.8%) of those diagnosed with other radiological techniques. The average duration of clinical and radiological followup was 19 months (range from 16 to 22 months). After followup, none (0/3) of the patients previously diagnosed with CTA who underwent surgical treatment had a recurrence and none (0/7) of the patients who were only scheduled for clinical and radiological followup had a complication. In the group of patients diagnosed with DSA, MRI, MRA and CT, 35.3% (6/17) of the patients treated surgically had a recurrence and 14.3% (1/7) of those followed up without surgical management had a complication.

Conclusions
In the context of an increased diagnosis of dissecting aneurysms, our study underlines the usefulness and growing importance of noninvasive diagnostic techniques, such as CTA. As expected, dissecting aneurysms diagnosed with CTA are less likely to exhibit a complicated morphology and often do not require a prompt treatment, thus reflecting the less severe and urgent clinical presentation of the patients diagnosed with techniques other than DSA.

Dual-Phase FDG-18 PET Brain Imaging to Evaluate Disease Progression vs. Pseudotumor: Do We Change Clinical Management?

F Choudhry¹, S Kurian¹, G Marano¹
¹West Virginia University, Morgantown, WV

Purpose
Aggressive intracranial neoplasms often are treated with debulking, radiosurgery, and chemotherapy with close followup to exclude disease progression. The differentiation of a recurrent or progressive tumor from radiation necrosis often is a radiologic dilemma. Early work shows the utility of immediate and delayed PET imaging in potentially differentiating disease progression (wherein neoplastic cells show further radiotracer uptake on latter scans) from radiation-induced pseudotumor. We set out to determine whether clinical management changed based on our radiographic findings.
Materials and Methods
We reviewed the clinical course of 16 adult patients with prior resection of aggressive primary and secondary intracranial neoplasms who had immediate and delayed F-18 FDG PET imaging. All studies utilized standard brain PET/CT protocol at our institution with 10-12 mCi F-18 FDG, performed on a Siemens Biograph or Phillips Gemini PET/CT scanner. Volumetric SUV measurements were obtained on the affected post-resection side and on the contralateral normal side at two timepoints at baseline and four hours using Vitrea software. We hypothesized that the difference in max SUV between timepoints as a percentage of initial max SUV value on affected side of the brain should be within 25% of the change on contralateral side. If the affected side increased greater than this cutoff or decreased less than contralateral brain region by over 25% we correlated this "predictor" with the radiologist's actual report. Neurosurgical management was reviewed retrospectively to determine whether any further imaging or surgery resulted from our imaging findings, and relevant pathology reports where applicable.

Results
Progression of disease was reported in seven of 16 patients. In all seven cases management changed, which entailed additional chemotherapy, additional imaging studies sooner than previously planned, or consultation for surgery or gamma knife. In all seven cases clinical findings or surgical pathology supported the radiologic conclusion. Of the nine of 16 patients reported to have no progression of disease, all were found to be stable on a subsequent imaging study performed at an interval determined before the PET/CT examination. Additional analysis of maximum SUV value in the post-treatment region of brain and corresponding contralateral region of brain at both timepoints correctly predicted progression in five patients, failing to identify two cases, and would incorrectly raise concern for progression in two patients with no visual evidence for disease progression.

Conclusions
Findings do suggest that radiologist interpretation of dual-phase PET/CT is a powerful tool in distinguishing progression of disease from pseudoprogression. Our analysis of maximum SUV value in the post-treatment region of brain and corresponding contralateral region of brain at both timepoints was less sensitive and specific than radiologist interpretation alone. The ability of the radiologist to detect abnormally enhancing or hypermetabolic tissue within or at the margins of resection bed is superior to any fixed mathematical criteria in our experience. We will continue to assess the utility of this modality in future patients.

Dynamic Contrast-Enhanced Perfusion MRI to Differentiate Recurrent Malignant Glioma from Radiation Change: Whole Volume or Peak Enhancement, Which Is Better?

T Su¹, H Chen¹, C Wu¹, W Chen¹, J Chai¹, C Chen¹
¹Taichung Veterans General Hospital, Taichung, Taiwan

Purpose
It is difficult to differentiate recurrent tumor or post-treatment changes in patient of malignant glioma while enhancing lesions show up during follow-up MR imaging (MRI). The purpose of this study is to evaluate the diagnostic ability of dynamic contrast-enhanced (DCE) MR angiography (MRA) for post-treatment glioma and to test which measurement method reflects the clinical condition well.

Materials and Methods
From 2011 to 2013, patients diagnosed as high grade glioma pathologically received follow-up MRI after treatment for more than three times, were recruited. Dynamic contrast-enhanced MRI was performed on a 1.5 T MRI. The patients were divided into two groups, progression and radiation change, according to clinical, radiological and pathological results. Permeability parameters from the whole tumor volume and from the peak enhancing foci of the lesion were
recorded. Mann-Whitney U test was used to evaluate the difference between two groups and receiver operating characteristic (ROC) curve was applied to compare the diagnostic accuracy with two methods.

Results
In our study, there are 10 patients with disease progression and the other five patients with radiation change. Peak Ktrans (P=0.024) and whole volume Ktrans (P=0.005) show significant difference between disease progression and radiation change. Peak Ve show significant difference (P=0.05) between two groups, but not the whole volume Ve. By using ROC curve, the cut-off value for peak Ktrans and whole volume Ktrans is 66.38 and 47.49 with sensitivity, specificity, and area under curve about 100%, 100%, 1 and 90%, 100%, 0.983, respectively.

Conclusions
Dynamic contrast-enhanced MRI is feasible to differentiate recurrent tumor from radiation changes in patient with high grade glioma. The measurement of peak enhancing area reflects the clinical condition as well as compared with measuring of whole tumor.

F Mehrkhani¹, S Kamalian², S Kamalian¹, M Lev¹, A Yoo¹
¹Massachusetts General Hospital, Boston, MA, ²Massachusetts General Hospital, Boston, MA

Purpose
Recent studies have demonstrated the utility of thin-section noncontrast CT (NCCT) images for visualizing the hyperdense vessel sign (HDVS) and measuring the hyperdense clot length of CT angiography (CTA)-confirmed proximal artery occlusions of the anterior circulation. However, no studies have evaluated whether these thin-section images are sufficient for identifying intracranial vessel occlusion, potentially obviating the need for CTA. We sought to characterize the accuracy of the HDVS on thin-section NCCT for determining the presence of arterial occlusion in acute anterior circulation ischemia.

Materials and Methods
We identified consecutive acute ischemic stroke patients presenting to our institution over a 6-month period (August 2011-February 2012). Inclusion criteria were presumed involvement of the anterior circulation territory and concurrent imaging with CTA and NCCT, the latter having available thin-section images (1.25 mm or thinner) for HDVS determination. Two neuroradiologists, blinded to all clinical information except suspected stroke side, separately evaluated the thin-section NCCT data for the likelihood of a hyperdense clot using the Likert scale (1: definitely absent, 2: probably absent, 3: uncertain, 4: probably present, 5: definitely present). Scores of 4 and 5 were considered positive for the presence of hyperdense clot. The test characteristics of the HDVS for identifying vessel occlusion on concurrent CTA were determined.

Results
There were 115 patients who satisfied study criteria. Mean age was 68.8±16.0 years. Median NIHSS score was 10 (IQR 5-16.5). Vessel occlusions were identified in 60 (52.2%) patients: 13 ICA, 24 M1 MCA, 14 M2 MCA, 4 M3/M4 MCA, and 5 ACA. Hyperdense clots were identified in 55 (47.8%) patients. The sensitivity and specificity of the HDVS were 70% (57-81%) and 76% (63-87%), respectively, for identifying vessel occlusion on CTA. Hyperdense clots were noted in 77% of ICA occlusions, 88% of MCA M1 occlusions, 64% of MCA M2 occlusions, 25% of MCA M3/4 occlusions, and 20% of ACA occlusions.

Conclusions
The hyperdense vessel sign on thin-section noncontrast CT is not sufficiently accurate for identifying intracranial artery occlusions. CT angiography should be performed to assess the neurovasculature in the setting of acute ischemic stroke, and is important when considering patients for possible intra-arterial therapy.

Evaluation of Absolute Brain Temperature Variability in Healthy Adults Using MR Thermometry

C Heyn¹, W Lee¹, J Sled¹, M Shroff¹
¹The Hospital for Sick Children, Toronto, Ontario, Canada
Purpose
Brain temperature in healthy individuals primarily reflects a balance between heat generation from brain metabolism and the dissipation of this heat through cerebral blood flow (1). In disease, an imbalance between cerebral blood flow and metabolic rate, or changes in arterial/core temperature result in local or global changes in brain temperature. The purpose of the study was to characterize the spatial and temporal variability of absolute brain temperature in healthy adults using MR thermometry as a first step toward validating a model of brain temperature that can be applied to neurological diseases.

Materials and Methods
The study was approved by the Research Ethics Board at the Hospital for Sick Children. Four healthy adult males and five healthy adult females (mean age = 26.2 years) were imaged on each of four consecutive days at approximately the same time every day. Body temperature was measured orally before and after scanning. MR imaging (MRI) was performed on a 3T MRI system (Tim Trio, Siemens) using a 12-channel head coil. The scanning protocol included a high-resolution anatomical – T1 MPRAGE (1mm iso; TR/TE/TI/FA=2300/2.96/900/9) and 12 spectroscopy acquisitions – PRESS (20mm iso, TR/TE = 2000/35; 32 averages; Vector = 2048; BW = 1200 Hz; no water suppression) for MR thermometry. MR spectroscopy (MRS) was acquired twice in each of six different regions of interest – left and right posterior frontal centrum semiovale, precuneus and occipital lobe. Water and metabolite peaks were modeled using Lorentzian line shapes following Fourier transformation and zero-order phase correction. Absolute temperatures were calculated based on the proton resonance frequency shift of water relative to reference brain metabolites NAA, Cho, and Cr using a well described methodology (2). Forty-eight temperature estimates were calculated across six brain regions for each of nine subjects. A mixed effects linear regression analysis was employed to evaluate the contribution of subject, visit, and brain region (modeled as random effects) and oral temperature (fixed effect) on brain temperature.

Results
Figure 1 illustrates intra-subject and inter-subject variability in brain temperature. For each subject, the brain temperatures from all brain regions were averaged and plotted for four separate scanning sessions (open circles). The mean of these four measurements is depicted by the horizontal lines and the error bars indicate the standard error. Brain temperature varied significantly across subjects (Friedman Test, p<0.01). For a given subject, the brain temperature changes very little over four consecutive days. These results are confirmed by the mixed effect analysis which showed a larger standard deviation for subject (0.3 C) versus visit (0.09 C). The standard deviation for brain region was 0.11 C indicating a small contribution of brain region to overall brain temperature variability. An analysis for sex also showed a small standard deviation. The t-value for oral temperature was 0.945 and therefore could not account for significant temperature variability.

