PROCEEDINGS

ASNR 2013

NEURORADIOLOGY FOR THE 21ST CENTURY

ASNR 51ST ANNUAL MEETING

SAN DIEGO CONVENTION CENTER | SAN DIEGO, CA | MAY 20 - 23, 2013

ASNR 2013

NEURORADIOLOGY FOR THE 21ST CENTURY

Dear ASNR Members, Visitors, and Neuroscience Colleagues:

It is my pleasure to invite you to the ASNR 51ST Annual Meeting in San Diego, California May 18-23, 2013. President-Elect and Program Committee Chair, Mauricio Castillo, MD, FACR, has planned an exciting symposium and intellectually stimulating Annual Meeting scientific program. The 2013 venue, the San Diego Convention Center is truly remarkable. Located on the San Diego Bay right in the heart of the magnificent downtown San Diego, the Convention Center is only steps away from our headquarters hotel, San Diego Marriott Marquis & Marina.

The Foundation of the ASNR Symposium 2013: New Concepts and Trends in Neuroimaging, will explore new and exciting concepts that include genetics of brain tumors, advances in epilepsy imaging, functional connectivity, neurocognitive disorders in children and adults and financial issues in clinical practice.

The 51ST Annual Meeting will provide informative updates on general neuroradiology and showcase specialty programming from the ASFNR, ASHNR, ASPNR, ASSR, and SNIS. As always, the heart of the meeting will be the invited lectures, original presentations, scientific posters, and educational exhibits.

There will be approximately 34.5 hours of continuing medical education credit available for the ASNR 51ST Annual Meeting (See pages XIV for details). We continue offering Maintenance of Certification (MOC) and Self Assessment Modules (SAM) with interactive audience response technology. We will again feature valuable non-CME "How To Sessions" sponsored by our commercial partners, updating you on the capabilities and use of their hardware and software.

This year, I am also thrilled to introduce a new series of lectures, CSI: San Diego (Computer Sciences and Informatics) formally known as Synaptic Junction Programming.

Among its most valuable functions, the Annual Meeting will be the ideal opportunity to stay connected with friends and colleagues and learn the latest in brain, spine, and head and neck imaging.

I look forward to a great meeting and seeing you in San Diego!

GENERAL INFORMATION

Meeting Location

San Diego Convention Center
111 West Harbor Drive
San Diego, CA 92101
619-525-5000

Meeting Registration

Registration is located in the Sails Pavilion of the San Diego Convention Center. The registration desk will be open during the following hours:

Friday, May 17 ..... 5:00 pm - 8:00 pm

Saturday, May 18 through Thursday, May 23 ..... 6:30 am - 6:00 pm

Speaker Ready Room Location & Hours

Room 3 (Upper Level)

Friday, May 17 ..... 5:00 pm - 8:00 pm

Saturday, May 18 through Thursday, May 23 ..... 6:00 am - 6:00 pm

Name Badges

Please wear name badges at all times while you are attending the scientific sessions, social programs, and technical exhibits. Badge colors are identified as follows:

ASNR Members, ASNR Members-In-Training & ASNR Specialty Societies (ASFNR, ASHNR, ASPNR, ASSR & SNIS) ..... Blue
Non-Member ..... Green
Other Professional ..... Yellow
Guest ..... Peach
Exhibitor ..... Gold
Staff ..... Purple

Emergency Service Procedure

STEP 1

SAN DIEGO CONVENTION CENTER

In the event of a medical emergency, please contract Security Control immediately. ASNR attendees may contact Security Control by dialing

- Extension **5911** for life threatening emergency on facility house phones (white in color)
- Extension **5490** for non-life threatening emergency on facility house phones (white in color)
- From a cell phone (or outside the center) dial: **619-525-5911** for life threatening emergency, **619-525-5490** for non-life threatening emergency

*All house phones in San Diego Convention Center are white in color and are located in public corridors and lobbies throughout the center, Security Control will be dispatched directly to your location.

SAN DIEGO MARRIOTT MARQUIS & MARINA HOTEL

In the event of a medical emergency, please contract Security Control immediately. ASNR attendees to contact Security Control by dialing

- Extension **53** for life threatening emergency on facility house phones (beige in color)
- Extension **6100** for non-life threatening emergency on facility house phones (beige in color)
- From a cell phone (or outside the hotel) dial **619-234-1500** and ask for ext **53**

*All house phones in San Diego Marriott Marquis & Marina are beige in color and located throughout all public areas and hallways, Security Control will be dispatched directly to your location.

STEP 2

The caller should provide the following:

1. Determine name of specific meeting room or exhibit hall where the situation has occurred.
2. Identify yourself as an ASNR attendee, reference your exact location, and provide details on the nature of the emergency situation.
3. Provide a brief but concise description of the problem, be prepared to answer any questions that the operator may ask you, and remain on the line.

ASNR Publications Booth: *Lobby 6*

Saturday, May 18 and Sunday, May 19: **7:30 am - 5:00 pm**

Monday, May 20 through Thursday, May 23: **8:30 am - 5:00 pm**

All attendees are invited to stop by the booth any time to tour the AJNR and Neurographics Web sites and AJNR Blog and app.

ASNR Publications

Dr. Mauricio Castillo, *AJNR*'s Editor-in-Chief, will be present at the Journal's booth Monday - Thursday from 11:00 am until noon to answer questions regarding the Journal's online features, listen to suggestions, talk about projects with prospective authors, and advise fellows regarding their future contributions to *AJNR*.

Neurographics

Neurographics is ASNR's quarterly online educational journal, featuring peer-reviewed scientific exhibits and select case reports. *Neurographics* is available free online www.neurographics.org. *Neurographics* Editor Dr. Barton Branstetter IV will be available in the ASNR Publications booth Monday through Wednesday from 11:00 am to noon to answer questions.

EXHIBITS

Scientific Posters, Electronic Posters, Electronic Excerptas, Education Exhibits, and Electronic Education Exhibits

Hall B1 (Ground Level)

Technical Exhibits

Sails Pavilion (Upper Level)

How-To Sessions

Ballroom 6AB (Upper Level)

Young Professionals Lounge

Room 16AB (Mezzanine Level)

VIP/The Foundation of the ASNR Donor Lounge

Room 14B (Mezzanine Level)

IMPORTANT INFORMATION FOR YOUNG PROFESSIONALS

(Fellows, Residents, Medical Students and Neuroradiologists in their first three years in practice)

Young Professionals Lounge

Saturday, May 18 - Thursday, May 23, 2013 6:30 am - 6:00 pm

Room 16AB (Mezzanine Level)

Visit the Young Professional Lounge in Room 16AB (Mezzanine Level) open from 6:30 am – 6:00 pm daily from Saturday, May 18 - Thursday, May 23. This will provide a "home base" for Young Professionals to network and share knowledge and experiences throughout the meeting.

Young Professionals Luncheon

Tuesday, May 21 • 12:15 pm - 1:15 pm

Room 16AB (Mezzanine Level)

Join ASNR Leaders for Lunch, at 12:15 pm on Tuesday, May 22, 2013 in Room 16AB (Mezzanine Level).

Young Professionals Sessions

Fellows, Residents, Medical Students and Neuroradiologists in their first three years in practice, the ASNR has designed specific program topics for learning during the ASNR Annual Meeting. You won't want to miss the following session presentations:

Tuesday, May 21

Room 1AB

8:45 am – 10:15 am
Choosing Your Career

SPECIAL PROGRAMMING

2013 Education Exhibits Tour

San Diego Convention Center
Hall B1 (Ground Level)

Monday, May 20 .....12:15 pm – 1:15 pm

Wednesday, May 22 .....12:15 pm – 1:15 pm

You will receive CME credits for participating in the Education Exhibits Tour!

Review Education Exhibits, visual presentation/educational displays designed to further the understanding of Neuroradiology by featuring cutting-edge material or by offering an instructional review of a particular topic. The session will allow for review of visually-oriented educational displays that demonstrate novel and innovative applications for computers in Neuroradiology clinical practice, training and research. Share this educational opportunity with your colleagues and primary Exhibit presenters and exchange in a lively Questions & Answers Session.

Another unique feature not to be missed at the ASNR. See you on the tour!

Case of the Day

San Diego Convention Center
Hall B1 (Ground Level)

Monday, May 20 through Wednesday, May 22

A continuing addition to the ASNR program for the ASNR 51st Annual Meeting is the Case of the Day (COD) program. Led by Drs. Mark Mullins and Achala S. Vagal, COD is scheduled from Monday, May 20 through Wednesday, May 22.

Cases will be presented in Hall B1 at the San Diego Convention Center and will be available in printed poster format as well as on a video loop at a nearby monitor. There will be 6 categories: brain, functional, head & neck, pediatric, spine and vascular/interventional, each with 1 case per day. Answers will be presented on the day following their respective questions.

An online system will be available for submission of preferred diagnoses (links are available through the ASNR Annual Meeting Mobile Application). Be sure to participate in this new interactive programming feature with a limited number of prizes awarded to those participants with highest daily correct responses.

No CME credit is available for this activity.

Annual Meeting Closing Reception

USS Midway Museum in Downtown San Diego

Wednesday, May 22, 2013 ..... 7:00 pm-10:00 pm

Harbored in the serene waters of San Diego Bay is the impressive USS Midway Museum which is the venue for the night's grand event. This is within walking distance from the San Diego Convention Center and the San Diego Marriott Marquis & Marina, the ASNR headquarters hotel.

Largely unaltered from the USS Midway's original operating state, guests can expect a truly genuine experience from the time they enter the ominous hangar bay. Many different exhibits throughout the carrier document her long and proud military service. You will also enjoy everything from docent led mini tours, to flight simulator rides, to a pre-dinner buffet reception on the flight deck. A variety of food and beverage stations will be available to tantalize your taste buds. We look forward to you joining us and experiencing the USS Midway's military tradition while networking and mingling with ASNR meeting attendees and exhibitor representatives throughout the evening's event.

Complimentary round-trip transportation to and from the USS Midway Museum will be provided. Badge required for entry.

CSF Flow Group

San Diego Convention Center
Room 10 (Upper Level)

Thursday, May 23 and Friday, May 24, 2013

The IHIWG (International Hydrocephalus Imaging Working Group) consists of neuroradiologists, neurologists, neurosurgeons, bioengineers, and basic scientists who meet twice a year in conjunction with ASNR and ISHCSF (International Society for Hydrocephalus and CSF Disorders). During our meeting we address all forms of hydrocephalus including DESH (Disproportionately Enlarged Subarachnoid Space Hydrocephalus) with emphasis on imaging NPH. We discuss phase contrast techniques to measure blood and CSF flow out of the brain and to dynamically model it and predict intracranial pressure. We review CSF production and resorption, role of aquaporins, and CSF flow measurements to study Chiari I malformations as well as potential sources of error in our measurements.

We discuss infantile hydrocephalus and benign external hydrocephalus and the role of the latter as a potential cause of NPH later in life. We examine changes in DTI and MR elastography in NPH and discuss related topics such as aqueductal stenosis and pseudotumor cerebri. We debate the value of imaging vs. detailed clinical assessment vs. a high volume tap test vs. saline infusion tests to select NPH patients for shunting.

No CME credit is available for this activity.

AWARDS AND HONORS

ASNR Gold Medal Award

The Gold Medal is intended to foster the highest standards of the American Society of Neuroradiology, recognizing exceptional service and achievement. The Medal is awarded on the basis of both professional and personal excellence, honoring individuals who are superb neuroradiologists, scientists, and/or physicians, and who also are truly outstanding people. Recipients will have consistently extended themselves beyond self-interest to make contributions that have benefited our entire field. The receipts are individuals who are clinicians, researchers, teachers, or neuroradiological statesmen and stateswomen may be considered for the Gold Medal. Candidates are not required to be members of the American Society of Neuroradiology. Nominees should have made extra-ordinary contributions to enhance the development and/or stature of neuroradiology, including service to the Society.

The recipient of the 2013 award is:

Eric J. Russell, MD, FACR

Northwestern University, Chicago, IL

Eric Jay Russell, MD, FSIR, FACR is a Professor of Radiology, Neurosurgery and Otolaryngology at the Feinberg School of Medicine of Northwestern University.

After graduation from Brooklyn College (City University of New York), he attended medical school in Buffalo, where he received the MD degree in 1974 (elected to Alpha Omega Alpha in his junior year). He then returned to New York City and to the Montefiore Hospital and Medical Center and served as an intern in Internal Medicine before completing his residency in Radiology under Harold Jacobson, his role model, Robert D. Zimmerman, who remains a close friend, and Norman Leeds and Thomas Naidich. As a fellow in Neuroradiology at NYU under the direction and guidance of Irvin I. Kricheff, with mentors including Norman Chase, Thomas Bergeron, Richard Pinto and Ajax George, he chose to work closely with Alex Berenstein, who had just arrived at NYU the year before. Interventional Neuroradiology was truly in its infancy in the US, and Alex's commitment and dedication to his patients strongly influenced Dr. Russell to continue this work.

Dr. Russell, as a junior attending in Chicago, benefitted greatly from the mentorship and support of Dr. Michael Huckman, who hired him for his first faculty position, at Rush-Presbyterian-St. Luke's Hospital. With his guidance, Dr. Russell was able to develop an Interventional Neuroradiology service along with his diagnostic responsibilities, as he began his academic career.

Six years later, Dr. Russell was recruited by Lee F. Rogers to become the Director of Neuroradiology at Northwestern across town. For 25 years, Dr. Russell was the director of the Division and also the Neuroradiology fellowship program, helping to recruit and train more than 60 fellows. In the 1990's, Dr. Russell twice served as interim Chair of the Department, before being named the Frederick John Bradd and William Kennedy Professor of Radiology and Chairman of the Department of Radiology at Northwestern University in 2002. During his time as Chair, the department doubled its faculty and its research portfolio. He has advocated for a strong clinical practice in Interventional Radiology, supporting the growth of an internationally recognized IR division and developing an outreach program to provide IR and neurointerventional services at local community hospitals. During a recent medical school leadership transition, he served as Interim President and CEO of the Northwestern Medical Faculty Foundation (NMFF), an academic practice plan with more than 700 full-time physicians, completing this term in 2011 and returning to Chair the Radiology Department a year ago. Dr. Russell has served Neuroradiology at many levels. A long-time board examiner for the ABR, he served on the examiner panel for the first CAQ examination in 1995, and currently serves on the CAQ/MOC examination preparation committee. He served as Scientific Program Chair for Neuroradiology at the annual meeting of the RSNA for several years, and currently serves as the RSNA representative to the Joint Commission Ambulatory Care Committee. He is an ACR fellow, served as editor-in-chief of the Neuroradiology II ACR Syllabus, was a member of the Illinois delegation to the ACR council, and is a long-term member the ACR Standards and Guidelines Committee, serving as lead author for the ACR Guideline for Cervicocerebral Angiography, recently revised.

His service to the ASNR is extensive; serving on numerous committees, and holding several offices including president-elect and program chairman for the 1999 ASNR meeting in San Diego. Importantly, the Ad Hoc Committee for the 1999 Annual Meeting which he chaired, recommended structural changes that were incorporated that year to strengthen the unity of the subspecialty societies by providing for formal input and direction from the sub-specialty societies into the meeting program, a structure that still is in place today.

Dr. Russell was installed as the 37th President of the ASNR on May 25, 1999 at the society's annual meeting in San Diego, and served his term as the 21st century began. Among other accomplishments, he worked with others to establish an ACGME approved neurointerventional training program acceptable to both Radiology and Neurosurgery, and he further supported the efforts of Arliss Pollock, Chair of the ASNR Clinical Practice Committee, to more fully involve the ASNR in socioeconomic activities. Seeing the need for close communication with interventional radiologists, he sat as a member of the SCVIR (now SIR) Executive Council for three years to facilitate communication, guideline development and joint planning. He was elected to fellowship in the SCVIR in 2000. Dr. Russell has served on the editorial boards of Radiology and the AJNR, currently serving a second term on the Radiology board. Dr. Russell also served a three year term as Chairman of the Board on the Neuroradiology Research and Education Foundation (NERF), and helped to shepherd it through the financial crisis of 2008-9. Dr. Russell's fascination with all aspects of the specialty accounts for the breadth of his academic focus, covering the spectrum of our specialty, with more than 140 peer-reviewed publications. Many have an interventional focus (including a highly cited early publication in AJNR on Functional Neuroangiography, stemming from his mentorship by Alex Berenstein and Pierre Lasjaunias while at

AWARDS AND HONORS

ASNR Gold Medal Award (Continued)

NYU). Early work on high resolution CT of the temporal bone, employing one of the first high-resolution CT algorithms (developed by Manlio Abele at NYU), stimulated his interest in Head and Neck Imaging, with subsequent publications that include the first anatomic/pathologic CT imaging study of the lacrimal drainage apparatus. His experience in CT of the head and neck led to his observation that enhancement was common at the margins of cervical disk herniations, improving their conspicuity. His investigations of the anatomical substrates of this enhancement in cadavers led to publications in Radiology, including the first in the US on contrast enhanced CT of the cervical spine in degenerative disease, and subsequently a "state of the art" article in Radiology on Imaging of the Cervical Spine. He was also an early clinical investigator for the pre-approval safety and efficacy trial of the first contrast agent for MR use, gadolinium-DTPA. His success as a local PI led to a first author publication on the Phase II placebo controlled clinical trial of Gd-DTPA (Magnevist), in Radiology. With material collected from the trial, he was one of the first to statistically prove the advantages of contrast-enhanced MRI for detecting cerebral metastases, at a time when many were skeptical that contrast-enhancement was necessary for MRI.

Dr. Russell has been married for more than 30 years to Sandra K. Fernbach, MD, a prominent academic pediatric radiologist who he met during his residency at Montefiore, recently retired. They have two wonderful girls, Gabrielle Robin, an intellectual properties lawyer in NYC and Meredith Jean, a research coordinator in the Department of Pediatrics, Pediatric Oncology practice, at the University of New Mexico Hospitals, married to Andrew Millard, an engineer at Sandia National Laboratory. The Russell's live in the Lincoln Park/Gold Coast area in downtown Chicago.

ASNR 2013

NEURORADIOLOGY FOR THE 21ST CENTURY

AWARDS AND HONORS

ASNR Honorary Member

Dr. Valery N. Kornienko has had a long career as a neuroradiologist in Moscow, Russia. Dr. Kornienko received his internal medicine degree from the Rostov-Don Medical Institute in 1959, and did a postgraduate course in neurosurgery and neuroradiology from 1962-1964. He then spent three years in a Fellowship at Burdenko Neurosurgery Institute, Moscow. Since 1980 he has served as Head of Neuroradiology at Burdenko Neurosurgery Institute, RAMS, Moscow. He has been Professor since 1985.