Conclusions
MR thermometry can provide reproducible measurements of brain temperature. Using this methodology, it is shown that brain temperature does not significantly differ between frontal white matter, precuneus and the occipital lobes. For healthy subjects, brain temperature does not change significantly from day-to-day but measurable differences between subjects are shown. The differences in brain temperature correlate poorly with oral temperature and the reason for the small brain temperature differences between healthy subjects is presently not known. An
explanation for the observed inter-subject temperature variability may ultimately provide validation for a brain temperature model that can be used to diagnose and study disorders of blood flow and metabolism in neurological disease.

Evaluation of MR Angiography Follow-Up of Intracranial Aneurysms Treated with Primary Coiling: Comparison Between Conventional Angiogram, MRA Time-Of-Flight, MRA Contrast-Enhanced and MPRAGE.

I Bonilla-Yoon¹, M Fusco², A Mazketly², R Bhadelia², R Rojas², D Hackney², C Ogilvy², A Thomas²
¹Beth Israel Deaconess Medical Center, Lexington, MA, ²Beth Israel Deaconess Medical Center, Boston, MA

Purpose
MR angiography (MRA) has become used more regularly as a method to evaluate intracranial aneurysms after primary coiling. Digital subtraction angiography (DSA) remains the gold-standard for follow up of these patients, given the concerns for artifactual limitations associated with MRA time-of-flight (MRA TOF) and MRA contrast-enhanced (MRA CE) (1, 2). However, even in the cases where complete aneurysmal occlusion is achieved by primary coiling, it is not uncommon for the aneurysm to recanalize (3). The invasiveness of DSA as a routine assessment tool for the evaluation of coiled aneurysm recanalization stands in contrast with the noninvasive nature of MR. Whether MRA could potentially substitute DSA in the follow up evaluation of patients after primary coiling of intracranial aneurysms remains incompletely evaluated (4). Our goal is to use a large database of patients that have undergone primary coiling of intracranial aneurysms, as well as follow up evaluation with DSA, MRA TOF, MRA CE and MPRAGE sequences to determine whether any or all of these noninvasive methods have the potential to substitute in some cases DSA as the primary method of follow up.

Materials and Methods
We are performing a retrospective study spanning from October 2007 through July 2013 and selected the cases that have only primary coiling, follow up MRA and DSA. Fifty-four patients from this cohort have been identified who meet these criteria and were evaluated. The study includes at total of 63 aneurysms to this point. Our studied patient population consisted of 62% of females and 37% of males, and an average age of 59.2 years (a range of 32-82 years old). In our group of patients, 46% presented with ruptured aneurysms and 54% presented with unruptured. We classified the aneurysms based on location, and found that the most common aneurysms in our study group were anterior communicating artery (27.1%), middle cerebral artery (15.7%) and right internal carotid artery ophthalmic segment (12.9%). MR angiographies were performed on a 1.5 T and 3.0 T scanner and filling was compared to a follow-up DSA. An interventional neuroradiologist interpreted the DSA independently from the two neuroradiologists who independently also evaluated MRA TOF, MRA CE and MPRAGE. Following the Raymond criteria, the aneurysm residual is categorized into one of three classes: 1) complete occlusion, 2) residual neck and 3) residual aneurysm. We calculated sensitivities and specificities for each of the MRA sequences, compared to DSA.

Results
Follow-up digital subtraction angiography (DSA) demonstrated 40 (63.5%) complete occlusions (class 1), 16 (25.4%) residual necks (class 2) and 7 (11.1%) residual aneurysms (class 3). Cases were evaluated by the MRA sequences listed under methods (TOF, CE and MPRAGE). When analyzing the aneurysm residual by MRA TOF, 27 of the occluded aneurysms (by gold-standard DSA) were identified as occluded. The sensitivity and specificity of MRA TOF to accurately identify class 1 aneurysm was 68% and 86%, respectively. In terms of the category of residual
necks (class 2), the sensitivity and specificity of MRA TOF compared to DSA were 64% and 66%. For class 3, MRA TOF had 43% sensitivity and 94% specificity. The calculations of sensitivity and specificity for MRA CE when the aneurysm was completely occluded (class 1 with DSA once again as the gold-standard), revealed a 65% sensitivity and 94% specificity. For class 2 aneurysms, MRA CE had a sensitivity of 73% and specificity of 61%, while class 3 aneurysms demonstrated 20% sensitivity and 93%. The MPRAGE sequence was once more compared to DSA as the gold standard. When the aneurysms were completely occluded (class 1), the sensitivity and specificity of MPRAGE were 72% and 88%, respectively. For aneurysms with a residual neck (class 2), the sensitivity was 70% and specificity was 71%. When the aneurysms had a residual aneurysm that is more than the neck (class 3), the sensitivity and specificity of MPRAGE is 33% and 92%.

Conclusions
Our study included a relatively large number of aneurysms (63). The specificity of all sequences (TOF, CE, and MPRAGE) to detect complete occlusion (class 1) or residual aneurysm (class 3) was very high, in the range 85% (class 1 for TOF versus DSA) to 94% (class 3 for TOF vs DSA). Sensitivity of the modalities was less robust, as described in the results section, mostly in the range of 0.6-0.7, although class 2 (residual neck) demonstrated particularly poor sensitivity across all sequences (0.2-0.4), compared to DSA as gold standard. These findings suggest that MRA TOF, MRA CE and MPRAGE are very reliable (high positive predictive value (PPV) above 0.9) at identifying patients with complete aneurysmal occlusion and may be used to follow a subset of patients after aneurysm coiling. We will continue to evaluate more patients from our database and expand on these findings.

Evaluation of peritonsillar abscess using reconstructed enhanced CT images: classification and lesion extent

K Toyoda\textsuperscript{1}, A Ohara\textsuperscript{2}, H Oba\textsuperscript{1}, M Osawa\textsuperscript{1}, T Kanda\textsuperscript{1}, R Hiraoka\textsuperscript{1}, J Kotoku\textsuperscript{3}, S Furui\textsuperscript{1}
\textsuperscript{1}Teikyo University School of Medicine, Tokyo, Japan, \textsuperscript{2}Kyorin University, Tokyo, Japan, \textsuperscript{3}Teikyo University, Tokyo, Japan

Purpose
Peritonsillar abscess is a commonly encountered emergency in the daily clinical setting. Formation of the abscess beside the tonsillar capsule promotes extension of inflammation into the surrounding tissues, requiring antibiotic administration and/or surgical drainage without delay. In particular, CT images are examined, since in the peritonsillar abscess at the lower pole, inflammation that is difficult to appreciate on inspection may spread downwards and complicate treatment. Few studies have reported on peritonsillar abscess in which the coronal and sagittal images were examined as well. This study is to evaluate the CT findings of peritonsillar abscess, comparing between lower and upper types with reconstructed coronal and sagittal images.

Materials and Methods
We retrospectively studied 100 consecutive case (from August 2008 to August 2013) who had
undergone contrast-enhanced CT and been diagnosed with peritonsillar abscess. Their age ranged from 15 to 84 years (mean 42.0 years), and there were 78 men and 22 women. Contrast-enhanced CT imaging from the skull base to superior mediastinum was begun from 100 sec after contrast administration (2 ml/sec). From these 3D volume transverse images, coronal and sagittal images were reconstructed. On CT, the distance from the hard palate to base of epiglottic vallecula was divided into two, with the peritonsillar abscesses mainly at the upper side classified as the upper-portion type, the lesions mainly at the lower side as the lower-portion type, and lesions that covered both the upper and lower sides as the upper-lower type.

Investigated items included morphology, which was classified into four types: lunar～crescent-shaped, elliptic～circular, lobular, and irregular, largest measured diameter on transverse and coronal and sagittal images and degree of edema.

Results
Peritonsillar abscess was bilateral in six cases, and unilateral in 94 (right; 44 left: 56 cases). Upper-portion type was seen in 51 cases, lower-portion type in 30, and upper-lower type in 13. Mean age of the cases with lower-portion type was higher (51.9 y) than those with upper-portion type (38.4 y). Regarding morphology, in the upper-portion type 68.6% of cases showed a lunar～crescent-shaped or elliptic～circular shape, whereas in the lower-portion type 70.0% showed a lobular or irregular one. Edema was absent or only somewhat present in 78.4% of the upper-portion type, in contrast to being present or marked in 73.3% of the lower-portion type.

Conclusions
By evaluating coronal and sagittal images in addition to transverse ones, the abscess morphology, range of involvement, and degree of edema could be investigated in greater detail. The lower-portion type tended to be more severe, show surrounding edema extending easily to the larynx and hypopharynx, be irregular in shape, and show an irregular lobular border. Reconstructed coronal and sagittal images were useful in evaluating the extent of lesion involvement.

Fate of diffusion restricted lesions in primary intracerebral hemorrhage

Y Tsai1, S Chang1, S Chen1, H Weng1
1Chang-Gung Memorial Hospital, Chiayi branch, Chiayi, Taiwan

Purpose
Primary intracerebral hemorrhage (ICH) is associated with greater mortality and more severe neurological deficits than any other stroke subtype. Prior studies have found that lesions with restricted diffusion on diffusion-weighted imaging (DWI) were observed in 13-41% of patients with acute ICH. In this study, we aimed to find out the fate of the DWI lesions in ICH patients and determine whether the presence of DWI lesions is associated with functional outcome in patient with ICH.

Materials and Methods
This prospective study enrolled 153 patients with acute ICH. Baseline MRI scans were
performed within two weeks after ICH for detecting DWI lesions and imaging markers for small vessel disease (SVD). Follow-up MRI scans were performed at three months after ICH for estimating the fate of the DWI lesions. We evaluate the associations between the DWI lesions with several clinical features and functional outcome.

Results
Seventeen of 152 patients (11.1%) had a total of 25 DWI lesions. Factors associated with DWI lesions were high initial systolic and mean arterial blood (MAP) pressure at emergent department, more lowering of MAP within 24 hours, presence of white matter hyperintensity and cerebral microbleeds. Thirteen of 25 DWI lesions (52%) were not visible on follow-up T2-weighted or fluid-attenuated inversion recovery images. An illustrated case of ICH patient with DWI lesion is shown in the figure.

Conclusions
Diffusion-weighted imaging lesions in ICH patients are associated with rapid blood pressure reduction as well as MRI markers of SVD such as cerebral microbleeds and white matter hyperintensity. More than half of the DWI lesions in ICH patients did not leave visible, long-term infarction. The DWI lesion may be regarded as a marker of SVD or a silent ischemia and not always indicates an absolute cerebral infarction or permanent tissue injury.

Getting Off the Couch: CT Head Imaging for the Obese Patient

L. Pretty¹, J Shankar²
Purpose
The increase in obesity in the general population brings more frequent challenges in imaging, as an increasing number of patients exceed the weight or girth limits of existing computed tomogram (CT) scanners. We describe a technique used for plain CT and CT angiogram of the head in the morbidly obese patient.

Materials and Methods
Patients imaged stood behind the CT gantry while bending forward and placing their head, prone in the head holder. The patients were alert, oriented and very cooperative. To better enable the patient to do this, we chose the CT scanner which had a narrower gantry (Siemens Sensation 64). The patients were able to support themselves with strategic placement of their hands on the gantry. The patient was told about the table movement with the scan, and allowed his head to move with the slow movement of the table. The images were acquired in the caudo-cranial direction, with the patient position designated as face down and leg first. Helical imaging was used to reduce motion artifact. Both a CT head and CTA angiogram have been acquired utilizing this method.

Results
The CT head images showed minimal motion artifact but were adequate for the diagnosis of hemorrhage in the suprasellar cistern and anterior interhemispheric fissure, along with a large sellar-suprasellar mass, possibly pituitary macroadenoma, extending towards the left cavernous sinus. The hemorrhage could be secondary to pituitary apoplexy, or could still be aneurysmal. A CT angiogram was felt necessary to answer this question. The table movement and expected sensation during the CT angiogram was discussed with the patients before proceeding. The patient was placed in the same position behind the gantry and intravenous contrast media was injected to acquire the CT angiogram. Timing had to be estimated. The images were suboptimal due to motion artifact. A possible anterior communicating (ACom) artery aneurysm was suspected, which in retrospect was not present.

Conclusions
The current CT scanners have a weight limit of 485 lbs. With the increasing incidence of obesity in North America, we require new imaging solutions for patients who exceed these limits. Our method can be used with existing CT scanners to obtain a plain head CT as well as more elaborate imaging such as CT angiogram of the head. Getting off the couch was the solution to imaging the obese patients and providing information to aid in their healthcare.

Haemorrhage in adult pilocytic astrocytoma; an under-recognised radiological feature

R McCreary¹, D du Plessis², S Mills², C Soh²
¹Salford Royal NHS Trust, Manchester, UK, ²Salford Royal NHS Trust, Manchester, Greater Manchester, UK
Purpose
A study of 138 cases of histologically proven pilocytic astrocytomas, which included both pediatric and adult patients, reported hemorrhage on pre-surgical imaging in 11 (8%) of patients (1). This is higher than previously thought. No distinction was made between pediatric and adult cases. This current study aims to assess the radiological presence of hemorrhage in adult pilocytic astrocytoma on pre-operative imaging.

Materials and Methods
Patients with histological confirmation of pilocytic astrocytoma were identified on the neuropathology database. Clinical records were reviewed to identify patients with a de novo pilocytic astrocytoma diagnosis and pre-operative imaging was reviewed to assess for features of recent or previous hemorrhage. The relationship between the location of tumor and hemorrhage also was assessed.

Results
Seventy-six cases of histologically proven pilocytic astrocytoma were identified. Clinical records were retrieved for 52 patients and 46 of these were reported to be de novo pilocytic astrocytomas. Appropriate pre-operative imaging was available for review in 37 cases and 11 cases were found to have evidence of recent or previous hemorrhage. Tumor location (supratentorial versus infratentorial) did not show any difference in rate of hemorrhage.

Conclusions
A significant number of pilocytic astrocytomas show evidence of hemorrhage on pre-operative imaging and this may reflect a difference between adult and pediatric populations. Further work is required to evaluate this.

Hemophagocytic Syndrome: Report of 5 cases (Including a Pair of Twins) Admitted to two Brazilian Tertiary Care Hospitals.

M Dalaqua¹, A Vaz¹, B Handfas¹, F da Silva², A Barbosa¹, G Dias¹, L Lucato², M Funari³
¹Hospital Israelita Albert Einstein, São Paulo, Brazil, ²Hospital das Clínicas/Universidade de São Paulo, São Paulo, Brazil, ³MD, São Paulo, Brazil

Purpose
Hemophagocytic lymphohistiocytosis (HLH) is a rare and potentially lethal multisystemic disease that affects all age groups and is characterized by fever, splenomegaly, jaundice, pancytopenia, cutaneous rash and pathological findings of hemophagocytosis in the bone marrow and other tissues, including the central nervous system. This condition, which shares features with sepsis and systemic inflammatory response syndrome (SIRS), has received increasing attention in recent years such that 85% of the 1500 or so publications on HLH have appeared in the last decade. This paper aims to present the radiological manifestations of brain disease in five patients (including two twin sisters) with hemophagocytic syndrome and review the available literature on educational purposes.

Materials and Methods
The primary form can be sporadic or familial (genetic or autoimmune), and the secondary form
can be diagnosed in association with infection (Epstein-Barr virus, HHV-6, CMV, bacteria, viruses and parasites), malignancies or prolonged immunosuppression. Clinical manifestations of the disease in the central nervous system are frequent (10-73%), such as seizures, altered level of consciousness, hemiparesis, nuchal rigidity and ataxia, and result from infiltration by lymphocytes and histiocytes. Radiological manifestations are variable and include leptomeningeal or parenchymal involvement, hemorrhage, tissue necrosis and demyelination, which may be represented by diffuse white matter changes, parenchymal atrophy, extra-axial hemorrhages, calcifications and enhancing leptomeningeal, perivascular or parenchymal lesions. Treatment options include chemotherapy, immunosuppression and, eventually, bone marrow transplantation. We review the images of brain disease in five patients admitted to two tertiary care services in the last years.

Results
We present the radiological manifestations of brain disease in five patients (including two twin sisters) and review the available literature on educational purposes.

Conclusions
It is important for the radiologist to be familiar with the diagnostic findings of Hemophagocytic syndrome, since neuroimaging may mimic other diseases and can have patterns that represent a diagnostic challenge, especially in immunocompromised patients.

Hippocampal sclerosis of aging may be distinguishable from other causes of dementia with in vivo MRI imaging.

N Miller¹, M Fuortes¹, T Moritani¹, A Capizzano¹
¹University of Iowa Hospitals and Clinics, Iowa City, IA

Purpose
Hippocampal sclerosis of aging (HSA) is a recently described pathological condition associated with dementia in elderly patients (1). Hippocampal sclerosis of aging is diagnosed postmortem by pathologic analysis that demonstrates hippocampal neuronal loss and gliosis out of proportion of Alzheimer (AD) pathology. Patients with HSA are older than patients with other causes of dementia. Previous studies have shown that changes related to HSA can be evaluated in vivo via MR imaging (MRI), with more severe atrophy and deformation of the hippocampus compared to AD (2). Hippocampal sclerosis (HS) is a well known MRI finding in patients with epilepsy, but also can be seen in dementia. The purpose of this study was to assess the prevalence of HS on clinical MRI performed for evaluation of dementia as well as to evaluate distinguishing features between HSA patients and other demented patients.

Materials and Methods
A retrospective review of the patients who received a clinical brain MRI protocol indicated for cognitive impairment showed 129 patients with exams dated from 9/27/2010 to 6/6/2013. Patients were scanned using 1.5 and 3 T scanners with conventional T1- and T2-weighted, 3mm FSE coronal T2-weighted perpendicular to the hippocampus, FLAIR, GRE and diffusion-weighted imaging (DWI) sequences. A clinical and demographic review was performed
excluding patients under age 50 or without a clinical diagnosis of dementia. Fifty-one patients remained after this exclusion. Mean age and gender distribution were 73.4 years, 53% female, 47% male. A review of the MRI images then was performed to evaluate for hippocampal sclerosis (defined by selective atrophy, T2 hyperintensity and loss of internal architecture of the hippocampus) and other findings related to dementia, including hippocampal atrophy, leukoaraiosis, hydrocephalus and subcortical ischemic vascular disease (SIVD) with chronic lacunes. Differences in the subset of patients with HSA in comparison to the larger set of patients with dementia without HSA were assessed.

Results

Of the 51 patients, 10 had findings consistent with HSA on MRI. Four had bilateral HS, while in the remaining six HS was unilateral. Clinical diagnoses of these patients included vascular, AD, mixed, and frontotemporal dementia. The average age of HSA patients was 79.5 years in comparison to 71.9 years in those without HSA. Independent measures t-test assuming unequal variance found a significant age difference (p = 0.00158). Furthermore, all of the patients with HSA had at least mild or moderate leukoaraiosis and SIVD while the larger subset of demented patients had a more even spread of leukoaraiosis and SIVD.

Conclusions

Clinical imaging findings consistent with HSA were identified in almost 20% of demented patients over 50 years of age. Hippocampus sclerosis of aging was unilateral in half of the cases, while AD changes are more frequently bilateral. Demented patients with HSA were significantly older than demented patients without HSA. The latter patients are also more likely to have moderate leukoaraiosis and SIVD. Although further studies with increased sample size and pathologic correlation will need to be performed, this initial study suggests that there is likely an in vivo imaging correlate of pathologically defined HSA that may identify a distinct subset of demented patients.

Identification of risk groups in mechanical thrombectomy using the pRESet-Stent-retriever: Are there risk-groups for procedure-related complications?

T Zoubi1, U Hanning2, W Schwindt1, W Heindel1, T Niederstadt2

1University Hospital of Münster, Münster, Germany, 2University Clinic of Münster, Münster, Germany

Purpose

Mechanical thrombectomy is an established method of recanalization in patients with acute stroke. Stent retriever represents a new kind of device. Our purpose was to identify patients with higher risk of periinterventional complications.

Materials and Methods

In our database of 159 interventional treated strokes, we identified 59 patients (ø66 ± 16 yrs) with acute thromboembolic occlusion of MCA, who underwent mechanical thrombectomy using the pRESet device (Phenox, Bochum, Germany). Time from stroke onset to hospitalization was less than six hours. All patients presented with NIHSS ≥ 8. In all patients NECT, CTA and PCT
were performed immediately before intervention. Grade of recanalization was measured using the TICI score. Duration of interventional procedure was represented by the time from first diagnostic angiography to revascularization. Density of the occluding thrombus was measured in NECT in relation to the contralateral MCA.