He has over 500 academic publications and 15 books. His most recent book is a three volume 1288 page textbook titled "Diagnostic Neuroradiology" and was published in 2009 by Springer, in English language. This work was awarded the Burdenko Prize by the Russian Academy of Medical Sciences in 2010. He was also awarded a State Prize for "The development and introduction of the pathogenic methods of diagnosis, prognosis and treatment of traumatic brain injury and its consequences" (1995), and in 2007 the Prize of the Government of the Russian Federation for "Development and implementation of a practice complex reconstructive techniques and minimally invasive neurosurgery in times of peace and military conflict".

This summer the Russian Society of Neuroradiology was founded, and Professor Kornienko was elected the Founding President of the Society.

The recipient of the 2013 award is:

Valery N. Kornienko, MD, PhD

Burdenko Neurosurgery Institute, Moscow, Russia

ASNR J. Arliss Pollock Memorial Lecture

The Pollock Memorial lecture is held in honor of J. Arliss Pollock, MD, a pioneering neuroradiologist who led the ASNR socio-economic and health policy programs for fifteen years. A true visionary, he was one of the first physicians to specialize in neuroradiology in California and the first to introduce cerebral angiography into a community based practice. We are indebted to him for his willingness to carve out a presence for the ASNR in the area of socioeconomics and health policy at a national level. He led the ASNR health policy efforts at the AMA CPT Editorial Panel Advisory Committee and the Relative Value Scale Update Committee (RUC). These highly influential multi-specialty committees create codes for new technologies and procedures and develop values that set the physician reimbursement rates. He served as a liaison to the ACR and AMA and many other societies when consensus was needed. In 2001, he received the ASNR's highest award, the Gold Medal. We dedicate a health policy lecture each year to recognize his exceptional leadership and commitment to neuroradiology.

The presenter of the 2013 lecture is:

Dieter R. Enzmann, MD

David Geffen School of Medicine at UCLA, Los Angeles, CA

"Radiology Value Chain"

Presentation Time: **Tuesday, May 21 - 1:25 pm - 1:50 pm**

Location: **Ballroom 6DE**

AWARDS AND HONORS

ASNR Cornelius G. Dyke Memorial Award

This award was established to honor Cornelius G. Dyke, one of the pioneers in neuroradiology, and is given to a trainee or junior faculty member in neuroradiology for excellence as demonstrated in a paper, which represents original, unpublished research in some aspect of neuroradiology.

The recipient of the 2013 award is:

Presentation Time: **Thursday, May 23 - 10:45am - 10:53am**

Location: **Ballroom 6DE**

Hediyeh Baradaran, MD

Weill Cornell Medical College, New York, New York

"Metabolic Reserve and Stroke Risk in Patients with Carotid Stenosis or Occlusion: A Systematic Review and Meta-Analysis"

Dr. Hediyeh Baradaran is a radiology resident at New York Presbyterian Hospital/Weill Cornell campus. She graduated from Weill Cornell Medical College and completed her internship at the University of Utah Medical Center. Her current research interests include imaging in patients with carotid atherosclerotic disease.

2012-2013 Specialty/Regional Society Awards

The American Society of Neuroradiology is pleased to announce the recipients of the 2012/2013 Special/Regional Society Awards. These individuals were selected by the respective societies as having the best presentation at each society's most recent Annual Meeting.

American Society of Spine Radiology (ASSR) (Mentor Award)

"Diffusion-weighted MRI (DWI) 'claw sign' is Useful in Differentiation of Infectious from Degenerative Modic I Signal Changes of the Spine"

Keyur Patel, MD
The Mount Sinai Medical Center, New York, NY

Eastern Neuroradiological Society (ENRS) (The Norman E. Leeds Award)

"Evaluating CT Perfusion Using Outcome Measures of Delayed Cerebral Ischemia in Aneurysmal Subarachnoid Hemorrhage"

Jana Ivanidze, MD
Weill Cornell Medical College, New York, NY

Southeastern Neuroradiological Society (SENRS)

"Functional Neuroimaging to Characterize the Effect of Chemotherapy on Visual System Development in Children Treated for Retinoblastoma"

Kathleen J. Helton, MD
St. Jude's Children's Research Hospital, Memphis, TN

Western Neuroradiological Society (WNRS) (The Gabriel H. Wilson Award)

"Direct Puncture Treatment of Orbital & Peri-orbital Vascular Malformations"

Gary M. Nesbit, MD
Oregon Health & Science University, Portland, OR

AWARDS AND HONORS

ASNR 2012 Outstanding Presentation Awards

ASNR is pleased to announce the winners of the Outstanding Presentation Awards. The overall quality of the paper and poster presentations at the New York meeting was excellent, and the winners should be commended for their outstanding work. A $1,000 award will be given to the primary author of each winning presentation.

Seven awards were presented in Six categories: in *Adult Brain/General Neuroradiology* (two awards, one awarded by the ASNR, and another awarded by The Foundation of the ASNR), *Functional Neuroradiology, Head and Neck, Interventional* (The Michael Brothers Memorial Award), *Pediatrics* (The Derek Harwood-Nash Award), and *Spine*. Both awards in Adult Brain/General Neuroradiology were selected by a panel of ASNR members under the direction of the Education Committee. The five subspecialty awards were judged by panels selected from each of the specialty societies, including ASFNR, ASHNR, ASPNR, ASSR, and SNIS. We would like to thank all of the judges for their tremendous effort in evaluating the presentations. Congratulations to the winners!

General Neuroradiology

(on behalf of the ASNR)

Paper 37: Cerebrovascular and Functional MR Imaging with the Blood Pool Agent Ferumoxytol: Initial Experience in Normal Subjects

Zaharchuk, G. • Christen, T. • Qiu, D. iNi, W. • Schmiedeskamp, H. • Bammer, R. • Moseley, M.E.

(Stanford University, Stanford, CA)

General Neuroradiology

(on behalf of The Foundation of the ASNR)

Paper 98: Imaging Genomic Mapping in Glioblastoma Multiforme: A Novel Quantitative Merge between Imaging and Genomics. The Creation of a Signature for Tumor Necrosis Using Image Genomic Analysis in 12,764 genes and 555 microRNAs

Colen, R.R.[1] • Mahajan, B.[1] • Bruyere, J.[1] • Jolesz, F.A.[1] • Sathyan, P.[2] • Zinn, P.O.[2]

([1]Brigham and Women's Hospital, Boston, MA,
[2]M.D. Anderson Cancer Center, Houston, TX)

Functional Neuroradiology

Paper 226: Beyond the Tip of the Iceberg: Widespread pH Abnormalities Detected with 31P-MR Spectroscopy in the Normal-Appearing Parenchyma of Patients with Cortical Malformations and Epilepsy

Andrade, C.S.[1] • Otaduy, M.C.G.[1] • Park, E.J.[1] • Valente K.D.R.[1] • Tsunemi, M.H. [2] • Leite, C.C.[1]

([1]Faculdade de Medicina da Universidad de Sao Paulo, Sao Paulo, Brazil,
[2]Universidade Estadual Paulista Julio de Mesquita Filho, Botucatu, Brazil)

Head and Neck Radiology

Paper 327: Repeatability of Pretreatment FDG-PET Compared to Early Treatment-Induced Changes for Head and Neck Cancer

Hoang, J.K. • Peterson, B.L. • Broadwater, G. • Das, S. • Yoo, D. • Brizel, D.D.

(Duke University Medical Center, Durham, NC)

Interventional Neuroradiology

(The Michael Brothers Memorial Award)

Paper 412: Cerecyte Coil Trial: Angiographic and Clinical Outcomes of Endovascular Coiling in Patients with Ruptured and Unruptured Intracranial Aneurysms Treated with Cerecyte Coils Compared with Bare Platinum Coils - Final Results of a Prospective Randomized Trial

Molyneux, A.J.[1] • Fox, A.[2] • Sneade, M. [1] • Clarke, A. [1] • Mehta, Z. [1] • Coley, S.[3]

([1]Oxford University, Oxford, United Kingdim,
[2]Sunybrook Health Sciences, Toronto, ON, Canada,
[3]Royal Hallamshire Hospital, Sheffield, United Kingdom)

Pediatric Neuroradiology

(The Derek Harwood-Nash Award)

Paper 181: Diffusion Tensor Imaging of the Normal Pediatric Spinal Cord Using an Inner-Field-of-View EPI Sequence

Barakat, N.[1] • Mohamed F.[1] • Hunter, L.[2] • Shah, P.[1] • Faro, S.[1] • Samdani, A.[2] • Finsterbusch, J.[3] • Betz, R.[2] • Gaughan, J.[1] • Mulcahey, M.[2]

([1]Temple University, Philadelphia, PA.,
[2]Shriners Hospital for Children, Philadelphia, PA.,
[3]University Medical Center Hamburg-Eppendorf, Hamburg, Germany)

Spine

Paper 523: Vertebral Artery Position in the Setting of Cervical Degenerative Disease: What is a "Safe Position" for Selective Cervical Nerve Root Block?

Fitzgerald, R.T. • Bartynski, W.S.

(University of Pittsburgh, Pittsburgh, PA)

AWARDS AND HONORS

The Foundation of the ASNR Scholar Award in Neuroradiology Research

Since 1995, The Foundation of the ASNR has been in the process of raising funds to support neuroradiology research. This is one of the most important goals of the The Foundation of the ASNR, and of the ASNR as the premier organization for neuroradiology. This award was created for young investigators in the early stages of their careers, to enhance their competency in areas important to the future of neuroradiology, including health services research, physiological imaging and interventional neuroradiology. It also affords the Foundation the opportunity to begin to develop leadership in these areas.

The recipient of the 2013 award is:

Monica Pearl, MD, DABR

Johns Hopkins University School of Medicine, Baltimore, MD

"Highly Selective MRI-Guided Targeting of Intra-arterial Chemotherapeutic Drug Delivery to the Brainstem in a Rabbit Model of Mannitol-Induced Blood Brain Barrier Disruption"

The Foundation of The ASNR Research Scientist Award

The Foundation of the ASNR established the Research Scientist Award to provide research opportunities for PhD investigators to advance the science of neuroradiology. Scientific research is the foundation upon which the clinical practice of neuroradiology is built. Research scientists in partnership with radiologists have traditionally led the development of new imaging technologies and image-guided procedures. The directive of this award is to assist young scientists in their transition to becoming independent investigators in neuroradiology research, as well as to help established investigators initiate new projects with relevance to neuroradiology.

The recipient of the 2013 award is:

Ali Tabesh, PhD

Medical University of South Carolina, Charleston, SC

"Diffusional Kurtosis MRI Evaluation of Medial Temporal Lobe Epilepsy"

The Foundation of the ASNR Comparative Effectiveness Research Award

The Foundation of the ASNR has established the Comparative Effectiveness Research Award to support investigators in the generation and synthesis of evidence that compares the benefits and harms of diagnostic imaging methods or interventions to prevent, diagnose, treat, and monitor a clinical condition or to improve the delivery of care. Comparative effectiveness research (CER) is valuable to clinicians, patients, purchasers, and policy makers in making informed decision that will improve health care at both the individual and population levels. Neuroradiologists have an important role in the development of new imaging technologies and image-guided procedures, as well as in the assessment of these techniques in the clinical care of patients.

No Award in 2013

Women in Neuroradiology Leadership Award

The Foundation of the American Society of Neuroradiology, American College of Radiology, and American Association for Women Radiologists have established an award to provide leadership opportunities for women in neuroradiology. Since neuroradiologists must be leaders in the field and women continue to be underrepresented in neuroradiology, this award is for mid-career women with demonstrated experience and promise for leadership in neuroradiology and/or radiology overall. The objectives are to provide the awardee with additional skills and insights to enhance opportunities for advancement.

The recipient of the 2013 award is:

Pina C. Sanelli, MD, MPH

Weill Cornell Medical College/New York – Presbyterian Hospital, New York, NY

The Foundation of the ASNR Award for Outstanding Contributions in Research

This award, created in 2004 in recognition of Neuroradiologists who have demonstrated consistent excellence and lifelong accomplishment in basic or clinical neuroscience research, particularly funded research from the NIH, NSF, March of Dimes, etc. This award is given to an ASNR senior member over the age of 50 recognized in the neuroradiology field for distinguished long term achievement in basic or clinical research.

The recipient of the 2013 award is:

William P. Dillon, MD

University of California, San Francisco
San Francisco, CA

Dr. William P. Dillon was born and raised in the Bay Area of Northern California. He was the oldest of 4 children, and credits his mother, Mary, for encouraging him to read by taking him to the public library each Saturday and his father, William, for showing him how to throw and catch a baseball. He attended Moreau Catholic High School and graduated from the University of Santa Clara where he studied biology and math. During his undergraduate years he worked at NASA-Ames Research Center in the lab of the late William Mehler, PhD, a master old school neuro-anatomist, who inspired Bill to a life of academia and science. Dr. Dillon graduated from UCLA School of Medicine in Los Angeles, California in 1978. He completed an internship in internal Medicine at Virginia Mason in Seattle, Washington, residency in radiology at the University of Utah (1982) and fellowship in neuroradiology (1983) at UCSF under the direction of Drs. Newton, Norman and Brant-Zawadaski. In 1983, Dr. Dillon joined the faculty of UCSF and advanced through the ranks to Professor of Radiology, Neurology and Neurosurgery. He was appointed neuroradiology section chief in 1992 and in 1997 was named as Vice Chair for Research. In 2004 he was honored with the Elizabeth A. Guillaumin Endowed Professorship of Radiology. In 2007, Dr. Dillon became the Executive Vice-Chair of the Department of Radiology at UCSF.

Dr. Dillon's research interests span several areas in neuroradiology. He began his career at the University of Utah where Dr. Tony Mancuso was an early mentor and inspired Dr. Dillon's work in head and neck radiology. Dr. Dillon's landmark paper on MR of the Nasopharynx was the first to describe the application of MR to head and neck oncology and with colleagues he described the major atrophic patterns on imaging in patients with cranial nerve deficits. Dr. Dillon became interested in MR applications and biomarker development in neurooncology, and helped pioneer the application of MR spectroscopy and perfusion techniques in brain tumor evaluation. Dr. Dillon became interested in the applications of CT and MR perfusion techniques in stroke, and was an early adopter of the stroke protocol that incorporated CTA and CT perfusion for acute stroke detection and management. He led the UCSF core laboratory that helped imbed these techniques in stroke clinical trials. Dr. Dillon turned his interest to spine imaging and therapy in the last decade. His work on the imaging features and treatment of intracranial hypotension brought attention to this disorder to the neuroscience community and with colleagues he described the entity of "pre-syrinx." At UCSF, Dr. Dillon was instrumental in starting the Precision Spine Center at UCSF, where he and colleagues have developed pioneer the use of low dose CT guidance for spine interventions.

Dr. Dillon has authored over 260 manuscripts in peer-reviewed journals, over 30 chapters to medical texts and reviews, and co-edited two Neuroradiology textbooks. For his work, Dr. Dillon has received the Gold Medal Award from the American Society of Head and Neck Radiology (2007), the Francis A. Sooy, M.D. Award for Clinical Excellence from the Department of Otolaryngology (1992), and the 2011 J. Elliott Royer Award for Academic Contributions to Neurology from the San Francisco Neurological Society. He served as Senior Editor of the American Journal of Neuroradiology from 1998-2011, President of the American Society of Head and Neck Radiology in 1993 and President of the ASNR in 2001. He continues to be active in the leadership of both societies, most recently chairing the 2013 strategic plan review for the ASNR.

With his wife, Irene, Dr. Dillon enjoys traveling, hiking, reading, sports and spending time with his three children, Alex, a second year medical student at NYU, Andrea, currently in Chile on a Fulbright fellowship, and Annelise, a sophomore at Stanford University.

CONTINUING MEDICAL EDUCATION (CME)

Take Your Official Continuing Medical Education (CME) Certificate Home With You!

An enhancement of the Continuing Medical Education online evaluation system allows for attendees to print out their official CME certificate for the number of hours claimed during The Foundation of the ASNR Symposium 2013 and ASNR 51ST Annual Meeting and take it with them when they leave. Go to any terminal in the CME Pavilion and follow the simple directions for printing out an official The Foundation of the ASNR Symposium 2013 and ASNR 51ST Annual Meeting CME Certificate.

Following the meeting, the ASNR 2013 CME certificate site will be available online by mid-July for 90 days for attendees to print out their CME certificates.

Please Note: Due to the availability of CME certificates online, certificates will not be mailed to attendees.

Letter of Attendance

If you wish to obtain a Letter of Attendance, please request one at the Registration Desk located in the Sails Pavilion of the San Diego Convention Center.

Continuing this year!

- **Evaluations available online with remote access 24/7 through the meeting**
- **Streamlined format**
- **Open throughout the meeting until Monday, June 10**

CME Pavilion - Room 4AB (Upper Level)

To access the CME evaluation program, scan the barcode on the front of your badge at the reader at one of the terminals and follow the simple directions for selecting and evaluating the sessions you have attended. The CME credit hours awarded to a session will automatically be recorded in your record when the evaluation for a session is completed. Evaluations can be completed at the end of a session, during breaks, at the end of the day or the end of the week, as well as on your personal device. You will be able to view a record of the sessions you have evaluated and the number of CME credit hours earned throughout the program. It will also be possible to print your certificate and transcript to take home with you.

Please Note: To receive CME credit for sessions attended at The Foundation of the ASNR Symposium 2013 and ASNR 51ST Annual Meeting, all evaluations must be entered by Monday, June 10.

Scientific Program and Meeting Evaluation

The 2013 Continuing Medical Education (CME) Pavilion allows online recording of CME credits via the Internet. The improvements have created a faster and more user-friendly system for evaluating sessions and speakers and recording CME hours electronically.

The CME Pavilion is easily accessible in Room 4AB at the San Diego Convention Center. Please complete the evaluations for each session to assist in planning future meetings and to help us maintain accreditation of future programs.

ACCREDITATION STATEMENT

The American Society of Neuroradiology is accredited by the Accreditation Council for Continuing Medical Education (ACCME) to provide continuing medical education for physicians. The American Society of Neuroradiology takes responsibility for the content, quality, and scientific integrity of the CME activity.

CREDIT DESIGNATION STATEMENT

The American Society of Neuroradiology designates this live activity for a maximum of *34.5 AMA PRA Category 1 Credit(s)™*. Physicians should claim only credit commensurate with the extent of their participation in the activity.

TARGET AUDIENCE

The 51ST Annual Meeting is the premier neuroradiology meeting in the world. It is designed for general radiologists who read Neuroradiology studies, dedicated neuroradiologists who strive to better integrate advanced imaging and image-guided diagnostic and therapeutic strategies into daily practice, and scientists who seek better understanding of the current state of these technologies and how they are applied to evaluate the brain, spine, head and neck. All participants will benefit from exchange of ideas with colleagues from around the world. Programming will include invited talks and original presentations of new results in imaging methods and techniques such as MR diffusion, and perfusion-weighted imaging, susceptibility-weighted imaging, magnetic resonance spectroscopy, functional magnetic resonance imaging, MR angiography, CT perfusion, CT angiography, CT interactive construction techniques, dual energy CT, catheter-based angiography and associated therapies, peripheral nerve imaging, image-guided spine interventions, new interventional devices, molecular imaging and positron emission tomography, MR PET, and functional connectivity. Sessions dealing with pediatric neuroradiology, head and neck imaging, diagnostic imaging of the spine and spinal therapeutic interventions, vascular imaging and interventions, functional and molecular imaging, and adult neuroradiology will be offered. There will also be sessions on multiple relevant socioeconomic and practice management issues as well as invited lectures on scientific publishing, best of the Asian-Oceanian Society of Neuroradiology and Head and Neck Radiology, Best of the European Society of Neuroradiology, the Brain Observatory, controversies in Neuroradiology, how the brain thinks, and evidence based imaging in brain trauma among others.

ASNR 51ST OVERALL ANNUAL MEETING EDUCATIONAL OBJECTIVES

OVERALL OBJECTIVES FOR THE 51ST ANNUAL MEETING

After attending the 51ST Annual Meeting, you will be able to:

- Review in MOC and SAM formats current concepts in spine, head and neck, interventional, brain and pediatric neuroimaging.
- Identify current mandates and how future changes in health care policy and socioeconomic factors will affect the practice of neuroradiology both diagnostic and interventional.
- Review new concepts in cerebrovascular disease pertaining to inflammation, vasoconstriction syndrome, dissections, stroke, and aneurysms.
- Describe the imaging findings in diseases and malformations affecting the neck, airway, sinonasal cavities, and base of skull.
- Utilize new Web-based resources, tablets and mobile devices, and computer-assisted diagnosis methods as they relate to neuroradiology.
- List emerging imaging techniques for the vertebral column and spinal cord.
- Discuss newer applications of functional MRI and MR PET.
- Describe the imaging findings in congenital malformations, tumors, and metabolic disorders in children.

Objectives for the Young Professionals Program

- Compare benefits of different types of Neuroradiology practices.
- Explain how to negotiate a contract in different types of neuroradiology practices.
- Review the post treatment changes in all regions of the head and neck.
- Describe how to implement MRS, fMRI, perfusion, and DTI into your practice.

ASNR 2013

NEURORADIOLOGY FOR THE 21ST CENTURY

HOW-TO-SESSIONS - BALLROOM 6AB

In addition to the Technical Exhibition, the leadership of the ASNR is pleased to announce the fifteenth annual slate of instructional How-To forums. These sessions presented in conjunction with major corporate contributors, deal with advances in imaging and procedures as well as principles in Neuroradiology and image information management. How-To Sessions are scheduled throughout the week. The How-To Sessions offer a unique opportunity for Neuroradiologists to discuss technical specialists from the imaging industry. Comments and suggestions from meeting registrants were integrated into this year's format. The sessions vary and include both didactic presentations and demonstrations, all with a strong practical emphasis. A significant portion of each session is devoted to questions and answers.

Monday, May 20 ..... 12:15 pm - 1:15 pm

SIEMENS

Creative Dose Control for Critical Neuro CT - Leveraging New Technology
Lawrence N. Tanenbaum MD, FACR
Mount Sinai Medical Center

Healthcare Today and Tomorrow
David N. Fisher
Siemens Medical Solutions USA, Inc.

Tuesday, May 21 ..... 12:15 pm - 1:15 pm

BRACCO
LIFE FROM INSIDE

Hot Topics in Brain MRI
Standard and Advanced MRI Techniques: Current and Future Applications to Patients with Multiple Sclerosis
Meng Law, MD, MBBS, FRACR
USC Keck School of Medicine and Medical Center

Optimizing Contrast-Enhanced MRI for Tumor Evaluation and Treatment
David S. Enterline, MD
Duke University Medical Center

Wednesday, May 22 ..... 12:15 pm - 1:15 pm

TOSHIBA

ASNR 51ST ANNUAL MEETING SCIENTIFIC PROGRAM OVERVIEW

Monday through Thursday: ASNR will provide Breakfast, Lunch, and Morning & Afternoon Breaks.
Monday through Wednesday: ASNR will provide Continuous Coffee Service in the Technical Exhibit Hall - Sails Pavilion

Monday May 20, 2013

6:30am - 7:55am	**Continental Breakfast**
7:25am - 7:30am	Opening Remarks
7:30am - 8:30am	(1) Maintenance of Certification Review Session - Spine (AR)
8:45am - 10:15am	(2) SNIS Programming: Acute Ischemic Stroke
8:45am - 10:15am	(3) General Programming: Computation Modeling in Cerebral Aneurysms
8:45am - 10:15am	(4) ASSR Programming: Spinal Cord Syndromes: Clinical Vignettes to Emphasize Anatomic Tracts
8:45am - 10:15am	(5) General Programming: I Don't Want to Read That Study! (SAM)* (AR)
8:45am - 10:15am	(6) General Programming: WFNRS Presents: Highlights of the 24th Annual Meeting of SILAN
10:15am – 10:45am	**Morning Beverage Break**
10:45am - 12:15pm	(7) Parallel Scientific Paper Sessions
	Session 7a Adult Brain: Dementia and Degenerative Disorders I
	Session 7b Functional Imaging I: fMRI and DTI
	Session 7c Adult Brain: Stroke I
	Session 7d Adult Brain: New Techniques and Novel Post Processing I
	Session 7e Spine: New Techniques

Monday Morning

7:25 AM - 7:30 AM
Ballroom 6AB

(0) Opening Remarks

O-1 **7:25 AM - 7:30 AM**

Opening Remarks

Castillo, M.
Univ. Of North Carolina School Of Medicine
Chapel Hill, NC.

Monday Morning

7:30 AM - 8:30 AM
Ballroom 6AB

(1) Maintenance of Certification Review Session - Spine (AR)

O-2 **7:30 AM - 8:00 AM**

Spine - Part I

Ortiz, A.
Winthrop University Hospital
Mineola, NY.

Presentation Summary
This session will cover key topics in diagnostic and interventional Spine radiology using the case method combined with audience participation. Some areas that will be addressed include congenital spine, spine trauma, degenerative spine disease, inflammatory spine disease, spine infection, spine tumors and metabolic spine disease.

O-3 **8:00 AM - 8:30 AM**

Spine - Part II

Riascos, R. F.
University of Texas Medical Branch
Galveston, TX.

Presentation Summary
The MOC of spine will cover six cases that will be discussed with one or two questions per case with companion cases to review the differential diagnosis. The topics covered include trauma, congenital disease, disk pathology, vascular malformations, tumors and neurocutaneous syndromes.

Monday Morning

8:45 AM - 10:15 AM
Ballroom 6AB

(2) SNIS Programming: Acute Ischemic Stroke

O-4 **8:45 AM - 9:15 AM**

IMS-3 Trial Results in Context: Where Do We Go from Here?

Tomsick, T. A.
Univ. Hosp./Univ. Cincinnati College Of Medicine
Cincinnati, OH.

Dr. Tomsick is Professor of Radiology at the University of Cincinnati Medical Center, and was Principal Neurointerventionist for the IMS I, II, and III Trials. He is Past-President of the American Society of Therapeutic and Interventional Neuroradiology (2001-2).

Presentation Summary
The IMS III Trial investigated full-dose IV rtPA versus reduced-dose IV rtPA in treatment of acute ischemic stroke from 2006 to 2012. The trial was halted for futility in April, 2012 after 656 of 900 subjects were enrolled. This presentation will focus on the clinical and revascularization outcomes in the trial, and consider reasons the trial proved futile as designed.

O-5 **9:15 AM - 9:45 AM**

Role of IA Stroke Treatment from the Neuroradiologist's Perspective

Saver, J. L.
David Geffen School of Medicine at UCLA
Los Angeles, CA.

Jeffrey L. Saver, MD is Director of the UCLA Stroke Center and Professor of Neurology at the David Geffen School of Medicine, University of California, Los Angeles. Dr. Saver received his medical degree from Harvard Medical School, and is a graduate of the Harvard-Longwood Neurology Training Program, the University of Iowa Fellowship Program in Behavioral Neurology and Cognitive Neuroscience, and the Brown University Fellowship Program in Vascular Neurology. An author or co-author of over 365 research articles, Dr. Saver's research interests are in acute stroke treatment, stroke prevention, neuroimaging, clinical trial design, and neurocognitive consequences of stroke. Dr. Saver has held numerous leadership positions in international and national stroke studies and organizations. He is the immediate Past Chair of the Stroke Council of the American Heart

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Association/American Stroke Association; Chair of the AHA Stroke Performance Measures Oversight Committee; Co-Chair of the NIH-NINDS Common Data Elements - Stroke Task Force; principal investigator of the NIH-NINDS Field Administration of Stroke Magnesium (FAST-MAG) clinical trial; editorial board member for the journals Stroke, Journal of Stroke and Cerebrovascular Diseases, Journal of Neuroimaging, and Reviews in Neurological Disease; and associate editor of the online textbooks Medlink Neurobase and Emedicine Neurology.

Presentation Summary
Despite the disappointing results of randomized trials of the first generation of endovascular recanalization therapy, noninterventional stroke neurologists recognize the promise and key potential role of catheter-based interventions. Intravenous tissue plasminogen activator is of only modest recanalization efficacy, achieving reperfuson in only 40% of treated patients. As a treatment that can be delivered quickly and that does not potentiate endovascular risk, IV thrombolysis will always play an important role in acute ischemic stroke care. However, it is an intermediate stage therapy, not a final destination. Highly effective second generation endovascular recanalization treatments, such as stent retrievers, are likely to demonstrate benefit in the next wave of randomized trials and become a useful anchor of clinical practice. Intensive efforts to shorten door to puncture and door to clot times are needed for endovascular therapy, following on the models of door to needle time care improvements for stroke and door to balloon time care improvements for acute myocardial ischemia. Once endovascular therapy is definitively shown to be beneficial, regional stroke systems of care will need to evolve to two tier systems, with rational routing of appropriate patients to widely disseminated Primary Stroke Centers and Hub Comprehensive Stroke Centers.

O-6 **9:45 AM - 10:15 AM**

Stroke Imaging: CT, MRI, Perfusion, Where Do We Stand Today?

Gonzalez, R.
Massachusetts General Hospital
Boston, MA.

Presentation Summary
With the development of effective therapies for acute ischemic stroke, a plethora of advanced imaging methods were developed to help triage patients to the most effective therapies. The management of patients with mild symptoms (NIHSS<5, no treatment) and moderate symptoms (NIHSS6-10, IV-tPA if <4.5 hours post ictus, only NCCT imaging essential) are well supported by the evidence. For patients with severe symptoms (NIHSS>10) advanced imaging provides essential information. Evidence-based analyses have shown that NCCT, CTA and DWI are Class I/Level A methods. Perfusion imaging by CT or MRI have been found to be unreliable and are Class IIb. The key parameters for assessing the acute stroke patient in order of importance are: neurologic status, site of occlusion, and size infarct core, which can be determined accurately and reliably with NIHSS, CTA (or MRA) and DWI, respectively. The clinically relevant penumbra in patients with a major anterior circulation occlusion can be deduced by combining the NIHSS score and the DWI lesion volume alone. Theoretical considerations and the inherently poor signal-to-noise ratio make CTP an unreliable, potentially misleading method to substitute for DWI to determine the size of the infarct core, and is unsuitable for patient triage decisions.

Monday Morning

8:45 AM - 10:15 AM
Ballroom 6CF

(3) General Programming: Computation Modeling in Cerebral Aneurysms

O-7 **8:45 AM - 9:15 AM**

Growth and Remodeling in Aneurysms

Robertson, A. M.
University of Pittsburgh
Pittsburgh, PA.

Anne M. Robertson is Associate Professor of Mechanical Engineering and Materials Science and Associate Professor of Bioengineering at the University of Pittsburgh, Pittsburgh, PA. Her research team carries out theoretical, computational and experimental research on cerebral vascular disease and constitutive modeling of soft biological tissues. Her research has been funded by the NIH, NSF, DOE and the Whitaker Foundation. Dr. Robertson has co-authored over 75 publications and is co-author of the book, Hemodynamical Flows: Modeling, Analysis and Simulation, Birkhauswer, 2008. She is a member of the editorial board of the International Journal for Numerical Methods in Biomedical Engineering. Dr. Robertson earned an MS and PhD from the Department of Mechanical Engineering at U.C. Berkeley and was a President's postdoctoral fellow in the Department of Chemical Engineering at U.C. Berkeley. She has held visiting research professorships at the Polictecnico di Milano (Italy), the Instituto Superior Technico in Lisbon (Portugal), the Bernouilli Center at the Swiss Federal Institute of Technology (EPFL, Switzerland), the University of Pisa (Italy) and RWTH University of Aachen (Germany).

Presentation Summary
Intramural cells in the walls of healthy arteries are

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

endowed with an ability to maintain the structural integrity of the wall through a continuous process of collagen turnover. Further, these cells have the capacity to remodel the extracellular matrix in response to changes in mechanical and chemical stimuli. The cellular content in the walls of cerebral aneurysms show tremendous heterogeneity across the population and can vary from an endothelialized wall with linearly organized smooth muscle cells (SMCs) to a thin hypocellular wall (e.g., (1; 2)). Diminished cell content and function within the aneurysm wall will hinder, or even prevent, the maintenance and repair of the extracelluar matrix and thereby influence disease progression towards stabilization, growth or rupture (1-3). The nature of the flow dynamics within the aneurysm sac is believed to play a vital role in determining this cell content and therefore, ultimately, the wall strength. In this talk, we will discuss the relationship between cellular content, extracellular matrix and mechanical function in both resected segments of human aneurysm walls as well as the walls of an elastase induced aneurysm model in rabbits (4-6). Consideration also will be given to the vital question of the extent to which the wall structure and content in the elastase induced aneurysms is similar to that of human aneurysms. For this work, collagen and elastin architecture were evaluated using a custom uniaxial loading device, designed to be compatible with a multiphoton microscope (7). Using this device, we were able to simultaneously perform mechanical testing and MPM imaging of the architecture in the aneurysm samples without destructive histological techniques (8). Unruptured human aneurysm domes were assessed at single time points. The growth and remodeling process was evaluated in the elastase-induced aneurysm model by investigating the changing collagen and elastin architecture at four time points.

O-8 **9:15 AM - 9:45 AM**

Computational Fluid Dynamics Pre- and Post-Aneurysm Treatment

Cebral, J. R.
George Mason University
Fairfax, VA.

Juan R. Cebral is a Professor at the Center for Computational Fluid Dynamics, College of Science, George Mason University, in Fairfax, Virginia, USA. He finished his undergraduate studies in Physics at the University of Buenos Aires, Argentina in 1991 and received his PhD in Computational Sciences and Informatics from George Mason University in 1996. He conducts research on image-based computational modeling of cerebral blood flow and aneurysms in close collaboration with clinicians from Inova Fairfax Hospital and other institutions in the USA and around the world. He has co-authored over 60 journal papers, 10 book chapters, and over 150 conference papers. His research has been funded by the National Institutes of Health, the American Heart Association, the Whitaker Foundation as well as industrial partners such as Philips Healthcare and Boston Scientific. He teaches graduate level courses in Fluid Mechanics, High Performance Computing and Foundations of Computational Sciences.

Presentation Summary
This presentation will discuss our investigations of the relationships between hemodynamic conditions created immediately after implantation of flow diverting devices to treat cerebral aneurysms and the long-term outcome of these interventions. These studies are carried out by connecting data from "patient-specific" image-based computational fluid dynamics models and clinical, animal and biological information.

O-9 **9:45 AM - 10:15 AM**

Use of Modeling in the Clinical Setting

Murayama, Y.
Division of Endovascular Neurosurgery, Department of Neurosurgery, Jikei University School of Medicine
Tokyo, JAPAN.

Presentation Summary
Computational fluid dynamics (CFD) has become a prominent subject in the research of cerebral aneurysms. Researchers conduct CFD analysis to understand mechanism of aneurysm rupture or difference between ruptured and unruptured aneurysms. The wall shear stress (WSS), which is the most commonly studied hemodynamic parameter, has been studied intensively. Several new parameters, such as energy loss (EL), oscillatory shear index (OSI), or pressure loss coefficient (PLC) have been introduced. Intensive research using CFD technology has been done; however, no conclusive result has been obtained to anticipate aneurysm rupture. Risk of rupture also is associated with multifactorial factors, such as genetics, or biological factors. Computational fluid dynamics technology also can be used for treatment planning, especially utilization of flow diverters. Furthermore, simulation of such endovascular device development can be performed in the virtual environment. We discuss current status and future of CFD research in the field of interventional neuroradiology.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Monday Morning

Ballroom 6DE

(4) ASSR Programming: Spinal Cord Syndromes: Clinical Vignettes to Emphasize Anatomic Tracts

O-10 **8:45 AM - 9:15 AM**

Extrinsic Cord Compression. State of the Art Imaging and Classification Schemes

Cianfoni, A.
Neurocenter of Southern Switzerland
Lugano, SWITZERLAND.

Presentation Summary
Spinal cord compression is a pathologic condition, potentially leading to devastating neurologic sequelae, that requires imaging to distinguish among specifically treatable causes. Clinical presentation includes a combination of motor and/or sensory deficit, often pointing to a definable level of involvement, pyramidal syndromes, neuropathic pain, gait disturbance, fever, with variable patterns of progression. There is a wide spectrum of conditions that may compress the spinal cord: degenerative disease, disk herniation and metastatic compression are the most common causes; other conditions include spine trauma, epidural abscess, epidural hematoma and neoplastic conditions other than metastasis. The role of imaging is to establish a radiologic diagnosis, to distinguish intrinsic spinal cord disease from extrinsic compression, to define mechanical spine stability, to evaluate the integrity of neural tissue and to provide further radiologic information if necessary. The spine is a complex anatomical environment, and in the setting of spinal cord compression imaging is required to assess osseous structures and soft tissues, as muscles, disks, ligaments, epidural fat planes, meninges, cerebro-spinal fluid, vessels and spinal cord. The need to image "across anatomical compartments" usually requires more than one imaging technique, with specific technical requirements. Multi-detector CT is progressively replacing plain radiography for the accurate assessment of the osseous spine, and actually is the preferred imaging modality in acute spine trauma. MR imaging is the best imaging modality to assess soft tissues, image the extra-dural, intra-dural and spinal cord compartments. Conventional MR imaging protocols need to be implemented with fat suppression techniques applied to multiplanar T2- and contrast- enhanced T1-weighted sequences. MR imaging helps in predicting neurologic recovery: conventional T1-weighted, T2-weighted and post-contrast images provide macroscopic information including both reversible and irreversible histologic changes. Diffusion tensor imaging (DTI) enables depiction of microstructural changes in the compressed spinal cord, which could further predict tissue viability, potential functional prognosis and patient recovery. The role of CT myelography is reserved to selected cases, when MRI is not feasible or results are unclear but, in the setting of spinal cord compression, intrathecal injection of contrast from below and above the compression level might be necessary to overcome the diagnostic limitations imposed by a myelographic block. Various spinal cord compression conditions will be presented, different in nature, arising from, or involving, different anatomical compartments. Respective best imaging modalities or combinations thereof will be discussed.