Results
Successful recanalization (TICI 2b or higher) was achieved in 56 patients (94.9%). In two patients the thrombus could not have been passed by micro wire. In one patient a major part of the thrombus could not have been mobilized by the stent retriever. In nine patients thromboembolic complications occurred. Thrombus material migrated into ACA territory (n = 5) and into distal MCA territory (M2/M3, n = 4). Lower relative density of the occluding thrombus led significantly more often to periinterventional complications (0.9 ± 0.2 vs 1.5 ± 0.5, p < 0.01). Thromboembolic complications occurred significantly more often, if the patients age was ≥ 75 yr (p = 0.01). Angio-to-recanalization time tended to be longer in patients with higher vascular risk score but did not show significance (p = 0.086). Thrombus length, number of passes of the device and vascular risk score had no influence on the number of complications.

Conclusions
Mechanical thrombectomy using the pRESet stent retriever device is an effective method of recanalization in patients with acute thromboembolic occlusion of MCA. Complications associated with thrombectomy occur, in our study significantly more often in patients with higher age or lower density of thrombus. The dependence of thrombus density and complication rate may originate from thrombus composition. The knowledge of risk factors may influence interventional options in patients with acute occlusion of the middle cerebral artery.

Increased Cerebrovascular Reactivity in the Days Following Sports-Related Concussion in College Athletes.

A Militana¹, M Donahue¹, M Strother¹, A Sills², G Solomon¹, V Morgan¹
¹Vanderbilt University, Nashville, TN, ²Vanderbilt University, Franklin, TN

Purpose
Sports-related concussion has entered the national conversation through widespread coverage by multiple media outlets in recent years. Despite this growing national interest, the role of traditional imaging remains limited in the management of this important clinical condition. While many researchers have investigated alterations in functional activation and connectivity using functional MRI (fMRI), relatively little research has been published regarding cerebrovascular alterations. Cerebral blood flow (CBF) is known to increase as a physiologic response to hypercapnia through cerebral arteriolar dilatation and cerebrovascular reactivity (CVR) is a measure of this response. To date, no study has been published using fMRI to assess CVR following sports-related concussion and what little has been published using other modalities has been inconclusive. The purpose of this study is to evaluate CVR using fMRI in college athletes in the days following a sports-related concussion.
Materials and Methods
Thus far, we have enrolled six college athletes (3M/3F, 18-21 yrs.) two-six days after suffering a sports-related concussion diagnosed by an athletic trainer and six healthy (3M/3F, 18-21 yrs.) college students who have never suffered a concussion. Cerebrovascular reactivity was measured by resting functional echo-planar imaging on a 3T MRI scanner. Subjects alternated breathing room air and room air with 5% CO2 via mask at intervals of two minutes. The average percent signal change between these intervals was divided by the average change in the partial pressure of expired CO2. Baseline CBF was quantified using arterial spin labeling techniques. A total of 18 regions of interest (ROIs) were evaluated across the brain.

Results
Figure 1 is a graph demonstrating the average CVR of college athletes within two-six days following a sports-related concussion (y-axis) and gender/age matched college controls (x-axis) with each data point representing a separate ROI. The black line represents a 1:1 relationship and any data point that falls on this line indicates that there is no difference in the average between patients and controls for this ROI. Figure 2 is a similar graph which shows the average CBF of the same 18 ROIs shown in Figure 1 with patients again represented on the y-axis and controls represented on the x-axis. Our data indicate that CVR is increased approximately 37% (average across all ROIs) in patients compared to controls (Figure 1). This is compared to baseline CBF values which differ less than 1% (Figure 2). These findings strongly suggest that the difference observed is the result of an increased vasodilatory response to increasing levels of carbon dioxide and not alterations in baseline CBF. Several ROIs have reached or are approaching statistical significance despite our study's current lack of power (6 patients and 6 controls). Because CVR is increased across all 18 ROIs in patients compared to controls, we suspect that our data represents a global process that is not limited to the ROIs that have already reached statistical significance.

Conclusions
We have observed markedly increased CVR in college athletes in the days following a sports-related concussion while baseline CBF remains unchanged. While the exact pathophysiology is unclear, we suspect that this hypereactive vasodilatory response is potentiated by the local metabolic environment surrounding cerebral arterioles following concussion. Furthermore, we believe our results suggest hypercapnia and the exaggerated vasodilatory response that ensues may represent a potential etiology for recurrent symptoms upon an athlete's return to play who is otherwise asymptomatic at rest. To our knowledge, this is the first set of data presented using fMRI to evaluate CVR in concussion patients. Additionally, our finding of increased CVR in the days following sports-related concussion has not been suggested previously in any published study regardless of modality. This work was supported in part by the Vanderbilt CTSA grant UL1 TR000445 from NCRR/NIH.

KEYWORDS: Cerebral Blood Flow, Concussion, FMRI
Purpose
New C-arm angiography systems allow acquiring CT-like images of brain parenchyma and intracranial vasculature, and measuring cerebral blood volumes (C-arm CBV) during diagnostic angiography or endovascular treatment. C-arm CBV examinations require two rotational acquisitions: a noncontrasted "mask run" and a contrasted "fill run", generating volumetric datasets that provide both CBV maps and anatomical images. To reduce the contrast medium necessary for these examinations, we investigated different injection parameters of the diluted contrast medium, injected via aortic arch route to obtain exploitable CBV maps. Our aim was to evaluate the influence of these parameters on C-arm CBV maps and volumetric anatomical images in clinical cases.

Materials and Methods
Thirty-eight patients with normal perfusion, detected through CT perfusion (CTP) studies, were investigated. For each, C-arm CBV images (syngoNeuroPBV-IR, Siemens, Forchheim, Germany) and anatomical images were acquired using a flat-detector angiographic system (ArtisZee-BA, Siemens, Forchheim, Germany). Patients were divided into three groups with different contrast concentrations and injection rates: group A (17 patients, 50%, 5ml/sec); group B (10 patients, 30%, 5ml/sec); group C (11 patients, 25%, 7ml/sec, fixed 9sec scan delay). In groups A and B, the scan delay time was individually determined for each patient via a test bolus injection. All studies featured an aortic arch injection with 4F diagnostic catheter positioned above the aortic valve. Depending on the delay, 75-119 ml of diluted contrast medium were...
injected continuously along the fill run. The C-arm CBV data were reconstructed on a separate workstation (syngoXWP-VB15D, Siemens, Forchheim, Germany). C-arm CBV and CTP-CBV were manually co-registered, and regions of interest (ROI) were placed in the anterior (ACA), middle (MCA) and posterior (PCA) cerebral artery territories and basal ganglia (BG). We calculated mean CBV values for each territory and the correlation coefficient between the three groups. We assessed the agreement between CTP-CBV and C-arm CBV clinical measurements through Bland-Altman analysis. Additional reconstruction of the fill run dataset was performed to evaluate the cerebral vasculature using slab maximum image projection (MIP) images, and compare the influence of the contrast medium concentrations.

Results
All studies were successful, without complications. Cerebral blood volume maps and cerebral vasculature images were obtained for all groups. No significant differentiation of C-arm CBV image quality was observed in the three groups. C-arm CBV values for all groups were higher than CTP-CBV values (p<0.01), with no significant differences in Right/Left ratios for C-arm CBV compared to CTP-CBV for PCA and BG (p>0.05). C-arm CBV Right/Left ratios in ACA and MCA for Group A and B were slightly higher compared to CTP-CBV, (p<0.01). The same tendency was observed in Group A and B. However, this laterality was slightly improved in Group C. For cerebral vessels, the noise was increased according to the high contrast concentration in the slab MIP images.

Conclusions
Preliminary results indicate that aortic-arch injections of 25% diluted contrast medium generate C-arm CBV maps and vascular images comparable to those obtained with 30% or 50% concentrations. C-arm CBV with 25% diluted contrast medium (9 sec delay) is easy to perform and may provide clinically useful information for patient management.

Intraclass Correlation Coefficients for the CTA Measurement of Carotid Plaque Thickness Performed on Axial and Orthogonal images

M Trelles de Belaunde1, K Eberhardt2, M Buchholz2, B Anna2, D Martin2, A Schindler2, K Nikolaou2, T Saam2

1UTMB Health, Galveston, TX, 2Ludwig-Maximilians University, Munich, Germany

Purpose
CT angiography (CTA) of the carotid arteries is performed routinely for the evaluation of carotid bulb stenosis. Recent studies have pointed towards increased cardiovascular risk related to soft plaque component thickness. It has been suggested that this thickness should ideally be measured on reformatted images which are orthogonal to the lumen. However, this reformattting is time consuming and therefore not applicable in clinical routine. The purpose of this study is to compare measurements of carotid plaque thickness based on axial and orthogonal CTA images. Materials and Methods
Twenty patients with suspected ischemic stroke or TIA with carotid CTA from April 2008 to December 2010 were reviewed. The maximum wall thickness and the maximum soft plaque
Component thickness was obtained from the CTA axial images by two experienced radiologists, blinded to each other's results using axial images. On a second sitting the measurements were repeated by one of the radiologists using images reconstructed orthogonal to the lumen of the internal carotid artery.

Results
A total of 40 vessels were evaluated. There was no significant difference of thickness measurements between reader 1 and 2 for axial images and between axial versus orthogonal measurements (p>0.05). The intraclass correlation coefficients (ICC) between reviewer 1 and 2 for axial measurements of maximum plaque wall thickness and maximum thickness of soft plaque component were 0.94 (0.89 - 0.97) and 0.95 (0.91 - 0.98) respectively. When comparing measurements obtained using axial and orthogonal images, the ICC were 0.93 (0.87 - 0.96) and 0.97 (0.94 - 0.98).

Conclusions
This study showed no systematic differences of measurements of plaque thickness when obtained on axial CTA images compared to images orthogonally reconstructed to the lumen. In addition excellent intra- and inter-reader reproducibility was obtained for plaque thickness measurements.

6:30AM - 9:00PM

Leukoaraiosis, hippocampal atrophy and Mean Diffusivity in differential diagnosis between subcortical vascular dementia and Alzheimer's disease.
Purpose
Considerable overlap exists between subcortical vascular dementia (SVD) and Alzheimer disease (AD) (Gorelich 2011), because subcortical white matter lesions occur even in AD, such that mixed pathology (AD+SVD) frequently is found in autopsic studies (Kovacs 2013). In clinical practice, some patients can fit both SVD (Ernikutti 2000) and AD (McKhann 2011) criteria. In this pilot study, with the purpose of differentiating vascular and degenerative factors in mixed dementias, we tested simple MRI indexes of cortical and subcortical abnormalities in clinically definite SVD and AD patients. Leukoaraiosis and hippocampal atrophy were rated by visual assessment scales (Fazekas 1987, Scheltens 1992), and mean diffusivity (MD) was measured in selected regions of interests (ROIs) known to be differently affected by vascular and degenerative factors (Fu 2012).

Materials and Methods
Nine patients with moderate SVD (77.7±7 yrs, 7 females) and nine with moderate AD (71.7±9.6 yrs, 5 females) were compared to 18 elderlies normal controls (NC, 72.4±6.7 yrs, 10 females). In patients, vascular risk factors by Hachinski scale (SVD: 7-10, AD: 2-5) and global cognitive impairment by Mini-Mental Examination (SVD: 18,5±3,8, AD: 16,6±5.8) were assessed. By a Siemens 3 T Skyra scanner equipped with a 32 phase-array head coil, each subject was scanned with a protocol including volumetric FLAIR (TR/TE: 5000/389, TI 1800, voxel size 0.7x0.7x1.1), high-resolution DTI (10000/97, 2x2x2, 64 directions, bvalue 1200 s/mm2), high resolution coronal T2 (8400/71, 0.4x0.4x2), total scan time 24 minutes. MPR axial planes of volumetric FLAIR were employed to evaluate leukoaraiosis by Fazekas scale (sum of periventricular and deep white matter:0-6). High resolution T2 coronal slices, perpendicular to the long axis of hippocampus, were employed to evaluate hippocampal atrophy by Scheltens scale (sum of left and right:0-8). In one SVD patient, DTI data were too affected by motion to be analyzed successfully. In the other 17 patients and in all 18 controls, from MD (calculated by Siemens Syngo built-in software) sagittal and coronal 2mm-planes were obtained. Then, nine circular (12mm2) ROIs were manually placed on midline sagittal plane in corpus callosum (genu, body, splenium) and on three coronal planes in each hippocampus (head, body, tail) (see Figure).

Results
Although visually assessed leukoaraiosis was significantly (p<0.005) higher in patient with SVD (4.6±1.4) compared to AD (2.5±1.1), most SVD patients overlapped with AD patients. Visually assessed hippocampal atrophy did not significantly differentiate SVD (5±1.3) from AD (5.9±1.9). MD in hippocampi was increased more in AD (952.2x10-6 mm2/s +92.4, p<0.01) than in SVD (929.3x10-6 mm2/s+66.1, p<0.05) compared to NC (880.1x10-6 mm2/s+37.7). MD in corpus callosum was increased in SVD (921.7x10-6 mm2/s+127.3, p=0.01), not in AD (835.9x10-6 mm2/s+84.4), compared to NC (831.3x10-6 mm2/s+43.3). Ratio between MD in hippocampi and MD in corpus callosum was lower in SVD (1.02±0.1) intermediate in NC (1.06±0.07), higher in AD (1.15±0.1), and differentiated SVD from AD (p=0.05).
Conclusions
By applying in a clinical setting the proposed protocol, the crucial features to differentiate SVD from AD can be assessed. MD in corpus callosum and hippocampi appears to be promising in differentiating vascular and degenerative factors in dementia.

Morbidity in brain tumor patients correlates with lesion distance to DTI

W Gaggl1, V Nair2, D Huss2, T Meier2, E Meyerand2, A Field3, V Prabhakaran2
**Purpose**
Language and motor deficits in patients following brain tumor resection frequently are observed. Even with presurgical planning using functional MRI (fMRI) and diffusion tensor imaging (DTI) there can be new postsurgical functional deficits. It has been suggested that the probability of occurrence of such new deficits is related to the proximity of the surgical lesion to eloquent brain structures. This lesion proximity related morbidity is not well understood and varies considerably even when controlling for tumor grade and stage. Our objective is to correlate the distance of the surgical lesion to eloquent language and motor brain areas and investigate their relationship to surgical functional deficits.

**Materials and Methods**
Adult patients with brain tumors (n=60) underwent pre-operative DTI scanning. The major language and motor white matter pathways (right and left superior longitudinal fasciculi and the cingulum, arcuate fasciculi, left and right motor fibers) were identified from the DTI images and their distance to the lesion measured. Postsurgical morbidity and mortality information for each of the included patients were collected from their medical records.

**Results**
Analysis of the patients' DTI showed that the lesion-tract-distances (LTD) from the DTI were significantly correlated to the occurrence rate of new surgical functional deficits. A significant linear relationship between the distance of the tumor to the right (p=0.013) and left (p=0.002) superior longitudinal fasciculi and language deficits was observed, with greater distances resulting in lesser impairment.

**Conclusions**
There are significant relationships of the proximity of the surgical lesion to the white-matter tracts. Patients with their surgical lesion further away from these structures showed a significantly decreased surgical morbidity. Our results suggest that a distance of 1cm or greater from white matter structures is indicated to avoid new deficits. The benefit of using FMRI to reduced new surgical deficits has been shown in previous studies. Our data indicate that adding DTI to presurgical planning increases the predictive value substantially.

**Morphometric Analysis and Diffusion Tensor Imaging Investigation in Brain of Alzheimer’s Disease Patients Without and With Depression**

C Chen¹, J Chai¹, H Chen¹, Y Chuo¹, T Lan¹, C Lin², W Chen¹, C Wu¹, S Lee¹  
¹Taichung Veterans General Hospital, Taichung, Taiwan, ²National Yang Ming University, Taipei, Taiwan

**Purpose**
This study is designed to elucidate the brain tissue difference between Alzheimer disease (AD) patients with and without depressive symptoms in the respect of the neuroanatomical volume
analysis and diffusion tensor imaging (DTI) alternations. We use morphometric analysis of brain MR imaging (MRI) in study of the brain tissue loss and use fractional anisotropy (FA) with mean diffusivity (MD) indices of white matter (WM) DTI for exploring the difference in their brain finding.

Materials and Methods

In this study, 21 Alzheimer disease (AD) patients (mean age 76, M/F 13/8) without depressive symptoms and 27 Alzheimer disease with depression (ADD) subjects (mean age 74, M/F 17/10) were enrolled. The MRI was performed by Siemens Magnetom Area 1.5 T MR scanner. The imaging protocol included T1-weighted imaging (T1WI) with 3D MPRAGE sequence, T2WI and fast FLAIR with SPACE technique. The DTI images were obtained by the single-shot EPI sequence with diffusion gradients in 30 directions and voxel size 2x2x2mm. Multispectral MRI segmentation was processed with the SPM8 software package. The region-of-interest (ROI) masks encompass the frontal lobe, temporal lobe, parietal lobe, occipital lobe, limbic lobe and sub-lobar region, derived from the International Consortium of Brain Mapping (ICBM) atlas using the WFU Pickatlas. Global and regional volume fraction of gray matter (GM) and white matter (WM) were calculated by using the volumes of GM and WM divided by the whole brain volume for correction of variant head sizes in different subjects in order to perform ROI analysis of brain morphometry. Diffusion-tensor imaging analysis was performed by using DTI Studio software for image processing and was registered to T1-weighted MPRAGE image. The aforementioned segmented ROI masks of GM and WM maps then were used to define the ROI in DTI. Then, the quantification of the microstructural alternations for each subject was acquired by averaging the FA, MD values within the ROI.

Results

Concerning regional neuroanatomical volume analysis, WM volume fraction in the sublobar region of the AD patients was significantly lower than that of the ADD patients, while there is no significant difference in other regions between these two groups. The DTI indices revealed significantly higher global FA and lower global MD in ADD patients than AD patients. Further analysis of regional WM integrities, ADD patients appeared to have higher FA and lower MD indices than AD patients in frontal lobe, temporal lobe and sublobar region.

Conclusions

The findings of significantly higher FA and lower MD in frontal lobe, temporal lobe and sublobar region demonstrate some different microstructural characteristics of white matter integrities in AD patients without and with depressive symptoms. According to our experimental results, we propose a hypothesis that there might be the linkage between depression and the network connectivity in the limbic-cortical-striatal-pallidal-thalamic circuit and which needs to be further confirmed. The investigation of morphometric analysis and DTI MRI alternation is helpful in revealing the difference of brain abnormalities in AD without and with depression.

Multimodality imaging features of intracranial blastomycosis – a great mimicker.

P Kochar¹, D Baruah², J Ulmer², A Klein², Z Bhatti², J Anderson², M Agarwal², C Lath²
Purpose
The aim of this exhibit is to explore the imaging appearance and pathophysiology of intracranial blastomycosis, enabling neuroradiologists to consider this entity in the differential of intracranial lesions.

Materials and Methods
Intracranial blastomycosis is an uncommon entity, though not infrequently seen in endemic areas. This easily can be confused with neoplastic lesions as well as other intracranial processes. In this review, we discuss imaging features of intracranial blastomycosis with relevant clinical case examples including computed tomography (CT), MR imaging (MRI) and advanced MR imaging techniques like MR spectroscopy (MRS).

Results
Blastomyces dermatitidis is a fungal pathogen that commonly presents as a pulmonary infection due to inhalation of spores. Central nervous system involvement can occur by hematogeneous spread or by direct extension from the paranasal sinuses or orbits. Though classic imaging findings of intracranial blastomycosis are lacking, careful evaluation of the imaging and the clinical background is crucial.

Conclusions
Blastomycosis is an uncommon infection of the central nervous system. In endemic areas, and even in nonendemic areas with the appropriate imaging and clinical presentation, blastomycosis should be considered in the differential diagnosis. This exhibit will help neuroradiologists understand and manage this uncommon but important entity.

Neuroimaging of Tuberous Sclerosis

Y Hirata1, B Elingson1, E Karavaeva1, N Salamon1, J Wu1, A Yogi1, S Yudovin1
1University of California Los Angeles, Los Angeles, CA

Purpose
Tuberous sclerosis complex (TSC) is one of the major causes of pediatric intractable epilepsy. Finding epileptogenic zone is challenging. The purpose of this study is to review imaging characteristics of epileptogenic tubers in young TSC patients.

Materials and Methods
From the UCLA epilepsy program TSC cohort, 19 consecutive patients (mean age, 5.91 year old) with 413 tubers were selected retrospectively. All patients underwent preoperative multimodality evaluation including MRI, FDG-PET, and magnetic source imaging. Epileptogenic tuber was defined with presurgery evaluation and result of postsurgical seizure freedom. Imaging findings include T2 signal intensity of the tuber surrounding cortex, tuber signal intensity type A, B and C were compared between epileptogenic tubers and nonepileptogenic tubers. Tubers Type A are isointense on volumetric T1 images and subtly
hyperintense on T2-weighted and fluid-attenuated inversion recovery (FLAIR). Type B are hypointense on volumetric T1 images and homogeneously hyperintense on T2-weighted and FLAIR. Type C are hypointense on volumetric T1 images, hyperintense on T2-weighted, and heterogeneous on FLAIR characterized by a hypointense central region surrounded by a hyperintense rim.