O-11 **9:15 AM - 9:45 AM**

Intrinsic Cord Pathology and State of the Art Imaging of Spinal Tracts - I

Van Goethem, J. W.
Antwerp University Hospital
Antwerp (Edegem), BELGIUM.

Presentation Summary
The spinal cord has a complex anatomy with a great concentration of different tracts in a small cross-sectional area. Although intrinsic cord pathology is relatively rare, many different diseases may effect normal spinal cord functioning. Benign intramedullary tumors, mainly astrocytoma and ependymoma, may disrupt normal cord functioning. Also inflammatory and infectious diseases, including multiple sclerosis and different kinds of myelitis will be discussed. A third important group of diseases affecting the spinal cord may provoke extrinsic cord compression or laceration and these can be seen in tumoral pathology, degenerative spinal disease and trauma. In general only magnetic resonance imaging (MRI) allows accurate visualization of intrinsic cord pathology. Previously the focus of imaging was on determining the etiology and the general location of spinal cord lesions. Delineation of gray and white matter is done nowadays in routine imaging. Discriminating the different spinal tracts is still challenging. New techniques, especially diffusion tensor imaging (DTI), however are promising in visualizing individual spinal tracts and, as consequence, lesions to spinal tracts. Techniques to optimize spinal cord DTI will be discussed and this will be illustrated with several examples.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Tinnitus: Imaging and Clinical Approach to Diagnosis

Phillips, C.
Weill Medical College of Cornell/NY Presbyterian
New York, NY.

Presentation Summary
Tinnitus is an incredibly common condition in the world, and is suffered by countless millions of people in the U.S., some of whom will be referred for imaging evaluation. Tinnitus is the perception of sounds by an individual in the absence of an external sound. It may be a ringing, buzzing, or other monotonous tone. The tone may vary with time, and can be pulse-synchronous, or may be unvarying. Continuous tinnitus is the unvarying form, and pulsatile tinnitus refers to a sound which varies with the cardiac cycle. Tinnitus may be an unremitting problem in patients, and may lead to referral for imaging. In this regard, it is a very problematic item of history for the radiologist, as it is a symptom with an incredibly wide range of potential etiologies. There is little acceptance of a standard imaging algorithm for diagnosing a potential cause of tinnitus. As expected, the pulsatile form may be vascular in nature, and a potential cause may be found more commonly on imaging, but the study to be recommended also is widely debated, without consensus. Continuous tinnitus is a particularly vexing clinical issue. Tinnitus without a radiologic abnormality is likely the most common form of tinnitus, and the radiologist may recommend a perfectly appropriate examination without a discovered diagnosis. Pulsatile tinnitus may be associated with vascular pathology, and with other lesions as well. A reasonable differential diagnosis includes arterial and venous anomalies, vascular neoplasia, and other less common but potentially diagnosable and treatable conditions, such as otospongiosis. Continuous tinnitus can be caused by a very wide range of pathology, including intracranial and IAC neoplasms, TMJ disease, brainstem lesions, intracranial hypotension or hypertension, or simply presbycusis. The diagnostic study ordered may be dependent on clinical factors, such as patient age, onset of symptoms, or potentially causative conditions. CT and MRI may be utilized, and CTA and MRA as well as venous studies may be useful in arriving at a cause. Temporal bone CT studies often are ordered, as are CTA. CT angiography has been proposed as a reasonable “one stop shopping” exam, yielding both vascular information and high quality temporal bone CT studies. However, brainstem, IAC and posterior fossa disease still is best studied with MR with and without contrast.

O-14 **9:10 AM - 9:30 AM**

The Post-Op Temporal Bone

Huang, B. Y.
University of North Carolina
Chapel Hill, NC.

Presentation Summary
In contemporary practice, imaging plays a crucial role in both the pre and postoperative assessment of the diseased ear. In this session, we review the role of imaging following common otologic surgical procedures. The most common procedures of the middle ear and mastoid cavity are performed to address the sequelae of chronic otitis media and Eustachian tube dysfunction or to address stapes fixation in patients with otosclerosis. The term tympanoplasty is used generically to describe surgical procedures within the middle ear performed to eradicate disease and, secondarily, to reconstruct the conductive hearing apparatus. They are performed frequently in conjunction with mastoidectomy and/or ossicular chain reconstruction. The postoperative appearances of temporal bones following tympanoplasty and other middle ear surgeries can vary drastically from case to case depending upon the specific procedures performed; therefore, correlation with the operative note, if available, should be a crucial part of the radiologic assessment. In all cases, the postoperative CT evaluation should include careful assessment of: 1) the status of the ossicular chain and/or reconstruction prostheses; 2) the presence of soft tissue or fluid in the middle ear and mastoid; 3) the

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

integrity of the tegmen tympani/mastoideum, lateral semicircular canal, sigmoid plate, and fallopian canal; and 4) the status of the inner ear. In cases in which there is soft tissue in the tympanum or mastoid, MRI can be useful for further tissue characterization. Common surgeries in the inner ear, IAC, and CP angle cistern include cochlear implantation and schwannoma resection. CT and plain radiography are the primary imaging tools used for assessing cochlear implants and adequately demonstrate electrode abnormalities, including electrode misplacement, migration, kinking, and fracture. Schwannomas of the IAC and CP angle typically are approached from one or more of three primary routes: 1) middle cranial fossa; 2) suboccipital; and 3) translabyrinthine. MR imaging is the preferred imaging test to evaluate the totality of tumor resection and to assess for surgical complications, which can include infection, hematoma formation, retraction injury to the temporal lobe or cerebellum, injury to the sigmoid sinus, or injury to the inner ear. Typical imaging features of each of these procedures will be demonstrated, along with examples of common causes of surgical failure or complication.

O-15 **9:30 AM - 9:50 AM**

The Post-Therapy Neck

Curtin, H. D.
Massachusetts Eye & Ear Infirmary
Boston, MA.

Presentation Summary
The post-therapy imaging study of the neck is one of the most avoided examinations in any radiology practice. The anatomy of the neck is normally complex and if distorted by surgery or radiation, the difficulty of image interpretation is magnified significantly. Knowledge of standard surgical resections and reconstruction strategies as well as an understanding of the most common sites of recurrences can help organize the interpretation strategy. Certain changes in the soft tissues are predictable after radiation and should not be confused with recurrence. The pretherapy imaging study and a clear knowledge of the therapeutic history should be considered indispensable resources for the radiologist making the interpretation. Certain surgeries are very standardized. For instance, neck dissections follow predicable patterns. Knowledge of the precise terminology can be confusing. Simply indicating that there has been a neck dissection and noting the structures that have been removed is usually sufficient. The jugular vein and sternocleidomastoid muscle as well as the submandibular gland should be mentioned. In the most limited of dissections only the nodes are removed and the gland, vein and muscle may remain. In this case, the only indicator of the dissection is loss of fat around the vessels. If the accessory nerve (XI) is removed the trapezius and sternocleidomastoid (if remaining) will atrophy. The various flaps used to reconstruction may be swung into place using the original blood supply (pedicled flap) or brought into the surgical site (free flap) from a more distant site and attached to the vessels of the neck. Radiation changes also are predictable with swelling of the aryepiglottic folds and apparent edema in the retropharyngeal space as well as stranding of the fat and linear enhancement of the mucosa. Recurrences are usually in relatively predicable locations along surgical approach path or along the edge of a flap as well as at the primary site. These tend to have more nodular appearance. It is very common that the radiologist must deal with an area of tissue that is indefinite. The radiologist can recommend a short interval follow-up examination or even a biopsy. A PET/CT may be done if the original exam was a CT. Being able to deal with this ambiguity is an important part of the post-therapy imaging of the neck. Not all cases have had surgery or radiation. In some cases, imaging may be performed after chemotherapy to follow the response of a primary tumor or lymph node. A decision must be made regarding continuation of chemotherapy or perhaps whether or not a lymph node dissection is warranted. Such studies usually are done with direct comparison to the recent pretherapy study such as PET/CT performed with very similar techniques and usually are not as difficult to interpret. The choice of examination to follow the patient after therapy is controversial. Many specialized head and neck radiologists rely on contrast-enhanced CT. Others prefer PET/CT as it may increase conspicuity of a recurrence that may not be obvious otherwise. A post-therapy patient with difficulty handling secretions often will have problems with MRI.

(6) General Programming: WFNRS Presents: Highlights of the 24th Annual Meeting of SILAN

O-16 **8:45 AM - 8:55 AM**

The Mission, Vision and Trajectory of SILAN

Rojas, R.
Beth Israel Deaconess Medical Center
Brookline, MA.

Presentation Summary
The Mission, Vision, and Trajectory of SILAN. The SILAN Society, whose formal name is "Sociedad Iberolatinoamericana de Neurorradiología Diagnóstica y Terapéutica", is a nonprofit scientific professional organization established in 1988 by the initiative of Dr.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Juan Taveras and Dr. Fernando Viñuela. The SILAN Society is an inclusive educational society, composed by Spanish and Portuguese-speaking neuroscientists, involved in neuroimaging and neuro-intervention. Its members are neuroradiologists, neurologists, and neurosurgeons from Spain, Portugal, Canada, United States, and all Spanish and Portuguese-speaking countries in America. The goals of the SILAN Society are: • To promote the progress of diagnostic and therapeutic neuroradiology in the member countries. • To develop training programs in neuroradiology, benefiting young talents from the member countries, helping to develop the future generations of neuroimaging and neurointerventional specialists in Latin America, Spain, and Portugal. • To sponsor an annual Scientific Meeting, bringing to a different country each year the latest advances in neuroradiology and neuroscience, through oral communications, scientific exhibits, and educational activities. • To promote the publication of scientific papers in professional journals, emphasizing the participation of young neuroradiologists in training. • To sponsor short-term visiting fellowships and formal training fellowships, in institutions internationally recognized for excellence in the field. Since its establishment, the SILAN Board of Directors had the vision to create various scholarships in diagnostic and interventional neuroradiology. There are currently training scholarships in academic centers in Buenos Aires, Argentina, Barcelona and Zaragoza in Spain, Augusta Georgia, USA, Shreveport Louisiana, USA, and Puerto Rico. The support of our scholarship program has been centered on our recently established SILAN Foundation, created by the initiative of Dr. Alex Berenstein and the SILAN Board of Directors, channeling funds exclusively designated to support and expand our educational mission. The SILAN Society has unfailingly sponsored an annual scientific meeting for the last 25 years, characterized always by high academic standards, acting as the international forum for presenting the latest advances in diagnostic and therapeutic neuroradiology from Europe and Latin America. The SILAN Society is very proud to participate in the 51st Annual Meeting of the American Society of Neuroradiology, presenting some of the highlights of our past conference in Quito, Ecuador in 2012. We want to take this opportunity to invite you to the 25th SILAN Annual Meeting, to be held in Ciudad de Panama on June 17-21, 2013.

O-17 **8:55 AM - 9:15 AM**

Changes that Occur in the Intervertebral Disk in Astronauts Exposed to Zero Gravity

Riascos, R. F.
University of Texas Medical Branch
Galveston, TX.

Presentation Summary
Exposure to microgravity has an effect on the spine of the astronauts, specifically on the intervertebral disks. Astronauts have an increased risk for back pain and intervertebral disk herniation, thought to be a result of the exposure to microgravity. The mechanical forces on the intervertebral disk are different in space, where the lack of cyclic mechanical stressors may reduce the nutrition of the disk, increase its water content and alter the normal configuration of the nucleus pulposus and annulus fibrosus. Disk expansion has been described in astronauts after exposure to prolonged space flight. We will discuss the exercises available to the astronauts in space, and the tests that are performed to detect the cause of these changes in the astronaut population with the terrestrial and in-flight imaging modalities available.

O-18 **9:15 AM - 9:35 AM**

3D STIR and DTI from the Spinal Cord to Peripheral Nerves: Techniques, Tips and Tricks

Vargas, M.
Geneva University Hospital, Neuroradiology
Geneva, SWITZERLAND.

Dr. Vargas was born in Ecuador. She attended secondary school in Ecuador where she graduated summa-cum-laude. She obtained her medical degree in 1994 from the Catholic University of Guayaquil-Ecuador and then worked for one year in the Galapagos-Islands. In 1996 she received a full scholarship from the Swiss government to study radiology at Geneva University. She completed her residency in Radiology in 2001 and achieved radiologist status. She completed a fellowship in neuroradiology at Strasbourg-France in 2002 and returned to Geneva to complete this specialization in 2006. She obtained the title of "Privat Docent" (Assistant Professor) in 2011 and then in 2012 the title of Associated Professor (Charge de Cours) at Geneva University. From 2007 until 2010, she was responsible for the education program in radiology and neuroradiology in the Department of Radiology. She received an award for the management of patients at the MRI unit in 2011. Currently she is Assistant Radiologist, Associated Professor and Head of the MRI section at Geneva University Hospital. Her areas of interest include epilepsy, spinal cord, peripheral nerves, new neuroimaging techniques, PET-MR and management in radiology. She has published more than 70 scientific papers and is also the author of 9 book chapters.

Presentation Summary
The presentation will be divided into two main parts: 3D STIR SPACE and diffusion tensor imaging (DTI). During the presentation the following questions will be answered concerning each technique: What is it? How is it done? What are the limits and clinical indications? Examples of each point mentioned above will be shown at the level of the peripheral nerves and the spinal cord.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

O-19 **9:35 AM - 9:55 AM**

The Good, The Bad and The Ugly of the Flow Diverters for the Treatment of Aneurysms

Diaz, O. M.
The Methodist Hospital
Houston, TX.

Presentation Summary
The Pipeline embolization device (PED) is the only flow diverter FDA-approved on the market today. Flow diverters are tubular stent-like device that are placed within the parent artery crossing the aneurysm neck to divert flow away from the aneurysm to achieve aneurysm occlusion. The advantage of this new modality is seen especially in giant aneurysms, which are very difficult to treat and have a higher incidence of recanalization. As with all stents, dual antiplatelet medication is necessary with its inherent risks that is especially necessary to decrease the incidence of in-stent thrombosis due to the larger lumen of metal. New to this device are delayed aneurysm rupture and intraparenchymal hematoma distal to the aneurysm, which will be discussed.

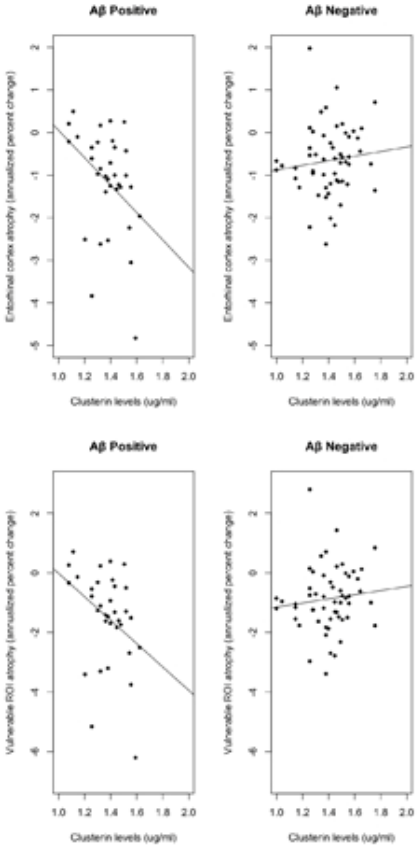
Amyloid-β Modulates the Effect of Clusterin on Alzheimer Neurodegeneration

Desikan, R. S.[1]·McEvoy, L.[1]·Thompson, W.[1]·Holland, D.[1]·Brewer, J.[1]·Andreassen, O.[2]·Dale, A.[1]
[1]University of California San Diego, San Diego, CA,
[2]University of Oslo, Oslo, NORWAY.

Purpose
Genome-wide association and biomarker studies indicate that clusterin (CLU) is associated with Alzheimer disease (AD). However, the mechanism by which CLU influences the earliest stages of the Alzheimer disease process is not well understood.

Materials & Methods
We examined 90 cognitively healthy older adults who underwent longitudinal MR imaging and baseline lumbar puncture. Using linear mixed effects models, we evaluated main and interactive effects between CSF CLU and CSF Aβ1-42, and CSF CLU and CSF phospo-tau (p-tau181p) on atrophy rate of the entorhinal cortex. We also examined the relationship between CSF CLU, CSF Aβ1-42, and CSF p-tau181p on atrophy rate of other AD-vulnerable neuroanatomical regions.
Results
We found a significant interaction only between CSF CLU and CSF Aβ1-42 on atrophy rate of the entorhinal cortex and other AD vulnerable regions indicating elevated volume loss in individuals with increased CLU and decreased CSF Aβ1-42. In contrast, we found no interaction between CSF CLU and CSF p-tau181p on brain atrophy.



Conclusion
Our findings indicate that in preclinical AD clusterin contributes to AD neurodegeneration predominantly via an Aβ-dependent mechanism.

3T MR Spectroscopy Reveals an Imbalance between Excitatory and Inhibitory Neurotransmitters in Amyotrophic Lateral Sclerosis

Foerster, B. R.[1]·Pomper, M. G.[2]·Callaghan, B. C.[1]·Petrou, M.[1]·Edden, R. A. E.[2]·Mohamed, M. A.[2]·Welsh, R. C.[1]·Carlos, R. C.[1]·Barker, P. B.[2]·Feldman, E. L.[1]
[1]University of Michigan, Ann Arbor, MI, [2]Johns Hopkins University, Baltimore, MD.

Purpose
To determine whether there are reductions in γ-aminobutyric acid (GABA) and elevations of glutamate + glutamine (Glx) levels in different brain regions of patients with amyotrophic lateral sclerosis (ALS) using proton magnetic resonance spectroscopy (1H-MRS).
Materials & Methods
Twenty-nine ALS patients and thirty age- and gender-matched healthy controls (HCs) underwent 3T short echo time (TE) and GABA-edited 1H-MRS centered on the left motor cortex (MC) and left subcortical white matter (SWCM). Short TE 1H-MRS also was performed centered on the pons. Data were analyzed using logistic regression, t-tests, and Pearson correlations. Post hoc analyses were performed to investigate differences between riluzole-naïve and riluzole-treated ALS patients.
Results
Amyotrophic lateral sclerosis patients had significantly lower levels of GABA in the MC compared to HCs (P<.01). Amyotrophic lateral sclerosis patients also had significantly lower levels of N-acetylaspartate (NAA) in MC (P<.01), SCWM (P<.05), and pons (P<.01) and higher levels of myo-inositol (mI) in MC (P<.001) and SCWM (P<.01) compared to HCs. Compared to riluzole-treated ALS patients, riluzole-naïve ALS patients had higher levels of Glx in MC (P<.05) and pons (P<.01), higher levels of Cr in MC (P<.001) and SWCM (P=.05), and higher levels of NAA in MC (P<.01).
Conclusion
There are reduced levels of GABA in the motor cortex of ALS patients. There are elevations of Glx in riluzole-naïve ALS patients compared to ALS riluzole-treated patients. These results point to an imbalance between excitatory and inhibitory neurotransmission, contributing to the pathogenesis of ALS.