Results
Forty-five epileptogenic tubers and 368 non-epileptogenic tubers were selected. In whole tubers, 205 tubers are located in frontal lobe, 81 in temporal, 68 in parietal, and 50 in occipital. Within the epileptogenic tubers, 20/45 tubers were in frontal lobe. Type A tuber was 190 within the whole tubers, type B was 20, and type C was 10. There could be a tendency that both shole tubers and also in epileptogenic group, type B was the most likely to be identified in three types. Tubers with calcifications were three in whole group, and two of them are epileptogenic. Tubers with T2 low intensity were detected 36 in whole, 28 in epileptogenic.

Conclusions
Conventional MRI can suggest epileptogenic tuber characteristics in young TSC patients (mean age of 5.9 years old) using lobe location, with presence of low T2 signal type A or B tubers.

Patterns of Dural Venous Sinus Compromise Following Acute Skull Fractures Using Multidetector CT Venography.

M Rischall¹, B Knoll¹, C Palmer¹, A McKinney²
¹University of Minnesota and Hennepin County Medical Centers, Minneapolis, MN, ²University of Minnesota and Hennepin County Medical Centers, Roseville, MN

Purpose
Dural venous sinus thrombosis (DVST) has been associated with increased morbidity and mortality in head trauma patients. Prior CT venography (CTV) studies have demonstrated that skull base fractures from blunt trauma that extend through the dural venous sinuses are at an especially high risk for DVST, reported as high as 41% (1). However, the assessment of DVST using CTV can be confounded due to the presence of concurrent traumatic extra-axial hemorrhage or gas, which can cause compression and narrowing of the adjacent dural veins, possibly leading to overestimation of the incidence of DVST. We set out to differentiate the prevalence of traumatic DVST versus dural venous compression.

Materials and Methods
IRB approval was obtained. We retrospectively reviewed all 64-, 128-, and 256-slice multidetector CTV exams performed at a level 1 trauma center between 12/2006-11/2013 for adult acute blunt trauma patients with skull fractures extending through a dural venous sinus (n=107). Three staff neuroradiologists independently reviewed the 0.6mm source CTV data in a minimum of three planes (axial, sagittal, and coronal) on a 3D workstation. Dural venous sinuses were placed into five categories: normal (category 0), solely venous compression (category 1), solely dural venous intraluminal thrombus (category 2), mixed venous compression and thrombosis (category 3), or indeterminate (category 4). Criteria for intraluminal thrombus
included the "delta" sign of an intraluminal filling defect surrounded by contrast, extension into another sinus caudally (e.g., IJV), or enlargement of the sinus with surrounding collateral veins. Criteria for compression included extension of the hematoma beyond the sinus margin, or gas compression the dural sinus.

Results
The most common fracture site was the transverse/sigmoid sinus (TSS=60%) followed by the superior sagittal sinus (SSS=21%) and multiple sinuses (MS=19%). Reviewer ranges for the status of the sinuses were normal (n=33-35), solely compression (n=41-49), solely thrombus (n=5-10), mixed compression/thrombosis (n=8-12), and indeterminate (n=9-14). Category 1 (sole compression) was present with a slightly greater frequency in the SSS (12/23) as compared to the TSS (25/65) and MS (6/19), but the frequency of categories 2-4 types of sinus compromise were much more common in TSS fractures (22/65 patients with TS fractures) and MS fractures (8/19), as compared to SSS fractures (1/23). Interobserver kappa was strong amongst the three readers (kappa=0.610-0.759 (p<0.0001). There was a significant association between the fracture site and the status of the underlying dural sinus (Fisher exact test, p=0.019).

Conclusions
Compromise of the dural venous sinuses following acute skull fracture is common, whether due to venous compression from extra-axial hemorrhage, thrombosis or a combination of the two. Both in TSS and SSS fractures, isolated venous compression was the most common pattern of sinus compromise identified, and the fracture site was associated with the type of compromise. Interestingly, fractures involving the TSS or MS seem more likely to be affected by thrombosis than the SSS, while the SSS seems more likely to undergo direct compression from hematoma.

Performance Metrics of Automated Hippocampal Volumetry for Discriminating Pathologically-defined Alzheimer’s disease from Controls in the national Alzheimer’s Disease Neuroimaging Initiative (ADNI) study

B Rathakrishnan¹, M Doraiswamy², J Petrella², K Choudhury²
¹Duke University School of Medicine, Durham, NC, ²Duke University Medical Center, Durham, NC

Purpose
New diagnostic criteria for Alzheimer's disease (AD), mild cognitive impairment (MCI) of the Alzheimer type, and Preclinical disease are based on pathologic (e.g., amyloid and tau positivity) and neuronal loss biomarkers (1). It has been known for over two decades that AD and MCI are associated with significant volume reduction in the hippocampus (2), amygdala, parahippocampal gyrus, and entorhinal cortex (3), suggesting a potential diagnostic role for volumetric MRI of the medial temporal lobe (4). However, one limitation has been that most prior volumetric studies have defined AD and MCI clinically without pathological verification. Further, the lack of standardization and methodologic issues [e.g., inter-user variability, lack of quick and simple volumetric techniques, and lack of nomograms (e.g., age adjusted cut points)] have limited clinical application of this technique. NeuroQuant® is a commercially available, completely automated volumetric software package that generates age-related and general morphometry reports immediately available for interpretation after a patient scan. The purpose of this study was to determine the sensitivity and specificity of this tool for separating pathologically verified AD and MCI from normal controls (NC) in a nationally derived cohort.

Materials and Methods
Three hundred thirty-four subjects (NC=97, MCI=160, AD=77) in ADNI with MRI and CSF biomarker data were subdivided further as pathology positive or pathology negative based on CSF tau to amyloid-beta 1-42 peptide levels (5). Baseline MRI scans were processed with NeuroQuant® to generate hippocampal volumetric data which then was normalized to total intracranial volume and used to obtain age-adjusted hippocampal volume percentiles.

Results
The mean hippocampal volume percentile decreased as a function of cognitive status and amyloid and tau pathology (Clinical grouping, mean, standard deviation: NC with negative pathology, 46.7, 3.3; NC with positive pathology, 39.8, 4.4; MCI with negative pathology, 21.1, 3.8; MCI with positive pathology, 18.5, 2.4; AD with negative pathology, 15.8, 8.6; AD with positive pathology, 11.8, 3.1). Post-hoc testing confirmed hippocampal measures for pathology negative NC were significantly larger than those of pathology positive AD (p<0.001) and pathology positive MCI patients (p<0.05), though there was no significant difference between MCI and AD subjects. Hippocampal volumes did not correlate with the CSF tau to amyloid beta ratio (r = -0.230). When specificity was set to 80%, NeuroQuant (hippocampal volume percentile threshold = 14) separated pathology positive AD from pathology negative NC with a sensitivity of 78%; the sensitivity was 64% for pathology positive MCI versus pathology negative NC. These sensitivities were the same (78% and 64%) when separating clinically defined AD and MCI from NC (Figure 1).

Conclusions
To our knowledge, this is the first study to validate the utility of automated hippocampal volumetric measurement, using NeuroQuant®, to discriminate pathology positive AD from
pathology negative NC. Our study also suggests that hippocampal changes in dementia or MCI may be largely independent of amyloid or tau pathology. We currently are examining the relationship between NeuroQuant® measured volumes and longitudinal outcomes in our sample to determine prognostic effectiveness.

**Perioperative myocardial infarction of carotid artery stenting**

Y Kawabata¹, F Horikawa², H Miyake³, T Tsukahara¹, K Yamashita⁴

¹National Hospital Organization Kyoto Medical Center, Kyoto, Japan, ²Hyogo Prefectural Amagasaki Hospital, Amagasaki, Hyogo, Japan, ³Hamamatsu Rosai Hospital, Hamamatsu, Shizuoka, Japan, ⁴Osaka Red Cross Hospital, Osaka, Japan

Purpose

Perioperative myocardial infarction (PMI) has been accepted as one of the most important
complications of carotid artery stenting. Based on our experience, we calculated PMI rate, and analyzed risk factors of PMI.

Materials and Methods
Since 2005, carotid artery stenting with emboli-protection devices was performed in 96 patients for 103 arteries at three institutions. Seventy-seven patients were male, and 19 were female, and the median age is 73 years (50-96 years). There were 46 symptomatic lesions and 57 asymptomatic lesions. Fifteen patients had bilateral lesions or contralateral occlusion.

Results
Perioperative myocardial infarction was observed in one patient preoperatively, in one patient intraoperatively, and in two patients postoperatively: PMI rate was 3.9% in total. Two patients with PMI were presented with chest pain, and two were asymptomatic. Thirteen patients who underwent carotid artery stenting prior to coronary artery bypass graft were not complicated with PMI. Fisher's exact test showed that the presence of contralateral carotid disease was associated significantly with PMI (p=0.013). Mann-Whitney test did not show age as a significant predictor of PMI.

Conclusions
This study showed that myocardial infarctions were not uncommon complications of carotid artery stenting, but they did not affect the prognosis. The presence of contralateral carotid disease is a significant predictor of PMI.

Prevalence of Incidental Findings on Research Brain MRI in Neurodegenerative Disease and their Impact on Clinical Referrals

S Liu, C Hess, C Glastonbury, M Weiner, W Dillon

1University of California San Francisco, San Francisco, CA, 2University of California San Francisco Medical Center, San Francisco, CA

Purpose

With the increasing use of brain MR imaging (MRI) for studies of aging and neurodegenerative disorders, incidental imaging findings are important to the ethical undertaking of research with human subjects. Our goal was to determine the prevalence and potential clinical impact of unexpected brain and head & neck (H&N) findings in a large series of patients and healthy volunteers recruited into clinical trials for neurodegenerative diseases.

Materials and Methods

From July 2006 to November 2013 over 4500 brain MRIs performed on subjects enrolled in multiple neurodegenerative research studies at our institution were reviewed by three CAQ-certified neuroradiologists. Of these, 3574 reports were archived in our electronic database and retrospectively analyzed for this study. Incidental findings were categorized by location (brain, head & neck, or spine) and divided into three groups based on recommendations for referral (no referral necessary, routine referral, urgent/immediate referral). For each group, the range of neoplastic and non-neoplastic lesions and vascular abnormalities was assessed together with age-specific prevalence by decade. Small vessel disease, small lacunes or microhemorrhage, and disk-osteophyte degenerative changes of the cervical spine in elder subjects, as well as mild mucosal inflammation or retention cysts in the H&N, were not accounted as incidental findings in this study.