KEYWORDS: Amyotrophic lateral sclerosis, MR spectrocopy

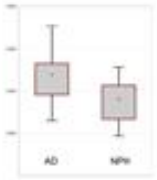
Sulcal Pattern Analysis Using Earth Mover Distance Differentiates Shunt-Responsive Normal Pressure Hydrocephalus from Alzheimer Disease

Rusinek, H.·Tyagi, V.·Serulle, Y.·Thakur, S.·Nutanson, I.·Gonen, O.·Shepherd, T.·Golomb, J.·George, A.
New York University School of Medicine
New York, NY.

Purpose
In patients with cognitive impairment and dilated ventricles, it can be difficult to differentiate normal pressure hydrocephalus (NPH) from cerebral atrophy associated with Alzheimer disease (AD). Existing radiologic criteria include quantitative volumetry of global gray matter and ventricles, and assessment for hippocampal atrophy. Patterns of sulcal widening also are used to differentiate the two conditions. This study evaluated the quantitative assessment of sulcal size and distribution of sulcal enlargement to distinguish between NPH and AD.
Materials & Methods
Subjects (17 AD, 15 NPH, 11 healthy elderly) received clinical and cognitive evaluation at the NYUMC Aging and Dementia center. High-resolution T1-weighted images (MPRAGE, Siemens 1.5T) from preshunt NPH and AD patients were used. Sulcal masks were obtained by automated segmentation. Masks were partitioned into eight 45^{o} wedges, resulting in a series V(θ), where V is the sulcal CSF volume and θ the polar angle encircling the axial section clockwise (left frontal→left temporal→left parietal→left occipital→right occipital⋯etc). Mean sulcal volume Vavg was computed for each subject and each sector, yielding the relative volume distribution D(θ) = V(θ)/Vavg. Differential earth mover's distance (EMD) measure then was computed for each subject using the NPH group pattern as reference.
Results
Sulcal volume was significantly larger in AD (3.19±0.68, mean±SD) compared to healthy controls (1.79±0.45), p=0.000001, T=6.02. Volume also was increased in NPH (2.87±0.76), p=0.0002, T=4.17 compared to healthy controls, but there was no volume difference between NPH and AD. Sulcal pattern as expressed by EMD, however, differentiated AD (0.482+0.131) from NPH (0.353+0.103), p=0.002, T=3.07 (Figures).

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Distribution of sulcal pattern index in AD and NPH groups. Dot = median, box = two middle quartiles, whiskers = minimum and maximum.

Polar plot (in blue) of relative sulcal volume in NPH patients. The green circle indicates homogenous distribution. NPH shows relatively smaller sulci in parietal and temporal lobes, larger sulci in the frontal lobes

Conclusion
Normal pressure hydocephalus is characterized by a predominantly frontal lobe distribution of larger sulci while AD is characterized by a predominately temporal and parietal lobe distribution of large sulci. The observed highly significant pattern difference between NPH and AD patients may help identify candidates for shunt placement.

KEYWORDS: Normal pressure hydrocephalus, Alzheimer disease

O-24 **11:09 AM - 11:17 AM**

Age-Matched Quantitative Atrophy Mapping in a Large Clinical MR Imaging Sample

Wright, B. W.·Anderson, J. S.
University of Utah
Salt Lake City, UT.

Purpose
Although neuroradiologists have long recognized that brains tend to atrophy with age, descriptions of atrophy in radiology reports are seldom more specific than “age-appropriate,” “mild,” “moderate,” or “severe.” Recent work has shown that atrophy in neurodegenerative diseases is not diffuse or random, but rather involves large-scale functional connectivity networks that are correlated with gray matter volume (Seely 2009). Our goals were (1) to identify patterns of atrophy in a large clinical MRI sample and (2) to create age-matched atrophy maps based on these data.
Materials & Methods
Most of the brain MRI exams at our institution currently include an MPRAGE sequence that undergoes brain tissue segmentation using SPM8 software (modulated, normalized). Five hundred (about 40%) of the MRI exams performed during a specified time period met the inclusion criteria of this study: ages 20-80 years, successful segmentation, and no tumor, stroke, or history of intracranial surgery. The tools of source-based morphometry (Xu 2009) were applied to identify independent components with similar covariance across subjects from the segmentation data. A model order of 16 was identified as optimal (Xu 2009) and 10 non-noise components were present by inspection. K-means clustering of voxels in a gray matter restriction mask based on their Z-scores in the independent components produced a 10-cluster parcellation of brain regions showing similar covariance across subjects.
Results
Ten bilaterally symmetric anatomical clusters were identified from the MRI segmentation data, including a frontal cluster, anterior temporal cluster, occipital cluster, and others. Notably, one cluster corresponds anatomically to the posterior nodes of the default mode network, specific brain regions (posterior cingulate/precuneus and bilateral lateral parietal) that demonstrate synchronous activity during rest on fMRI and may be disrupted preferentially in Alzheimer disease. Age-matched atrophy maps based on these 10 clusters appear to be robust to gyral/sulcal variation in individual subjects given the large cluster size.
Conclusion
Based on source-based morphometric analysis of segmented gray matter images from a large clinical MRI sample (n = 500), we have parcellated the brain into 10 clusters that tend to covary similarly across subjects from 20 to 80 years old. Rapidly accessible, evidence-based atrophy maps will enable neuroradiologists to make more specific, clinically relevant observations about quantitative brain atrophy patterns in time consistent with clinical workflow.

KEYWORDS: Brain aging, Brain morphometry, Brain mapping

How Sensitive Are the Proposed Imaging Criteria for the Diagnosis of the Primary Progressive Aphasia?

Sajjadi, S. A.[1]·Sheikh Bahaei, N.[1]·Scoffing, D.[2]·Cross, J.[2]·Gillard, J.[1]·Nestor, P. J.[1]
[1]University of Cambridge, Cambridge, UNITED KINGDOM,
[2]Addenbrooke's Hospital, Cambridge, UNITED KINGDOM.

Purpose
Primary progressive aphasia (PPA) is a major subtype of frontotemporal dementia. It is a clinically and pathologically heterogeneous condition. Nonfluent (nfv), semantic (sv), logopenic (lpv) and mixed PPA are the

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

currently recognized variants. To circumvent the uncertainty surrounding the early diagnosis of PPA subtypes on clinical grounds alone, the recent recommendations on classification of PPA have advocated certain patterns of atrophy as supporting features for the diagnosis of PPA variants. Perhaps surprisingly, the recommendations are all based upon group-level statistical comparisons of PPA subjects against control participants. It is, however, unknown whether individual patients present with the prescribed patterns of atrophy. The aim of the present study was to evaluate the utility of the proposed imaging criteria and to assess the neuroradiologists' intra- and inter-rater agreement.
Materials & Methods
The cohort comprised 51 patients with a root diagnosis of PPA and 26 matched control participants. The breakdown of the PPA subjects was 21 svPPA, 14 nfvPPA, 14 mixed PPA, and 2 lvPPA. All study participants were scanned on a Siemens Trio 3T system. T1-weighted anatomical images were acquired using 3D magnetization-prepared, rapid gradient-echo (MPRAGE). Statistical parametric mapping (SPM) implemented in SPM5 was used for group level comparison of patient groups against control participants. Three neuroradiologists - blind to the clinical diagnoses - separately reported all unprocessed T1 sequences. In order to assess intra-observer agreement, 28 scans (N = 7) for each diagnostic group) were duplicated.
Results
There was no statistical difference between the groups for any of the demographic parameters. Assessment of the sensitivity of the proposed imaging markers, based on the lobar distribution of the abnormalities, revealed almost perfect results in the svPPA individuals (Mean: 98%) but low sensitivity in the other PPA variants. Imaging markers were least sensitive for the diagnosis of the nfvPPA participants (Mean: 29%). In terms of the intra-rater agreement values, with the exception of the nfvPPA group the mean kappa values in the other groups were above the widely accepted threshold of 0.6. Pair-wise inter-observer agreement outcome indicated a similar dichotomized pattern of perfect agreement in the svPPA group but only moderate agreement for mixed and nfvPPA.
Conclusion
This study provides the first objective assessment of the utility of the proposed imaging markers in supporting the diagnosis of various PPA variants. While the group level atrophy patterns were in precise agreement with the proposed imaging criteria reliability of the proposed measures at a single-subject level is necessary for determining the diagnostic utility of the proposed criteria.

Objective Criteria Utilizing Unique Midbrain Angle Measurements to Evaluate for Progressive Supranuclear Palsy

Raz, E.[1]·Dietrich, A.[1]·Shields, M.[1]·Pantano, P.[2]·Piattella, C.[2]·Fatterpekar, G.[1]
[1]New York University, New York, NY, [2]Sapienza University, Rome, ITALY.

Purpose
Progressive supranuclear palsy (PSP) is the second most common neurodegenerative cause of parkinsonism (after Parkinson disease). It is characterized by midbrain atrophy, identified qualitatively on imaging as the "hummingbird" sign. However, this appearance is sometimes difficult to assess and also can be seen in patients other than PSP. The purpose of our study was therefore to identify objective measurement criteria to evaluate for midbrain atrophy in routine clinical practice for diagnosing PSP.
Materials & Methods
MR imaging obtained in 15 patients with progressive supranuclear palsy which included a T1-MPRAGE, were identified retrospectively. Thirty healthy age-matched subjects (imaging studies obtained for headache or dizziness with no history of dementia), 15 patients with multiple system atrophy (MSA) and 20 patients with Parkinson disease were used as controls. Two neuroradiologists assessed these studies evaluating three angles: (1) internal ventral cerebral peduncle angle (ivCPA), defined as the angles comprised between the cerebral peduncles, (2) external dorsal cerebral peduncle angle (edCPA), (3) external ventral cerebral peduncle angle (evCPA). The studies were evaluated for any statistically significant difference between the different populations using a t test and an ANOVA. Inter- and intra-observer variability were assessed using a Bland-Altman analysis.
Results
For observer one, the ivCPA, edCPA, and evCPA average measurements were: PSP patients [62º (6.7); 84.6º (13.7); 68.8º (14.6)]; healthy controls [52.2º (9.7); 66.4º (10.8); 81.8º (12.5)]; MSA [55.2º (11.2); 74.2º (14.7); 87.5º (9.4)]; Parkinson disease [54.1º (8.4); 77.3º (9.20); 83º (12.7)]. For observer two, the ivCPA, edCPA, and evCPA average measurements were: PSP patients [75.7º (4.0); 75.7º (4.0); 75.7º (4.0)]; healthy controls [62.2º (7); 59.6º (12.1); 71.5º (13.8)]; MSA [53.4º (7); 75.7º (8.2); 83.4º (4.0)]; Parkinson disease [53.4º (3.0); 73.7º (7.3); 85.7º (9.3)]. A statistically significant difference was noted by both observers in the ivCPA measurements (observer 1: $p<0.001$; observer 2: $p = 0.024$) between PSP and all the other subjects. The other two angles were not significantly difference. The Bland-Altman analysis for inter- and intra-observer variability demonstrated a bias of -6.9º (6.8, -20.4 - 6.7), -25.5º (8.1, -41.8 - -9.2), and -0.6º (11.9, -4.4 - 23.2) for angles ivCPA, edCPA, and evCPA, respectively.
Conclusion
Utilizing unique midbrain angle measurements, especially

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

ivCPA measurement, helps to accurately assess for midbrain atrophy in patients with PSP.

Brain MR Imaging Findings in Fragile X Premutation Carriers with and without the Fragile X Tremor Ataxia Syndrome

Brunberg, J. A.[1]·Adams, P.[1]·Mu, Y.[2]·Tassone, F.[2]·Seritan, A.[1]·Boyd, A.[1]·Nguyen, D.[2]·Hagerman, P.[2]·Hagerman, R.[1]
[1]University of California Davis, Sacramento, CA, [2]University of California Davis, Davis, CA.

Purpose
FXTAS is diagnosed in aging previously normal relatives of children with mental retardation due to fragile x syndrome, and in elderly patients, having no known family history of childhood cognitive impairment, who present with gait instability, tremor, autonomic instability, neuropathy, and/or cognitive decline. To expand our prior reports of FXTAS-associated MR findings, an independent cohort of control subjects and male fragile-x premutaton carriers, with and without FXTAS, was evaluated.
Materials & Methods
MR imaging was completed in 65 premutation carriers, 52 of whom had FXTAS, and in 37 controls. Clinical neurologic findings sorted the premutation carriers into two groups: those with normal (n = 7) or with only questionable tremor or balance problems (n = 6) who were classified as unaffected, and into those with tremor or balance problems that were mild (n = 13), moderate with occasional falls (n = 19), severe requiring a cane or walker (n = 16), or severe requiring a wheelchair (n = 4), who were classified as having FXTAS. Age, clinical staging, number of CGG repeats in the 5' untranslated X-chromosome region, and psychometric testing were correlated with MR imaging findings. Images were characterized for altered size and T2SI within supratentorial and infratentorial regions of interest. Linear measurements were made of the pons, middle cerebellar peduncles (MCP) and ventricles. Imaging findings in supratentorial and infratentorial ROIs were characterized otherwise as normal or as demonstrating mild, moderate or severe abnormality.
Results
Significant ($p < 0.025$) differences were found between FXTAS and unaffected permutation carriers for the presence of increased T2SI involving MCPs, cerebellar deep WM, pons, subependymal and deep cerebral WM, body and splenium of the corpus callosum, columns of the fornix, and gray and white matter immediately deep to the insular cortex. Significant ($p < 0.025$) volume loss was demonstrated in FXTAS versus unaffected carriers, as enlarged cerebral and cerebellar sulci, as lateral and III ventricular enlargement, as volume loss involving the amygdala and hippocampal gyri, and as diminished dimensions of the pons and MCPs. Mean CGG length was significantly ($p<.0001$) increased in FXTAS (100.3 $\pm$ 18.1) versus asymptomatic carriers (80.8$\pm$ 16.4), and in asymptomatic carriers versus normal controls (28.8 $\pm$ 4.4).
Conclusion
Adult symptomatic fragile-x premutation carriers demonstrate characteristic MRI findings of cerebral, brainstem and cerebellar volume loss, with increased T2SI in MCPs, cerebral and cerebellar WM, in subinsular gray and white matter, and in the body and splenium of the corpus callosum. The presence and severity of imaging findings statistically correlate with clinical staging of tremor and balance dysfunction, with the presence and severity of cognitive and behavioral alterations, and with CGG repeat length in permutation carriers. FXTAS must be included in the differential diagnosis for MR imaging studies obtained on adult subjects presenting with tremor, gait instability and/or cognitive impairment.

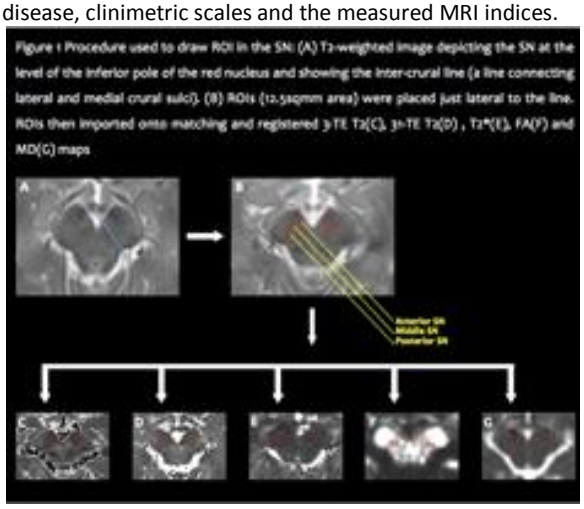
Substantia Nigra in Parkinsonian Disorders: A Multimodal MR Imaging Assessment at 3T

Al-Helli, O.·Massey, L.·De vita, E.·Thornton, J.·Yousry, T.
University College London
London, UNITED KINGDOM.

Purpose
The substantia nigra (SN) is a key nucleus in the pathogenesis, pathology, and treatment of Parkinsonian disorders. It is sometimes difficult to clinically differentiate Parkinson disease (PD) from its mimics - Progressive supranuclear palsy (PSP) and Multi-system atrophy (MSA). We performed a clinico-radiologic, cross-sectional, case-control multimodal MRI study.
Materials & Methods
Fifty-nine subjects were recruited: 20 patients with PD, 20 with PSP and 19 with MSA in addition to 20 age- and gender-matched control subjects were scanned using a multi-sequence MRI protocol that included: multi-echo (3 and 31 echo times) T2 relaxometry, T2* relaxometry and MTR sequences, ROIs were defined on T2-weighted images and transferred to the co-registered T2, T2*, FA and MD maps. SPSS 20.0 for Mac was used for statistical analysis.
Results
There were no between-group differences in age at onset or disease duration. The PSP group had higher clinimetric scores on the Hoehn & Yahr, UPDRS parts II scales. Our T2, T2*, MD and FA values of the STN are comparable to those of previous studies. Values were overlapping between the four subject groups, and did not correlate with age, disease duration or clinimetric scores. T2 obtained using the 31-TE sequence of the posterior part of the SN in the PD patients were significantly lower than in PSP, MSA and

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

controls, whereas T2 obtained from 3-TE sequence showed only a trend for lower values. T2* values were lower in the posterior part of the SN in the PD group in comparison to the other groups. However, such difference was not statistically significant. Fractional anisotropy and MD values between disease groups did not show significant differences. Contrary to other studies, we have not found significant correlation between age, duration of disease, clinimetric scales and the measured MRI indices.



Conclusion

Using 31-TE T2 sequence, there are significant differences in T2 relaxation times in the posterior part of the SN in PD in comparison to control and PSP groups. However, in order to find clinical utility there are several hurdles that need to be overcome including differences in scanning parameters and differences in signal-to-noise ratio between 3T systems at different sites using different systems, and difficulties with reproducing accurate region-of-interest studies between observers particularly in small midbrain structures.

Role of Apolipoproteins in Preclinical Alzheimer Disease

Desikan, R. S.[1]·McEvoy, L.[1]·Thompson, W.[1]·Holland, D.[1]·Brewer, J.[1]·Andreassen, O.[2]·Dale, A.[1]
[1]University of California San Diego, San Diego, CA, [2]University of Oslo, Oslo, NORWAY.

Purpose

Epidemiological and genetic studies indicate an association between hypercholesterolemia and Alzheimer disease (AD). Here, we examined the relationship between cerebrospinal fluid (CSF) levels of apolipoproteins (Apo), proteins that bind lipids, and AD-associated neurodegeneration.

Materials & Methods

We examined 90 cognitively healthy older adults who underwent longitudinal MR imaging and baseline lumbar puncture. Using a linear mixed effects model, we evaluated the relationship between CSF levels of Apo A-I, Apo C-III, Apo-D, Apo-E, and Apo-H and entorhinal cortex atrophy rate. We also examined whether an interaction between CSF apolipoprotein levels and CSF $A\beta_{1-42}$, CSF phospo-tau ($p\text{-}tau_{181p}$), and CSF tau effects entorhinal cortex atrophy rate.

Results

We found a significant relationship between CSF Apo C-III and entorhinal cortex atrophy rate. We also found a significant interaction between CSF Apo C-III and CSF $A\beta_{1-42}$ on entorhinal cortex atrophy rate. In the presence of CSF $A\beta_{1-42}$, CSF Apo C-III significantly associated with volume loss of the entorhinal cortex; in the absence of CSF $A\beta_{1-42}$, the relationship between CSF Apo C-III and brain atrophy was not significantly different from zero. We found no interaction between CSF Apo C-III and CSF $p\text{-}tau_{181p}$ or tau on brain atrophy.

Conclusion

Our findings suggest that a synergistic interaction between intracranial lipid biology and amyloid pathology underlies the earliest stages of Alzheimer neurodegeneration. These findings have implications for early AD prevention strategies.

Application of a Radiologic Severity Score for Brain Amyloid-Related Imaging Abnormality with Edema or Effusion in Phase 3 Clinical Trials of Intravenous Bapineuzumab in Alzheimer Disease

Ketter, N.[1]·Barkhof, F.[2]·Miaux, Y.[3]·Arrighi, H.[1]·Guenzler, V.[1]·Purcell, D.[4]·Gass, A.[5]·Collins, P.[1]·Miloslavsky, M.[1]·McGovern, M.[1]·Morris, K.[1]·Brashear, H.[1]
[1]Janssen Alzheimer Immunotherapy R&D, LLC, South San Francisco, CA, [2]VU University Medical Center, Amsterdam, NETHERLANDS, [3]Synarc, Newark, CA, [4]California Pacific Medical Center, San Francisco, CA, [5]Universitätsklinikum Mannheim, Mannheim, GERMANY.

Purpose

To assess the extent and severity of amyloid-related imaging abnormality with edema (ARIA-E), and other MRI findings in mild to moderate Alzheimer disease patients, in 2 phase 3 placebo-controlled clinical trials of bapineuzumab. Background: ARIA-E is defined by parenchymal or sulcal FLAIR hyperintensity on MRI, consistent with edema or effusion. The relationship of ARIA-E with other MRI findings such as gyral swelling, ARIA-H [(hemosiderin deposition (small HD or microhemorrhages) and Age Related White Matter Changes (ARWMC)] is not well understood.

Materials & Methods

A total of 15,713 MRI scans in 1,331 APOE*E4 noncarriers and 1,121 APOE*E4 carriers were reviewed by five pairs of

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

trained neuroradiologists after patients had completed trial participation using a standardized, sequential, locked reading process. Differences in final results within a pair were adjudicated by consensus. The extent and location of sulcal hyperintensity, parenchymal hyperintensity, and gyral swelling were recorded for each brain region in addition to ARIA-H, ARWMC and other findings.
Results
ARIA-E was identified in 243 subjects. The incidence of treatment-emergent ARIA-E was higher in APOE*E4 carriers (active 21.2%; placebo 1.1%) than in noncarriers (active 7.1 %, placebo 0.6%). The mean maximum ARIA-E score was slightly higher in patients treated with the same dose in APOE*E4 noncarriers (14.0) than carriers (12.3); there was a trend towards lower scores when ARIA-E occurred with later infusions in APOE*E4 noncarriers. The overall agreement for the five pairs of neuroradiologists was good for both presence of ARIA-E (kappa 0.73) and ARIA-H (kappa 0.69). For the presence of parenchymal hyperintensity, sulcal hyperintensity and gyral swelling, the kappas were 0.63, 0.72, and 0.70, respectively. Within reader pairs, the intraclass correlation coefficient for severity scores was lowest for gyral swelling, highest for sulcal hyperintensities and intermediate for parenchymal hyperintensities. Gyral swelling was not found in the absence of sulcal/parenchymal hyperintensity. The mean maximum radiologic scores were similar in patients regardless of whether they were dosed through an episode of ARIA-E or not. Patients with pre-existing sHDs at baseline had a higher incidence of ARIA-E. There was a higher incidence of treatment-emergent sHDs in APOE*E4 carriers than noncarriers and a higher incidence with increasing dose in noncarriers. The incidence proportion of ARIA-E was higher in patients with a higher ARWMC score. The presence of radiologic evidence of ARIA-E generally was not associated significant clinical symptoms. Preliminary analyses did not show evidence of ARIA-E-associated decline in cognition or function.
Conclusion
Slightly higher total maximum ARIA-E radiologic scores were noted in APOE*E4 carriers at the equivalent dose; the highest scores were seen with ARIA-E that occurred early in APOE*E4 noncarriers. Bapineuzumab dosing may not need to be withheld in the presence of asymptomatic ARIA-E as continued dosing was not associated with a worse radiologic or clinical outcome. A relationship of the severity of ARIA-E to presence and quantity of amyloid remains to be assessed. The radiologic score of ARIA-E may be a useful parameter when differentiating doses or treatments and the scale provides a reliable quantitative assessment of radiologic severity and location.

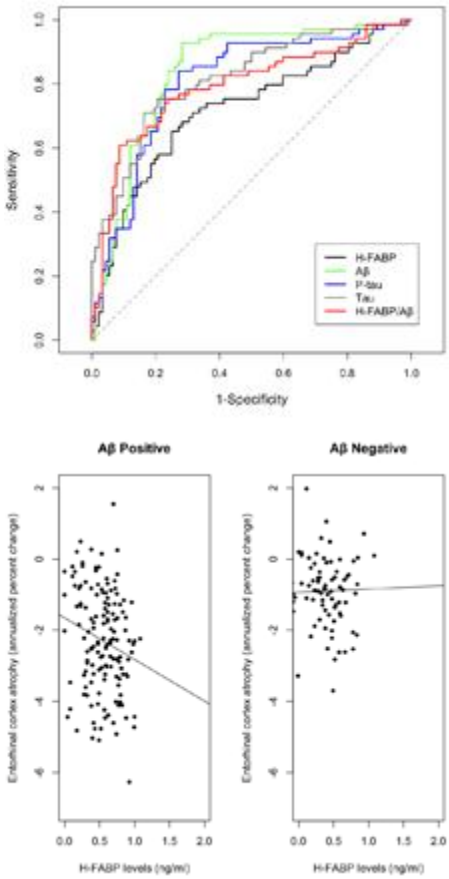
Heart Fatty Acid Binding Protein: A Biomarker for Alzheimer Disease

Desikan, R. S.[1]·McEvoy, L.[1]·Thompson, W.[1]·Holland, D.[1]·Brewer, J.[1]·Andreassen, O.[2]·Dale, A.[1]
[1]University of California San Diego, San Diego, CA, [2]University of Oslo, Oslo, NORWAY.

Purpose
Epidemiological and experimental findings suggest a relationship between Alzheimer disease (AD) and dyslipidemia. Here we evaluated the feasibility of using heart fatty acid binding protein (H-FABP), a carrier protein of fatty acids, as a diagnostic and prognostic marker of AD neurodegeneration.
Materials & Methods
We assessed longitudinal structural magnetic resonance imaging and baseline cerebrospinal fluid (CSF) levels of H-FABP, amyloid-β (Aβ1-42), tau and phospho-tau (p-tau181p) in 229 nondemented individuals (90 cognitively normal older adults and 130 memory impaired individuals). For comparison, we also evaluated 69 patients with AD.
Results
Cerebrospinal fluid H-FABP and H-FABP/Aβ levels differentiated patients with AD from cognitively normal older adults. Among individuals with memory impairment, CSF H-FABP/ Aβ1-42 levels significantly predicted time to progress to AD. Among nondemented older individuals, CSF H-FABP levels significantly correlated with CSF levels of Aβ1-42, tau, and p-tau181p and longitudinal atrophy of the entorhinal cortex and other AD-vulnerable brain regions. In a linear mixed effects model, there was a significant interaction between CSF H-FABP and CSF Aβ1-42 on atrophy of the entorhinal cortex and other AD-vulnerable brain regions. In the presence of Aβ1-42, CSF H-FABP was significantly associated with volume loss; in the absence of Aβ1-42, there was no relationship between CSF H-FABP and brain atrophy. There was no interaction between CSF H-FABP and CSF tau or CSF p-tau181p on atrophy of the entorhinal cortex and other AD-vulnerable brain regions.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Conclusion
Our findings suggest the diagnostic and prognostic utility of CSF H-FABP and H-FABP/ Aβ1-42 as an AD biomarker. These results also indicate that a synergistic interaction between lipid biology and Aβ pathology underlies Alzheimer neurodegeneration.

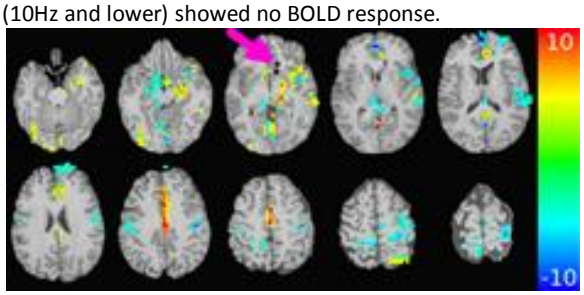
Direct Intracranial Stimulation and Simultaneous Functional MR Imaging Using Implanted Electrodes

Jones, S.·Avitsian, R.·Bhattacharyya, P.·Bulacio, J.·Enatsu, R.·Gonzalez-Martinez, J.·Nair, D.·Najm, I.·Phillips, M.·Zhang, M.
Cleveland Clinic Foundation
Cleveland, OH.

Purpose
Cortico-cortical evoked potentials (CCEPs) use direct intracranial electrical stimulation (DES) and recording to study electrophysiologic connectivity (EC), helping identify the epileptogenic zone (EZ) and networks and guide resective surgery. The fMRI BOLD response also can reveal networks. We present the first investigation of simultaneous BOLD response to DES using stereotactic EEG (SEEG) electrodes. Unlike prior related studies, we compare stimulated EC and BOLD activation throughout the brain, in human subjects and in the context of intractable epilepsy.
Materials & Methods
Epilepsy patients undergoing invasive surgery evaluation were implanted with up to 16 SEEG electrodes. Cortico-cortical evoked potentials were recorded while stimulating the hypothesized EZ and non-EZ control areas (1Hz, 8mA), using the RMS as a measure of EC. During explantation, one electrode remained for stimulation, and fMRI was performed in an intraoperative MRI while under general anesthesia, using a block paradigm for DES. Four acquisitions included 20Hz stimulation of the hypothesized EZ at low (4mA) and high (8 or 15mA) current, with similar control stimulation of distal contacts. Functional MRI analysis used AFNI. Extensive safety testing on phantoms preceded this investigation. Seven patients have been imaged to date.
Results
The figure shows a typical pattern of BOLD activation(threshold $|t| > 3$), with signal changes up to 4%. Stimulated contacts (15mA) were in the medial left orbitofrontal lobe (arrow), deemed in the EZ. There is strong network activation in the limbic system, extending to the hippocampus and lateral orbitofrontal lobe. Also evident is strong negative activation. Cortico-cortical evoked potentials activity at recording contacts showed significant correlation with fMRI *t*-values (r = .45, p = 8.6e-

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

6). Other patients also showed activation networks, with varying CCEP-fMRI correlation (*r* between .2 and .6). Activated networks are similar for low and high current stimulation. Two patients showed greater activation when stimulated in the EZ versus non-EZ, while two others showed the opposite pattern. Low frequency stimulation (10Hz and lower) showed no BOLD response.



Conclusion
To our knowledge, we present the first simultaneous DES-fMRI experiment in humans with comparison to EC. Further experiments will explore optimal stimulation parameters and effects of the EZ, but early data show stimulated fMRI patterns are consistent with CCEPs. Given the clinical utility of CCEPs and complete spatial coverage afforded by fMRI, this technique has great potential for aiding epilepsy surgery. Studying CCEPs and BOLD in tandem can improve our understanding of both processes, in particular basic mechanisms of BOLD.

Role of the Secondary Motor and Language Cortices in Postoperative Morbidity and Mortality: A Retrospective Functional MR Imaging Study of Surgical Planning for Patients with Intracranial Tumors

Maksimovic, J. H.·Voss, J.·Meier, T.·Friedel, R.·Prabhakaran, V.
University of Wisconsin
Madison, WI.

Purpose
Functional magnetic resonance imaging (fMRI) commonly is utilized by neurosurgeons to pre-operatively identify brain regions associated with essential behaviors, such as language and motor abilities. This study investigated the relationship between the distance from tumor border area to functional activations in secondary motor and language cortices to patient morbidity and mortality.
Materials & Methods
Subjects were selected from a database of 423 patients who received pre-operative fMRI at the University of Wisconsin Hospital and Clinics between June 1999 and July 2011. Of these, 52 patients had tumors encroaching on the secondary motor area and 72 patients had tumors encroaching on the secondary language area. The lesion-to-activation distance (LAD) was measured in each subject relative to the supplementary motor area for motor tasks and pre-supplementary motor area for language tasks. The LAD were categorized into the following: 1) less than 1 cm, 2) between 1 and 2 cm, and 3) greater than 2 cm. The association between LAD and the incidence of deficits was investigated using Fisher's exact tests of significance. Any record of preoperative or postoperative weakness and/or aphasia was included in the analysis as deficits. Mortality information was collected for all patients using medical records that were cross referenced with multiple sources. The impact of other variables, including age, handedness, gender, and tumor grade also were investigated. In a subset of subjects, logistic regression was performed to identify the likelihood of deficits based on LAD to primary and secondary regions. Finally, Mantel-Cox log-rank tests were performed to determine whether survival time significantly related to LAD to secondary motor and language areas.
Results
A significant association was observed between LAD to the SMA and the incidence of motor deficits, with the percentage of patients with deficits dropping for those in the LAD > 2 cm group. The relationship between LAD to the pSMA and the incidence of language deficits was not significant. Logistic regression demonstrated that the LAD to primary sensorimotor cortex does affect the incidence of motor deficits, but LAD to SMA does not. Finally, we observed no relationship between LAD to secondary regions and patient mortality.
Conclusion
This investigation of the relationship between tumor distance to fMRI responses in secondary language and motor areas shows a significant association with the incidence of language and motor deficits. These results demonstrate that LAD to SMA structures does affect morbidity, although not to the extent of LAD to primary structures. In addition, motor deficits are significantly associated with LAD to secondary structures, but language deficits are not. This should be considered by neurosurgeons for patient consultation and pre-operative planning.

Changes in Functional MR Imaging Functional Connectivity of Distributed Neural Networks after Selective Thalamic Ablation in Humans

Druzgal, T. J.·Wintermark, M.·Huss, D.·Loomba, J.·Khaled, M.·Frysinger, R.·Monteith, S.·Sperling, S.·Elias, J.
University of Virginia
Charlottesville, VA.

Purpose
Magnetic resonance-guided focused ultrasound (MRgFUS) is an emerging technology for performing targeted

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

neurosurgery without skin incisions. In a cohort (n = 15) of patients with essential tremor, we have used MRgFUS to ablate the ventral intermediate nucleus (Vim) of the thalamus corresponding to the dominant hand of each patient. For the majority of our patients, the clinical results of this trial have been striking, immediate, and durable at one-year followup. Compared to the established treatment of deep brain stimulator placement, the MRgFUS technique also provides a unique opportunity to use blood oxygen level dependent (BOLD) functional magnetic resonance imaging (fMRI) to study the effects of focal brain lesions on distributed neural networks.
Materials & Methods
Resting-state BOLD fMRI data and MPRAGE anatomical data were obtained successfully from 14 patients on a Siemens Trio MRI. Data were obtained both before and after unilateral Vim ablation with MRgFUS. The Data Processing Assistant for Resting-State fMRI Advanced Edition (DPARSFA) was used both for data preprocessing and to assess changes in the temporal synchrony of the motor networks as a result of the MRgFUS ablation. DPARSFA preprocessing included steps of: fMRI data realignment, coregistration of anatomical and fMRI data, nuisance covariate regression, and motion scrubbing. After calculation of functional connectivity metrics - such as degree centrality - the output data for each subject was normalized to a standard template brain. If individual voxels within brain regions are characterized as nodes in a larger network, degree centrality of each node can be characterized by the edges connected to each node. The edges in the network are defined by peak cross-correlation of resting state functional MRI time series between individual nodes. The strength of each node is defined as the sum of weights from edges connecting to a node. For an individual voxel, this sort of analysis represents an assay of how closely its activity is tied to activity in the remainder of the brain.
Results
Degree centrality analyses reveal that focal ablation of the Vim nucleus of the thalamus has broad effects in the node strengths throughout the core of the motor network (primary motor cortex, premotor cortex, and cerebellum). In addition, changes in functional connectivity extend to frontal regions not typically described as core motor areas. Several of these frontal regions have been suggested to perform general control and inhibition that modify basic motor phenomena.
Conclusion
These findings begin to suggest mechanisms whereby neurodegeneration of deep gray nuclei (a common theme across several movement disorders) may result in the more subtle cognitive effects associated with conditions such as essential tremor.

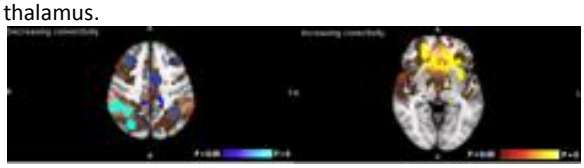
Longitudinal Changes in BOLD Functional Connectivity after Mild Traumatic Brain Injury Revealed by Serial Resting-State Functional MR Imaging

Liu, C. J.·Li, Y.·Cooper, S. R.·LaHue, S. C.·Manley, G. T.·Mukherjee, P.
University of California San Francisco
San Francisco, CA.