Results

Mean age was 66.2 years (SD 13.1, range 18-99). Overall, 1131 scans (31.6%) demonstrated incidental findings, of which approximately half (15.0%, 537 of 3574 subjects) required no further evaluation. The 16.6% (594) required referral for further evaluation (11.4% for brain, 4.2% for head & neck and 1.0% spine, respectively). Routine referrals were recommended in 15.2%, and urgent/immediate referrals were recommended in 1.4%. There was no difference in the proportion of incidental findings identified in subjects by age (Kruskal-Wallis test, p=0.554,
mean 17.2% ± 1.6% for ages <90). The prevalence was 35.7% in those over 90 years, most likely reflecting the small sample size in this age group (only 14 participants). Incidental tumors were found in 2.2% (77 subjects), including meningiomas in 0.9% (33), pituitary lesions in 0.7% (25); and head & neck masses in 1.3% (48). Non-neoplastic abnormalities found included Rathke's cleft cyst in 2.0% (72) and arachnoid cysts in 1.5% (55). The overall prevalence of vascular abnormalities was 3.6%, including developmental venous anomalies in 1.8% (65 subjects), intracranial aneurysms in 0.7% (26), and cavernous malformation in 1.0% (36). Urgent referral was recommended for all participants who had finding of intracranial aneurysms.

Conclusions
Review of research brain MRI scans by subspecialty certified neuroradiologists frequently detects abnormalities. In this large series of subjects enrolled in neurodegenerative studies, potentially clinical relevant incidental findings was found in 16.6% in 3574 participants, including unexpected tumors in 3.5% and aneurysms in 0.7%.

Quantification of T1Rho and T2 in Cortical and White Matter Plaques in Multiple Sclerosis: A Cross-sectional Study.

J Gonyea¹, R Watts¹, A Applebee², T Andrews¹, S Hipko², J Nickerson², L Thornton³, C Filippi⁴
¹University of Vermont, Burlington, VT, ²University of Vermont College of Medicine, Burlington, VT, ³Rutgers University-New Jersey Medical School, Newark, NJ, ⁴Columbia University Medical Center, New York, NY

Purpose
To determine quantitative T1rho (T1ρ) and T2 values of cortical lesions and white matter plaques in patients with multiple sclerosis (MS) using a novel, volumetric T1ρ sequence (1).

Materials and Methods
This prospective, IRB-approved study of 27 MS patients (8 male) ages 28 to 60 years investigated T1ρ and T2 mapping of MS lesions at 3.0 T. Whole brain axial T1ρ and T2-weighted MR images were acquired using a 3D turbo spin echo (TSE) sequence with fluid suppression (1.8 x 1.8 x 1.8 mm³), TR/TE = 4800/24ms, TI 1650, FOV-250mm and spin lock frequency 500 and 0 Hz, respectively, with spin-lock times of 0, 20, 40, 60, 80, and 100ms. For lesion detection and segmentation 3D T1 turbo field echo, 3D FLAIR, and 3D double inversion recovery were acquired. Whole brain T1ρ and T2 maps were co-registered to the T1. Regions-of-interest measurements were drawn over GM and WM lesions by a CAQ-certified neuroradiologist. T1ρ and T2 values were calculated for cortical and white matter plaques, as well as segmented normal-appearing GM and WM. Spearman correlations with Extended Disability Status Scale (EDSS) were calculated for each measure.

Results
Lesion T1ρ and T2 values are both approximately 20% higher than the surrounding tissue. The T2 values of NAWM in MS are consistent with previous studies (2, 3). Of all the measures listed in Table 1, only the standard deviation of the T1ρ and T2 values of all white matter correlated significantly with EDSS (Spearman r=0.38/0.39, p=0.04/0.04, respectively). The standard deviation represents the heterogeneity of the white matter, including both visible and qualitatively occult lesions, and is weighted by both the total volume of the lesions and their conspicuity.

Conclusions
T1ρ MR imaging may be a useful tool for measuring both global and focal changes in cortex and subcortical white matter lesions. The standard deviation of T1ρ in WM is a simple, but useful measure of MS disease burden that does not require explicit lesion segmentation, and so could be automated relatively easily. Further investigation is needed to determine whether such quantitative neuroimaging techniques may be used as a biomarker for treatment management or prognostication.

Relationship between the intraplaque calcification on MRI and increase of HDL-C under aggressive LDL-C lowering statin therapy
Purpose
MR imaging (MRI) can noninvasively assess plaque volume, and composition of carotid atherosclerotic lesions. A prospective, open-label blinded end-points trial (CHALLENGER) assessed the effects of rosuvastatin on carotid plaque composition. Because an intraplaque calcification (CA) is considered as stabilized status of the plaque, we aimed to assess the relationships between the intraplaque calcification and clinically available biological serum markers.

Materials and Methods
Prospective, open-label blinded end-points trial was performed using 1.5 T MRI to image carotid plaques with multicontrast images; T1/T2/PD-WI, T1-WI-Gd and TOF-MRA. Patients with maximum carotid intima-media thickness (IMT) > 1.8 mm as measured by ultrasound (US) and a plasma LDL-C of more than 120 mg/dl without statin treatment were recruited from 2007 to 2010. All patients were administered rosuvastatin 5mg/day after baseline MRI. Scan was performed at baseline, after 12 and 24 months of treatment. Each pair of baseline and follow-up MRI assessments was analyzed in a blinded fashion. Then, compared with the laboratory data sets at each visit.

Results
After 24 months, 38 patients had taken MRI scans to compare by reviewers blinded to clinical data, and temporal sequence of scans. LDL-C was significantly reduced from baseline (46.6%, p<.001). HDL-C was significantly increased from baseline (20.2%, p<.001), and there was a significant correlation shift towards increased ratio of CA (r=0.69, p=0.012) and increased volume of CA (r=0.60, p=0.038). No correlation shifts were observed toward eGFR.

Conclusions
Rosvastatin treatment showed marked LDL-C lowering and HDL-C increase. In a present study, it is indicated that an increase in HDL-C can be an indicator for a stabilization of carotid plaque.

The Majority of Metallic Intracranial Implants and Extracranial Hardware are Compatible with Serial Monitoring of Cerebrovascular Reactivity with Hypercarbic MRI

A Desai1, C Faraco2, L Dethrage3, P Clemmons3, D Brown3, L Jordan3, M Donahue2, M Strother3
1Vanderbilt University Medical Center, Nashville, TN, 2Vanderbilt University, Nashville, TN, 3Vanderbilt University School of Medicine, Nashville, TN

Purpose
Cerebral hemodynamic evaluation can be achieved by serial monitoring of cerebrovascular
reactivity (CVR) without exogenous contrast agents by exploiting T2* lengthening secondary to hypercarbia-induced changes in blood oxygenation (i.e., the blood oxygen level-dependent, BOLD, effect) (1, 2). However, for such measurements to be reliable in routine clinical practice, susceptibility-induced influences of endovascular and surgical interventions on the long-TE MRI contrast must be characterized, as BOLD MRI is particularly sensitive to susceptibility variations between different structures (3). The purpose of this study is to calculate the volume and artifact extent arising from different intracranial and extracranial hardware; results highlight that noninvasive CVR monitoring is feasible in the majority of patients with such hardware, and also report which hardware precludes accurate CVR measurements and should be avoided when possible.

**Materials and Methods**

BOLD (3.0T; in-plane spatial resolution=3 x 3 mm2; echo time=35 ms; single-shot gradient echo EPI) MRI was performed in patients (n=32) with metallic implants (n=8) and surgical procedures that required placement of extracranial hardware (n=24). Make, model, and composition of hardware, along with the total artifact volume, were recorded.

**Results**

Intracranial implants included stents or clips composed of titanium or titanium and nickel alloy, as well as platinum embolization coils. The average artifact volume associated with intracranial hardware was 3.7 cm3 +/- 3.4 cm3 (mean +/- standard deviation), with a range of 1.1-9.4 cm3. Extracranial hardware primarily included closure devices composed of titanium alloy, as well as a ventriculoperitoneal shunt with an extracranial programmable valve composed of a combination of 316L stainless steel, unalloyed titanium, tantalum, and neodymium magnets (4). The average artifact volume associated with extracranial hardware was 33.0 cm3 +/- 25.6 cm3 (range 6.1-139.6 cm3). As a point of reference, the average volume of the human brain is approximately 1380 cm3 (5). Cerebrovascular reactivity data were obtainable in all patients, with the exception of the single patient with the extracranial programmable valve and siphon gauge. In patients with intracranial stenosis, results varied asymmetrically with vascular disease burden as quantified by angiography.

**Conclusions**

Reliable CVR maps, including those consistent with lateralizing vascular disease in patients with intracranial stenosis, can be obtained from BOLD MRI performed on patients with a variety of implanted intracranial devices and extracranial hardware, the notable exception being ventriculoperitoneal shunts with a programmable valve and siphon gauge.

The MR Imaging Findings of Pituitary Abscess

K Ahn¹, H Choi², J Jang², S Jung², B Kim², B Kim²
¹Seoul St. Mary's Hospital The Catholic University of Korea, Seoul, Korea, ²The Catholic University of Korea, Seoul, Korea
Pituitary abscess is a rare disorder characterized with central nervous system infection, mass effect and endocrine dysfunction. The correct diagnosis of pituitary abscess is difficult because there are nonspecific symptoms and it often is radiologically indistinguishable from other pituitary lesions. To better understand the imaging findings of pituitary abscess, we conducted a review of patients treated for pituitary abscess in our hospital.

Materials and Methods
A total of six consecutive patients with pituitary abscess were included. All patients underwent surgery and antibiotic therapy and were surgico-pathologically proved to be an abscess. A complete history, a thorough record of signs and symptoms, pituitary imaging and biochemical panels were obtained for each patient.

Results
Most of the patients presented with complaints and symptoms consistent with a sellar mass. Diabetes insipidus, hypopituitarism and headache were the most common clinical manifestations and in three patients, fever was accompanied with headache. A sellar cystic mass with enhancing rim is the most common findings on sellar MRI in patients with pituitary abscess. These findings were indistinguishable from those of the cystic adenoma. However, in four patients irregular thickenings were noted along the cystic wall or pituitary stalk, and these findings were very valuable in differentiation of pituitary abscess from pituitary adenomas.

Conclusions
Presentation of a sellar cystic mass with an enhanced rim and specific clinical manifestations such as diabetes insipidus or hypopituitarism may be suggestive of a pituitary abscess. In addition, irregular thickenings along the cystic wall or pituitary stalk should be very valuable imaging findings in differentiation of pituitary abscess from pituitary adenomas.

The value of advanced MR imaging techniques in the evaluation of nonenhancing gliomas: Perfusion-weighted imaging compared with proton magnetic resonance spectroscopy and tumor grade

N Sahin1, E Melhem2, S Wang3, J Krejza4, H Poptani3, S Chawla3, G Verma3
1Sifa University School of Medicine, Izmir, Turkey, 2University of Maryland Medical Center, Baltimore, MD, 3University of Pennsylvania, Philadelphia, PA, 4University of Maryland School of Medicine, Baltimore, MD

Purpose
A significant number of nonenhancing gliomas are reported to be malignant. The purpose of this study was to compare the value of advanced MR imaging techniques, including T2*-dynamic susceptibility contrast PWI (DSC-PWI) and proton magnetic resonance spectroscopy (1HMRS), in the evaluation of nonenhancing (NE) gliomas.

Materials and Methods
Twenty patients with NE gliomas underwent MRI including DSC-PWI and 1HMRS. The relative CBV (rCBV) measurements were obtained from regions of maximum perfusion. The
peak ratios of choline/creatine (Cho/Cr) and myoinositol/creatine (mIns/Cr) were measured at a TE of 30 ms. Demographic features, tumor volumes, and PWI- and 1HMRS-derived measures were compared between low-grade gliomas (LGGs) and high-grade gliomas (HGGs). In addition, the association of initial rCBV ratio with tumor progression was evaluated in LGGs.

Results
No significant difference was noted in age, sex, or tumor size between low-grade and high-grade tumors. Cho/Cr ratios were significantly higher in HGGs (1.7±0.63) than in LGGs (1.2±0.38). The receiver operating characteristic analysis demonstrated that a Cho/Cr ratio with a cutoff value of 1.3 could differentiate between LGG and HGG with a specificity of 100% and a sensitivity of 71.4%. There was no significant difference in the rCBV ratio and the mIns/Cr ratio between LGG and HGG. However, higher rCBV ratios were observed with more rapid progressions in LGGs.

Conclusions
Cho/Cr ratios are useful in distinguishing NE LGG from HGG and can be helpful in preoperative grading and biopsy guidance. On the other hand, rCBV ratios do not help in the distinction.

Using CSF as an internal quality control marker in quantitative diffusion MR imaging

R Bosca¹, ( Debnam¹, H Liu², N Guha-Thakurta¹, J Wang¹
¹The University of Texas MD Anderson Cancer Center, Houston, TX, ²University of Texas Houston, Houston, TX

Purpose
Diffusion tensor imaging (DTI) indices such as apparent diffusion coefficient (ADC) and fractional anisotropy (FA) frequently are being used for longitudinal monitoring of a patient’s brain tumor status and assessing treatment response. This requires repeatable, consistent and accurate DTI measurements. The needs of ensuring consistency and accuracy in functional MRI imaging have been well recognized and there are nationwide efforts to address those needs, i.e., Quantitative Imaging Biomarkers Alliance (QIBA) which mostly focuses on phantom work. In this study, we assess the possibility of using CSF as an individualized internal quality control (QC) calibrator for quantitative DTI.
Materials and Methods
Diffusion tensor images of 20 patients with GBM (Group I), (a total of 180 studies; average of nine scans per patient), 47 patients with leptomeningeal disease (Group II), and 40 patients with prior breast cancer but no current active disease (Group III), were analyzed retrospectively. The variations and reproducibility of ADC and FA measurements of the CSF in the lateral ventricles of patients in the three groups were measured. The changes of ADC over time for the patients undergoing treatments also were measured. Regions of interest (ROIs) were placed in the left and right lateral ventricles. Mean ADC and FA values, standard deviations, and coefficients of variation (CVs) were calculated from pixels within the ROIs in two ways. First, individual calculations were made on all exams for each patient; all measurements in the left and right ventricles were included in these calculations for a given patient. Second, mean ADC and FA values, standard deviations, and CVs were calculated for all ROIs and over all imaging exams at 1.5 T and 3.0 T, separately. An unpaired t-test was used to elucidate any differences in mean values of ADC and FA measured before and following treatment with bevacizumab and at different field strengths with statistical significance being defined for P<0.05.

Results
For the GBM (group I), CVs for ADC and FA values calculated across all exams for each individual patient ranged from 2.0% to 9.1% and 8.7% to 20.3%, respectively. Inter-patient CVs for ADC and FA measurements calculated over all imaging exams were 4.2% and 14.2%, respectively, for all patient (Groups I-III) scans at 1.5 T. For studies at 3.0 T, the CVs for these measurements were 6.2% and 19.7%, respectively. The CV of the ADC measurement over all imaging exams was 5.0%, while that of the FA measurement was 16.5%. No obvious changes were seen subsequent to the administration of bevacizumab in Group I, indicating stability in the ADC value of CSF despite possible biological changes induced by treatment. For the entire group of patients (Groups I-III), the mean ADC values of the right and left atria of the lateral ventricles were (3.150 ± 0.20)E-9 mm2/s. Unpaired t-test performed on imaging exams at 1.5 T and 3.0 T showed no statistically significant difference between main field strengths for either ADC or FA.
Conclusions
Our study suggests that both intra- and inter-patient ADC measurements of CSF in the lateral ventricles are reproducible at 1.5 and 3.0 T, even following treatment with the anti-angiogenesis agent bevacizumab. An internal QC marker based on ADC measurements of CSF in the lateral ventricles with this level of reproducibility could provide the framework for establishing comparability of long-term longitudinal or multi-institutional data. However, measured FA values for CSF in the ventricles exhibited notably larger CVs for both intra- and inter-patient measurements, suggesting CSF may be a poor candidate for an internal QC marker for FA.

Ventricular apparent diffusion coefficient values in patients with glioblastoma

J Debnam\textsuperscript{1}, N Guha-Thakurta\textsuperscript{1}, N Buisson\textsuperscript{2}, B Strickland\textsuperscript{3}, J Weinberg\textsuperscript{1}, R Mayer\textsuperscript{3}, J Wang\textsuperscript{1}

\textsuperscript{1}The University of Texas MD Anderson Cancer Center, Houston, TX, \textsuperscript{2}Tulane University, New Orleans, LA, \textsuperscript{3}Baylor College of Medicine, Houston, TX

Purpose
On MR imaging (MRI), the apparent diffusion coefficient (ADC) is a measure of the magnitude of fluid diffusion within a voxel. Restricted molecular movement in a sampled tissue is characterized by a lower ADC value, while free diffusion is characterized by a higher value. The purpose of this study was to evaluate the ADC values in the lateral ventricles in patients with glioblastoma (GBM) and compare to controls.

Materials and Methods
The ADC values were measured in 12 patients with GBM and 20 patients as a control group who had a history of cancer, but no clinical or radiological evidence of active disease. Measurements were taken in the anterior body and atrium of the lateral ventricles, and the 4th ventricle. Apparent diffusion coefficient values were excluded from analysis if there was marked compression upon the ventricle.

Results
The mean ventricular ADC value in the patients with GBM were 3.36E-09 and 3.34E-09 (right and left anterior body), 3.2 E-09 and 3.07E-09 (right and left atrium), and 3.19E-09 (4th ventricle). In the control group, the values were 2.93-09 and 2.97E-09 (right and left lateral ventricle), 2.65E-09 and 2.7E-09 (right and left atrium), and 3.09E-09 (4th ventricle). Simple T-test comparisons showed that the difference in ADC values was statistically significant in the lateral ventricles \([p=.0082 \text{ and } p=.0095 (\text{right and left anterior body}); p=.0015 \text{ and } p=.0326 (\text{right and left atrium})]\), but not in the 4th ventricle \((p=.4861)\).
Conclusions
The ADC values in patients with GBM are significantly greater than control patients in both the anterior body and atria of the lateral ventricles, but not the 4th ventricle. Future applications may include ADC measurement in the lateral ventricles to assess tumor aggressiveness and treatment response.

Voxelwise Correspondence of Resting-State and Task-Based FMRI Brain Maps

E DeYoe¹, D Ritchie², J Mathis², J Ulmer¹
¹Medical College of Wisconsin, Wauwatosa, WI, ²Medical College of Wisconsin, Milwaukee, WI

Purpose
Resting-state functional MR imaging (fMRI) can provide brain maps of cortical vision, motor, language, and attention networks without the use of an overt behavioral task, thereby making this technique potentially valuable for planning and guidance of brain surgery in behaviorally/cognitively impaired patients and young children (1). Presurgical resting-state mapping could be appropriate for patients with brain tumors, arteriovenous malformations, epilepsy and other pathologies. However, it is not clear that resting-state fMRI signals necessarily reflect the same functional limits and specificity as task fMRI, especially at the level of individual voxels. To test the correspondence of task fMRI and resting-state fMRI, we obtained both types of data in the same imaging session from volunteers and compared the patterns of activation on a voxel-by-voxel basis.

Materials and Methods
One healthy subject and three brain tumor patients underwent conventional task fMRI vision mapping using an expanding checkered annulus extending to 20 degrees eccentricity plus a 5-10 minute resting-state fMRI scan with eyes closed. Task fMRI data were subjected to a temporal correlation analysis using a model of the task timing convolved with a standardized hemodynamic response function (2). Resting-state data were processed using FSL Melodic Independent Component Analysis (ICA) (3). A region of interest (ROI) including the occipital lobe plus adjacent portions of the parietal and temporal lobes was manually outlined on each subject’s anatomical data. Within this ROI, the task fMRI and resting-state fMRI signals were compared for each of 441 combinations of statistical threshold settings for each signal type. For each voxel, the presence (+) or absence (-) of resting-state fMRI and task fMRI signals were scored as one of four logical combinations (+/+,+/-,/-+,/-) and the number and probability of occurrence of each combination was recorded for all voxels in the analysis ROI. Volumetric brain maps of the voxel classifications were constructed and pseudocolored to show regions of high predictive validity (+/+ and -/-) versus zones in which the two activity patterns were mismatched (+/- and -/+).

Results
Optimal threshold combinations, yielded brain maps in which the resting-state fMRI and task fMRI patterns matched to a high degree (approximate probabilities of occurrence: 0.75, 0.75, 0.25, 0.25 for +/+,+/-,-/+,-/ respectively), though some regions of mismatch were evident.