Purpose
Cognitive impairment following mild traumatic brain injury (mTBI) has been hypothesized to result from disruption of white matter tracts connecting disparate brain regions. We use resting-state functional MRI (fMRI) to investigate longitudinal changes in functional connectivity following mTBI.
Materials & Methods
Twenty-two subjects who have suffered mTBI (Glasgow Coma Scale 13-15 in the Emergency Department), with loss of consciousness less than 30 minutes and post-traumatic amnesia less than 24 hours, underwent resting state fMRI at <2 weeks after the injury and again at six months after the injury. All mTBI patients were imaged on a 3T scanner with a whole-brain 2D multislice single-shot gradient echo blood oxygenation level-dependent (BOLD) sequence (TE 28 ms, TR 2000 ms). Two hundred brain volumes were collected in seven minutes. The data were analyzed after correction for subject motion supplied in the FMRIB Software Library (FSL) toolbox. Fifteen seed regions of interest (ROIs) for computing resting-state networks were chosen from a literature review of BOLD functional connectivity following head trauma. A one-sample randomized test was performed to generate the group level functional connectivity map, with a two-tailed two-sample nonparametric permutation test applied to z-scores on voxels with group significance from the one sample test to examine for statistically significant group differences within subjects between the <2 weeks and six-month time points. The resulting difference maps were thresholded by cluster area size and then corrected for multiple comparisons at a false discovery rate of $p < 0.05$.
Results
Comparisons of the functional connectivity maps of mTBI subjects at <2 weeks versus six months after injury demonstrates decreasing connectivity over time in the right supramarginal gyrus and right precuneus at six months compared to the acute time point. There is increasing connectivity at six months compared to <2 weeks in bilateral orbitofrontal cortex, anterior cingulate gyrus, inferior temporal gyrus, amygdala, caudate, and thalamus.



Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Conclusion
The serial resting-state fMRI findings demonstrate statistically significant changes in functional connectivity between acute and chronic time points after mTBI. Some regions show decreasing connectivity over time, whereas others show increasing connectivity. These complex patterns may result from both long-term degenerative changes following mTBI as well as compensatory changes such as neuroplasticity.

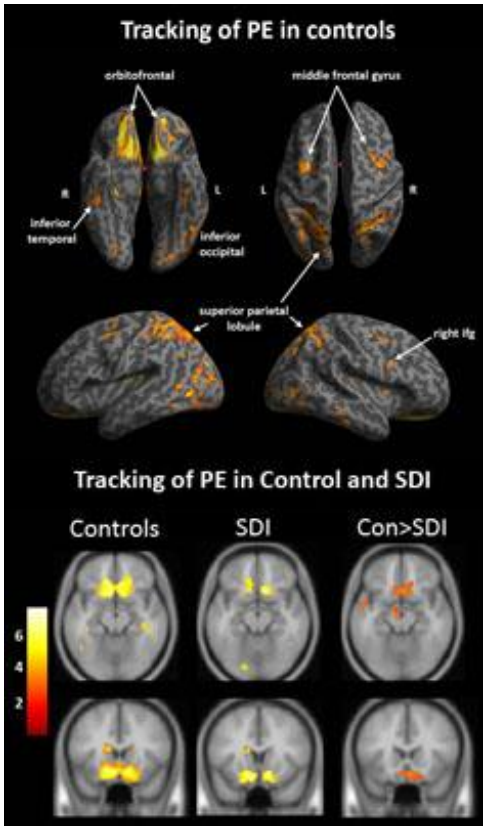
Tracking Prediction Error Learning Signals Using Computational Functional MR Imaging in Substance Dependence

Tanabe, J. L.[1]·Reynolds, J.[2]·Krmpotich, T.[1]·Claus, E.[3]·Thompson, L.[1]·Du, Y.[1]·Banich, M.[4]
[1]University of Colorado Denver, Denver, CO, [2]Denver University, Denver, CO, [3]Mind Research Network, Albuquerque, NM, [4]University of Colorado Boulder, Boulder, CO.

Purpose
Substance dependent individuals (SDI) make poor decisions. Goal-directed decision-making depends upon several factors, including how sensitive individuals are to feedback and how well they learn based on such feedback. A physiologic signal known as prediction error (PE) guides decision-making based on feedback, is carried by striatal dopamine, and is hypothesized to be involved in the pathophysiology of drug addiction. *The current study tested the hypothesis that compared to controls, Substance dependent individuals would show altered processing of frontal-striatal PE during goal-directed decision-making.*
Materials & Methods
Thirty-two SDI and 30 controls performed a decision-making task during fMRI scanning. Behavior and fMRI blood-oxygen-level-dependent (BOLD) signal were modeled using a computational model of PE. Tracking of PE was compared across group using a 2-sample t-test. Statistical threshold was set at voxel-level of $p < 0.005$, uncorrected, and $p < 0.01$ whole-brain cluster-corrected, corresponding to an extent threshold of 39 voxels based on 10,000 Monte Carlo simulations.
Results
In controls, trial-to-trial PE tracked most strongly in the striatum and medial OFC consistent with expected loci of prediction error processing and previous model-based fMRI studies (left Figure). Compared to controls, SDI showed weaker tracking of PE in medial OFC (right Figure) and striatum. Substance dependent individuals also showed significantly lower performance on the task.



Conclusion
Decreased neural tracking of PE in SDI suggests that learning processes involving frontal-striatal regions may contribute to decision-making deficits in substance dependence. Our findings also suggest that computational model-based fMRI can provide a mechanistic account of learning impairments in clinical populations.

Magnetoencephalography Imaging Reveals Reduced Cortical Activity in Patients with Traumatic Brain Injury During Re-Orienting of Visuospatial Attention

Dale, C. L.·Luks, T. L.·Findlay, A. M.·Tarapore, P. E.·Cooper, S. R.·LaHue, S. C.·Lee, H. A.·Honma, S. M.·Mizuiri, D.·Nagarajan, S. S.·Mukherjee, P.
University of California San Francisco
San Francisco, CA.

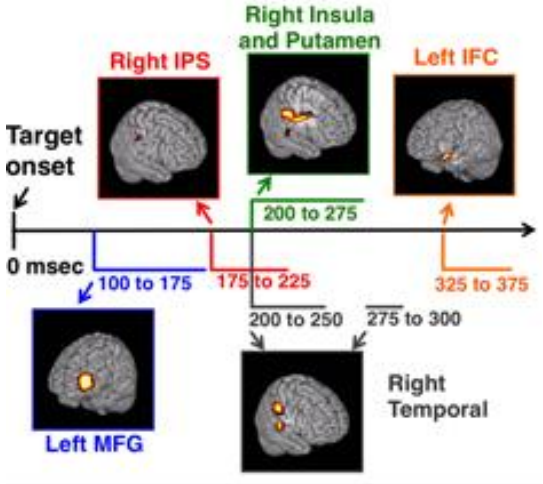
Purpose
Traumatic brain injury (TBI) often produces chronic deficits in cognitive function that affect patients' quality of life. To investigate attention-related neural activity differences associated with TBI, we measured whole-head magnetoencephalography (MEG) signals during a cued visuospatial attention task.
Materials & Methods

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Magnetoencephalography data from 19 patients with mild-to-moderate symptomatic TBI and 18 healthy control participants were analyzed using an adaptive spatial filtering technique (NUTMEG, http://bil.ucsf.edu/nutmeg), and coregistered to individual brain anatomy prior to normalizing images for within- and between-group comparisons. We examine high gamma band activity (63-117 Hz) arising from Incongruently- versus Congruently-cued target stimuli.

Results

Using Family-wise Error (FWE) correction for comparisons across voxels, in healthy participants we observe activations in left middle frontal gyrus (LMFG) from 100 to 175 ms, followed by largely concurrent right hemisphere activity from 175 to 300 ms in areas of right inferior parietal sulcus (RIPS), insula, putamen, and superior temporal cortex and, subsequently, at ~325 ms left inferior frontal cortex for a 50 ms period. In these regions, TBI patients exhibited reduced activity relative to healthy participants and, as a group, showed no alternate compensatory pattern of activity that survived the FWE correction threshold. Linear discriminant analyses revealed that activity levels in just two of these five regions, LMFG and RIPS, reliably predicted injury status. Furthermore, activity in LMFG showed negative correlation with both the Head Injury Symptom Checklist for postconcussive syndrome (HISC-PCS) and a measure of cognitive failures.



Conclusion

These results suggest reduced activation due to TBI within a frontotemporal high-gamma oscillatory network subserving spatial attention.

Regional Abnormally High Aniostropy Predict Better Attention Three Months following Mild Traumatic Brain Injury

Lewkowitz-Shpuntoff, H. M.·Rosenbaum, S.·Kim, N.·Avner, S.·Provataris, J.·Smith, J.·Zimmerman, M.·Lipton, R.·Lipton, M.
Albert Einstein College of Medicine
Bronx, NY.

Purpose

Low fractional aniosotropy (FA) has been widely reported as a manifestation of mild traumatic brain injury (mTBI) pathology. Abnormally high FA also has been reported, but its pathologic and prognostic implications are an area of uncertainty. The purpose of this study was to assess the relationship of abnormally high FA, identified at the time of mTBI, with attention performance three months later.

Materials & Methods

Twenty-four patients meeting diagnostic criteria for mTBI were recruited from a local emergency center, and 40 healthy volunteers were recruited via advertisement. T2-weighted FLAIR and SWI images disclosed no abnormalities. DTI was performed at 3T (32 directions, b = 1000) within two weeks of injury and tests of attention were administered three months post injury using a computer-based battery. Regions of abnormally low FA and abnormally high FA were identified using a voxelwise t-test ($p<0.05$, corrected) comparing the patient and control groups. Additionally, voxelwise Z-score maps were computed for each patient based on the control group, with bootstrap resampling of the variance and thresholding at $p<0.05$, corrected. Predictor variables were the number of voxels of abnormally high or abnormally low FA, both across the entire brain and within regions (frontal, temporal and parietal white matter) expected to be substrates of attention function. Measures derived from occipital white matter and internal capsule served as controls. The association between the number of voxels with abnormally high or low FA and attention was assessed using Spearman's rank correlation analysis.

Results

We detected significant associations between the number of voxels with high FA and better attention performance at three months post injury in the right parietal white matter ($p = .001$, $n = 24$, $R = .647$), the right temporal white matter ($p = .047$, $n = 24$, $R = .408$). No significant association of number of voxels with abnormally high FA and attention was found in the remaining control regions: right internal capsule ($p = .092$, $R = .352$), or the occipital lobes (Right: $p = .773$, $R = .062$ and Left: $p = .775$, $R = .071$) Only one control region, the left internal capsule, showed a significant association with attention ($p = .033$, $n = 24$, $R = .436$).

Conclusion

Higher regional volume of white matter (number of voxels) containing abnormally high FA predicts better attention

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

performance three months after mTBI. Supranormal aniosotropy in these regions may indicate a neuroplastic response to the injury rather than injury pathology per se.

Relationship between Lesion Distance to Diffusion Tensor Imaging White Matter Tracts and Postoperative Speech Deficits

Holdsworth, R.·Hussain, N.·Greenstein, M.·Huss, D.·Voss, J.·Prabhakaran, V.
University of Wisconsin Hospital
Madison, WI.

Purpose
Prior research, including our own work (Wood et al, 2011), has shown that intracranial mass lesions located within 1-2 cm of an eloquent region of cerebral cortex identified by functional magnetic resonance imaging (fMRI) is associated with increased incidence of postoperative deficits. Our purpose was to see if this relationship also applies to the distance between an intracranial lesion and the specific white matter tracts which connect these functional areas with the hypothesis that lesions less 2 cm from major functional white matter tracts would have an increased incidence of postoperative deficits.
Materials & Methods
In retroprospective fashion, we evaluated 60 patients with an intracranial mass lesion who had both pre-operative DTI mapping and subsequently underwent surgical lesion resection. Distance between the lesion and the superior longitudinal fasciculus, corticospinal tracts, and cingulum were measured using diffuse tensor imaging (DTI) maps overlaid on anatomical MR imaging. Patients with postoperative speech deficits were identified by a systematic review of the electronic medical record.
Results
Of the 60 patients enrolled, 23 patients had postoperative speech deficits, 13 of which were new deficits compared to pre-operative evaluation. Of all patients with postoperative speech deficits, a significantly higher proportion had lesions less than 2 cm from the left superior longitudinal fasciculus ($p = 0.016$). In subgroup analysis of the patients with new postoperative speech deficits, a higher proportion had lesions less than 2 cm from the left superior longitudinal fasciculus which trended towards significance ($p = 0.058$). The odds ratio of having lesions less than 2 cm from the left superior longitudinal fasciculus and all postoperative speech deficits or new postoperative speech deficits were 0.94 ($p<0.001$) and 0.96 ($p = 0.04$), respectively.
Conclusion
Patients with lesions less than 2 cm from the left superior longitudinal fasciculus are more likely to experience postoperative speech deficits. These results are similar to our previous work regarding the distance between an intracranial lesion and a region of eloquent cortex identified by fMRI. Work is ongoing to further evaluate this association and the possible association between lesion distance to other white matter tracts and postoperative deficits; for example, the corticospinal tracts and postoperative motor deficits.

Changes in Regional White Matter Integrity in the Prefrontal Cortex in Patients with Systemic Lupus Erythematosus

Sundgren, P. C.[1]·Cagnoli, P.[2]·Wang, P.[2]·Schultz, T.[3]·McCune, J.[2]·Schmidt-Wilcke, T.[4]
[1]Lund University, LUND, SWEDEN, [2]University of Michigan, Ann Arbor, MI, [3]Max Planck Institute, Tübingen, GERMANY, [4]Ruhr Universität Bochum, Bochum, GERMANY.

Purpose
Systemic lupus erythematosus (SLE) is an autoimmune connective tissue disease that can affect the central nervous system with neuropsychiatric symptoms variously reported to occur in 25-70% of patients with SLE. Although clinical assessment is the cornerstone of the SLE diagnosis, confirmation of the diagnosis is difficult and presumptive. The purpose was to investigate if regional differences in white matter integrity exist between a) patients with SLE and healthy controls (HCs) and b) between SLE with neuropsychiatric symptoms (NPSLE) and those without neuropsychiatric symptoms (non-NPSLE) patients. The second aim was to test whether it is possible to build a classifier(e.g., a support vector machine) to differentiate between patients with SLE and HCs, respectively between NPSLE and non-NPSLE patients.
Materials & Methods
dMRI images (15 gradient directions at b=800s/mm^2, plus one b=0 image) were obtained, using a 3T MR scanner, of 19 NPSLE patients, 19 SLE and 18 healthy controls HCs. Image preprocessing and statistical analyses were performed using FSL, following the standard TBSS pipeline. A general linear model with threshold-free cluster enhancement was used to assess significant differences between the three groups (HC versus SLE; HC versus NPSLE; non-NPSLE versus NPSLE) while correcting for FWE with permutation testing; age was included as a covariate of no interest. For classification, we used fraction anisotropy (FA) values at all 102,898 skeleton voxels as a feature vector. Fractional anisotropy values in each voxel were weighted by their F score, in order to decrease the weight of voxels less relevant to the classification task. Classification accuracy was estimated by training a linear support vector machine on the resulting vectors in a leave-one-out manner; care was taken to exclude test data from feature weighting via the F score.
Results

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Statistical analyses revealed decreased FA in several regions in the prefrontal white matter both in non-NSLE and NPSLE patients. The regions of significant changes in the NPSLE patients were larger than in the non-NSLE patients. In a post-hoc analysis, those additional areas were found to exhibit an FA decrease also in the non-NPSLE cohort, albeit below the $p<0.05$ significance threshold. Classification analyses revealed a better than chance classification when testing all SLE patients versus HCs (82%), NPSLE patients versus HCs (70%), and non-NPSLE patients versus HC (68%). In all cases, a binomial test rejected the null hypothesis that these results were achieved by chance($p<0.05$). It was not possible to classify non-NPSLE versus NPSLE patients (40% accuracy, not significantly different from chance).
Conclusion
Our data suggest that changes in regional white matter integrity, in terms of a decrease in FA, are present in SLE patients (as compared to HCs) in the prefrontal cortex, especially in NPSLE patients. Fractional anisotropy images in this study were suited to distinguish between SLE patients and HCs, but not between NPSLE and non-NPSLE, which might be indicative of white matter involvement in both types of SLE. Further research is needed to investigate the underlying neurobiology of white matter changes, and to determine whether neurocognitive deficits and fatigue, are related to these changes.

Evaluation of Functional MR Imaging during Virtual Tennis Playing

Demirci, A.·Demirci, D.·Anik, Y.·Akansel, G.·Kaya, A.
Kocaeli University
Kocaeli, TURKEY.

Purpose
To identify the brain areas activated in viewing and thinking of the response while watching video of tennis play, filmed from the subject's perspective across the opponent, to compare activation areas among tennis players and no players.
Materials & Methods
Via 3T MR scanner, in a block-design, functional MR imaging (fMRI) study, 29 tennis players, 25 sedentary as a control group watched video clips of tennis play. The main stimulus conditions were (1) watch the play and think of what to do subsequently, (2) resting lack of watching. Brain activation regions were delineated and areas under those regions were compared among both groups.
Results
In tennis players activation was seen on optic nerves, optic tractus, lateral geniculate nucleus, occipital cortex, calcarine sulcus, superior temporal gyrus and sulcus, middle temporal gyrus, precuneus, precentral gyrus, midfrontal gyrus, right inferior frontal gyrus, angular gyrus and short gyri of insula. The whole activation areas were significantly greater in tennis players compared with that of the control group ($p = 0.002$). There was a linear moderate significant correlation among activation areas and years of tennis playing ($p = 0.013$, $r = 0.457$).
Conclusion
Perceptual skills improve significantly in tennis players, and this can be shown by fMRI.

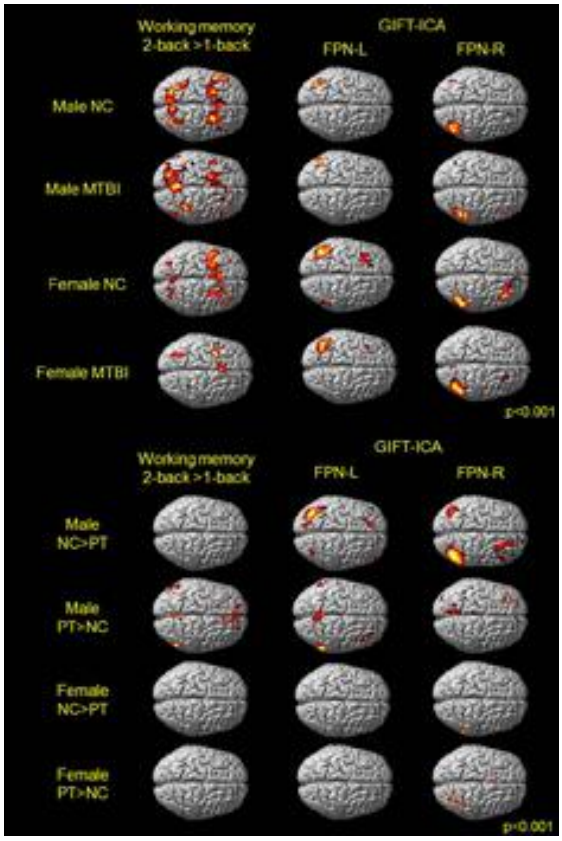
Does Gender Affect the Functional MR Activation during Working Memory after mTBI?

Chen, C.·Chen, D.·Liao, Y.·Wang, W.·Ku, J.·Huang, Y.
Taipei Medical University/Shuang Ho Hospital
Taipei, TAIWAN.

Purpose
It is controversial in the literature whether female gender is a protective factor or aggregative factor in mild traumatic brain injury (mTBI). The aim of this study is to evaluate the influence of gender on working memory activation in functional magnetic resonance imaging (fMRI) after mTBI.
Materials & Methods
Research ethics committee approval and patient written informed consent were obtained. Brain activation patterns in response to a working memory task (n-back; 1 and 2-back conditions) were assessed with fMRI on a 3T MR system in 34 mTBI patients (male:female = 1:1) within one month after their injury and in 34 age-matched healthy control subjects (male:female = 1:1). Resting-state fronto-parietal attention network (FPN) also was analyzed by independent component analysis (ICA) method using "Group ICA for fMRI toolbox" (GIFT version 2.0d).
Results
In the male group, the patients had more activation than controls in bi-frontal and bi-parietal regions (in 2b > 1b condition, p-value < 0.001). The male patients had decreased functional connectivity in bilateral FPN than controls. This could be explained by a compensatory working memory activity (i.e., think hard) in male patients due to the disruption of their fronto-parietal connectivity. In the female group, there was no significant signal change between the patients and controls in working memory activation (in 2b > 1b condition, p-value < 0.001).

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Conclusion

Our result showed that the male patients had increased working memory activation and decreased fronto-parietal connectivity after mTBI. This phenomenon was not observed in the female patients which may suggest female gender to be a protective factor in mTBI.

Diffusion Tensor Imaging in Deep Brain Stimulation Patients at Very Low Radiofrequency Power

Sarkar, S. N.·Papavassiliou, E.·Alterman, R.·Hackney, D. B.·Stormann, J.·Rojas, R.
Beth Israel Deaconess Medical Center, Harvard Medical School
Boston, MA.

Purpose

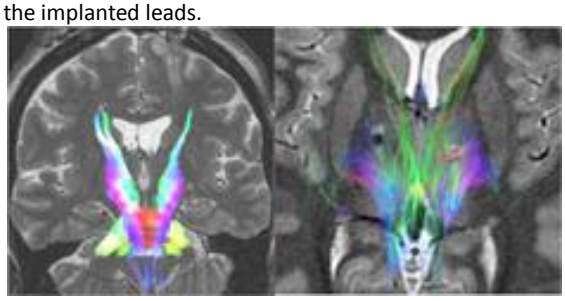
Due to the unavailability of low RF power (Low-SAR) MRI (0.1 W/kg, FDA approved limit), many patients with implanted deep brain stimulators (DBS) do not benefit from many MR sequences. Sequences including DTI, T2 and fast STIR produce 1-3 W/kg of SAR. The current practice of using atlas-based, indirect targeting of deep brain nuclei is imperfect. Recent reports that claim diffusion tractography improves targeting accuracy, also show significant variation to co-localize the cingulate gyrus targets in depression or thalamic targets for tremor with MR images. Such issues may be resolved if advanced techniques like DTI can be applied routinely at FDA approved low-SAR level for patients with indwelling electrodes. We propose localizing DBS leads by T2 and fast STIR sequences that are more useful for delineating deep nuclear boundaries than conventional MPRAGE followed by superimposing white matter connectivity, all at FDA-approved RF power.

Materials & Methods

Five Parkinson's and two dystonia patients underwent DBS implantation followed by low-SAR MR imaging (≤ 0.1 W/kg, 1.5T) to assess postsurgical accuracy with FSET2 and fastSTIR sequences (resolution 1x1x3mm3, scan time 7 min, 16-24 slices) as well as by 25-direction DTI (resolution 2x2x3mm3, scan time 5 min, 30 slices) in addition to 3D MPRAGE. Three patients also were scanned at high SAR at 3T (pre-DBS surgical planning for implanting 1st DBS). The low-SAR sequences used low refocusing flip angles and stretched RF pulses as proposed in a recent work. Coregistration between diffusion-based fibers and underlying structural T1/T2/fSTIR volumes was done by NordicBrainEX Diffusion/DTI Module *(NordicNeuoLab, Bergen, Norway).* [Figure below, synchronized fibers on T2(left) and on fast STIR(right)].

Results

The signal voids at the metallic leads were 4 mm or three times the lead diameters in 3D T1 MPRAGE and 3 mm or two times the lead diameters in 2D FSE T2 or fastSTIR images. The fractional anisotropies in DTI maps at basal ganglia level were virtually unchanged irrespective of underlying structural image used (MPRAGE or T2 or fast STIR) although the later two delineated deep nuclear boundaries with significantly better G/W contrast. High-SAR (pre-DBS, 3T) and low-SAR (post-DBS, 1.5T) DTI fiber tracts were qualitatively similar with minimal effects from the implanted leads.



Conclusion

We have demonstrated that it is possible to obtain high resolution, T2 and fast STIR-weighted low-SAR MR images which, combined with tractography, can map changes in brain connectivity in deep gray/white matter areas for patients treated with deep brain stimulation.

MR Imaging Findings in Childhood Posterior Reversible Encephalopathy Syndrome: What is Different Than the Adults?

Donmez, F. Y.·Guleryuz, P.·Agildere, M.
Baskent University
Ankara, TURKEY.

Purpose
Posterior reversible encephalopathy syndrome (PRES) is a clinical scene presenting with convulsion, vision abnormalities, altered mental status and headaches in the presence of an underlying etiology and diagnosis can be made by support of radiologic studies. In this study, we evaluated the MRI findings of PRES in children and compared our findings with that of the known features in adult patients, and find the pathophysiologic reason that may cause the difference.
Materials & Methods
Twenty-nine children (13 male, 16 female, aged 1-17 years, mean age 10 years) diagnosed as PRES clinically and by radiologic workup were reviewed retrospectively. Clinical records were analyzed for the clinical symptoms at the time of MRI study and the underlying etiology. MR images were evaluated for the distribution of the lesions, contrast enhancement, diffusion restriction and any complication such as hemorrhage.
Results
Twenty-four of the patients presented with seizure, five had altered mental status, one patient had vision abnormality and one had ataxia. Underlying etiologies were variable: Chronic renal disease (n:8), leukemia (n:3), lymphoma (n:3), Wilson's disease (n:3), acute hepatitis (n:3), liver transplant recipient (n:3), hemolytic uremic syndrome (n:2), hemophagocytic syndrome (n:2), aplastic anemia (n:1) and metastatic osteosarcoma on chemotherapy regimen (n:1). Mean blood pressure was 130/85. Parietal (90%) and occipital (72%) involvement are the most common findings as expected; however, frontal lobe (66%) edema also is not uncommon, with rates close to occipital involvement. Temporal lobes were only involved if the edema was extensive in all parts of the brain (21%). Isolated temporal lobe involvement in absence of parietooccipital edema was not seen. The most interesting finding was the cerebellar involvement which was present in almost half of the patients (48%) and which was also atypical in adult patients. There were two patients with atypical presentation, with involvement of the thalami and basal ganglia and the brainstem. Contrast enhancement is also another finding which was found more common than the adults (39%). Twenty-six patients had diffusion-weighted imaging, diffusion restriction was seen in four of them (15%) and four patients had hemorrhage (15%); which are almost the same frequencies as in the adults.
Conclusion
The explanation of the posterior involvement related to lack of sympathetic innervation of the arterioles supplied by the vertebrobasilary system also is not entirely correct in children with PRES. However, the increased incidence of cerebellar involvement may show that the posterior circulation in children is more vulnerable than the adults. The contrast enhancement which is seen more common than in the adults may show that the pathophysiology in children may be related to blood-brain barrier breakdown more commonly, which can support the theory of the toxic endothelial injury. Mean blood pressure was not very high in our study group, only some of the children with kidney diseases had hypertension, which also makes it not possible to explained the syndrome solely by hypertensive effects and promote the toxic endothelial injury theory to be more commonly encountered in children with PRES.

CT Angiography in Acute Stroke: A Subgroup Analysis of the Third International Stroke Trial

Mair, G.[1]·Wardlaw, J. M.[2]·Sandercock, P.[2]·Lindley, R.[3]·von Kummer, R.[4]·Farrall, A. J.[2]·IST-3 Collaborative Group
[1]Western General Hospital, Edinburgh, UNITED KINGDOM, [2]University of Edinburgh, Edinburgh, UNITED KINGDOM, [3]University of Sydney, Sydney, AUSTRALIA, [4]Dresden University Stroke Center, Dresden, GERMANY.

Purpose
The Third International Stroke Trial (IST-3) is a multicenter, randomized controlled trial (RCT) testing intravenous thrombolysis (rt-PA 0.9mg/kg) given within six hours of acute ischemic stroke. In addition to prerandomization and follow-up brain imaging performed for all patients, CT angiography was obtained routinely in some centers. We aimed to identify relationships between CT angiography (CTA), early noncontrast CT signs of ischemic stroke, clinical presentation and outcome and whether CTA improved diagnosis or prognosis prediction over noncontrast imaging alone.
Materials & Methods
All IST-3 patients with prerandomization and follow-up noncontrast CT and concurrent CTA were included. A single observer (GM) analyzed the images, blinded to treatment allocation, clinical and follow-up data. On noncontrast CT, we recorded the presence, extent and

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

location of ischemia (ASPECT and IST-3 scores) and/or hyperattenuated arteries (HAS). We assessed hemorrhage on follow-up scans. We dichotomized CTA as normal/abnormal. The location/extent of CTA abnormality was graded using validated scales (TICI, TIMI, Clot Burden Score, collateral score). We compared imaging findings with baseline clinical assessments (including National Institutes of Health Stroke Scale - NIHSS, atrial fibrillation - AF) and six-month functional outcome (Oxford Handicap Scale - OHS, death). Significant univariate associations were included in multivariate models.

Results

We included 234 patients (42% male, median age 81 years, IQR 71-86). Follow-up imaging was performed within 48 hours for 92%. Acute ischemia was apparent in 28%, rising to 67% at followup. Hyperattenuated arteries were present in 26%. CT angiogrpahy was abnormal in 40% and was strongly related to HAS ($\chi2 = 80$, $p<0.001$). Acute ischemia was apparent in 47% of those with abnormal CTA, rising to 91% at followup ($\chi2 = 49.0$, $p<0.001$) and compares with rates of 34% and 90% in the presence of HAS. On univariate analysis, those with abnormal CTA were more likely to be older ($p<0.001$), female ($\chi2 = 7.3$, $p = 0.007$) have a shorter time to prerandomization CT ($p = 0.005$), a higher NIHSS ($p<0.001$), be in AF ($\chi2 = 5.2$, $p = 0.023$), have a worse OHS ($p<0.001$), or be dead ($\chi2 = 29$, $p<0.001$) at six months. Similar univariate results were obtained for HAS but relationships were more likely to be statistically significant in the presence of abnormal CTA. A poor collateral supply was associated with lower ASPECT scores ($p = 0.014$) and increased prevalence of acute ischemia on prerandomization scan ($\chi2 = 4.8$, $p=0.028$). Neither CTA findings nor HAS were associated with hemorrhagic transformation post-randomization. Multivariate analysis demonstrated that abnormal CTA (or HAS), increasing age and more severe NIHSS independently predicted both dependency and death at six months. Neither ASPECTS score nor ischemia on noncontrast prerandomization CT were predictive of outcome.

Conclusion

CT angiography may image more completely than noncontrast CT the impact of stroke on the brain by demonstrating low attenuation thrombus and collateralization, thus providing additional prognostic information. Further analyses are now required to determine if this additional information leads to improved outcome after rt-PA, accounting for factors such as delay to treatment, utility and cost of CTA.

Utility of CT Perfusion in the Detection of Lacunar Infarction

Das, T.[1,2]·Huynh, T. J.[1]·Eilaghi, A.[1]·Jakubovic, R.[1]·Symons, S. P.[1,2]·Swartz, R.[1]·Aviv, R. I.[1,2]
[1]Sunnybrook Health Sciences Centre, Toronto, ON, CANADA, [2]University of Toronto, Toronto, ON, CANADA.

Purpose

Twenty to 25% of ischemic strokes are lacunar. Lacunar strokes are challenging to detect early and detection remain a limitation of advanced CT stroke protocols including CT perfusion (CTP). There is some evidence of the beneficial role of thrombolysis in lacunar infarction. The purpose of this study is to systematically examine the utility of CT perfusion (CTP) in detecting acute lacunar infarction in the absence of major vessel occlusion.

Materials & Methods

Patients with acute lacunar stroke without vessel occlusion, evaluated with CTP within 4.5 hours of symptom onset, were extracted from a prospective stroke database. Of 450 cases, 170 met the inclusion criteria. CT perfusion was performed on a 64-slice CT scanner (GE Healthcare, Waukesha, WI) with a z-axis spatial coverage of 4 cm. Patients underwent follow-up MRI within 30 days of presentation. Cases in which a diagnosis of infarction was made from follow-up imaging were classified retrospectively as true positive (TP) if detected on the admission CTP or false negative (FN) if not detected on CTP. Ischemia or infarction on CTP was defined as decreased cerebral blood flow and increased mean transit time with or without corresponding decreased cerebral blood volume. Lacunar infarcts were defined as ≤ 15 mm in long axis within the basal ganglia or supratentorial deep white matter. Baseline clinical and radiographic variables including age, gender, NIH Stroke Scale, 3-month modified Rankin score, time to presentation and final infarct size were compared between TPs and FNs.

Results

Thirty-eight percent of all infarcts were classified as lacunar. There were 28% TP and 67% FN cases. The sensitivity of CTP for the detection of lacunar infarcts was 63%. Baseline characteristics between TP and FN lacunar infarcts were compared. True positive cases showed a lower time to presentation compared to FNs (96 ± 29 minutes versus 112 ± 32 minutes $p = 0.04$). There were no significant differences in other measured variables. The added role of CTP over a combination of NCCT and CTA for lacunar infarct detection will be reported.

Conclusion

CT perfusion detects lacunar infarcts with moderate sensitivity but requires the perforator territory to be examined specifically for small CTP defects. However, the lower spatial resolution and inherent noise of CTP remains a challenge. Earlier time to presentation of TP patients may attest to a capsulostriate, rather than a lenticulostriate etiology. In the former, a larger number of

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

perforators are affected increasing the size of the CTP defect.

High Frame Rate Dynamic Oxygen Extraction Fraction Changes Using Parameter Assessment by Retrieval from Signal Encoding MR Imaging

Menon, R. G.[1]·Cantrell, C. G.[1]·Walsh, E. G.[2]·Twieg, D. B.[3]·Carroll, T. J.[1]
[1]Northwestern University, Chicago, IL, [2]Brown University, Providence, RI, [3]University of Alabama at Birmingham, Birmingham, AL.

Purpose
Oxygen extraction fraction (OEF) is a crucial perfusion marker and shown to be an independent predictor of stroke. Here we show that we can measure dynamic changes in OEF (OEF reactivity) by inducing mild hypercapnia using a breath-hold experiment. This surrogate measure for cerebrovascular reserve provides complementary information on collateralization, and correlates with favorable outcomes in revascularization therapy.
Materials & Methods
A parameter assessment by retrieval from signal encoding (PARSE)-based MR OEF sequence was implemented on a clinical 3T MR scanner. In a series of five normal volunteers (M/F 3/2, age = 26 ± 10 years) we acquired single slice, 5.0 mm thick, 220 mm x 220 mm FOV, 64 x 64 matrix, resolution = 3 x 3 x 5.0 mm3 2D PARSE images. Volunteers were tested with four conditions: normal breathing, breath-hold at the 1st, 5th and 10th measurement. PARSE acquisitions were taken every three seconds through the breath-hold, for a total of 20 measurements. The frequency change maps were calculated from PARSE reconstructions. Spatial ICA analysis then was performed on these frequency maps to separate out other confounding static effects from the dynamic OEF components.
Results
The change in OEF following a breath-hold experiment is seen in the representative fractional OEF difference maps (Figure 1). The OEF reactivity for different breath-hold conditions is shown in Figure 3. OEF reactivity is seen soon after the breath-hold induced physiologic stress.

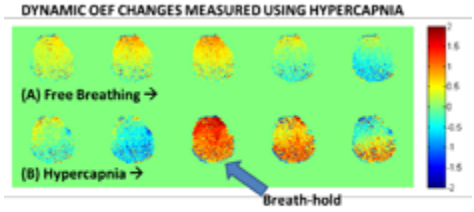

Figure 1: A PARSE acquisition acquired every 3s is used acquire frequency maps that measure dynamic OEF changes that occur during mild hypercapnia. (A) Free Breathing, and (B) Hypercapnia induced by a breath-hold experiment. Shown here are difference maps which have static components removed, to make the dynamic components visible.

Conclusion
While the free-breathing condition ΔOEF does not change measurably, the mild hypercapnic conditions do cause a measurable change in ΔOEF. This technique can provide supplemental information regarding the vascular reserve in patients who typically receive diamox/acetazolamide challenge to determine information on collateralization. The speed of the MR OEF technique allows for multiple measurements in a single breath-hold experiment thus allowing measurement of dynamic OEF changes. Clinical validation of this technique on patients needs to be done to establish the efficacy of this technique.

Association between African American Ethnicity, ApoE4 and Lacunar Infarction in the Dallas Heart Study

King, K.[1]·Warren, M.[2]·McColl, R.[1]·Weiner, M.[1]·Peshock, R.[1]
[1]University of Texas Southwestern Medical Center, Dallas, TX, [2]Duke University Medical Center, Durham, NC.

Purpose
African American ethnicity has been associated with a higher prevalence of lacunar infarction, but the etiology for this is unclear. Apolipoprotein E4 (ApoE) may increase stroke risk and in the Dallas Heart Study Brain Aging cohort African Americans have increased ApoE4 allele frequency compared to other ethnicities. We reviewed genetic data and brain MRIs to determine the independent contribution of African American ethnicity and ApoE4 towards odds of lacunar infarction.
Materials & Methods
This IRB-approved HIPAA compliant project examined data from 526 Dallas Heart Study participants 55 or more years of age that underwent genotyping in the first wave of the study in 1999 and brain imaging approximately seven years later. The presence of lacunar infarction was determined from 3T MRI (Achieva; Philips Medical Systems, Best, The Netherlands) of the brain using 3D magnetization prepared rapid acquisition gradient echo, FLAIR and T2. Lacune criteria were size of 3-20 mm, isointense to CSF on T2 and lack of cortical involvement with verification by a neuroradiologist. Logistic regression was performed to evaluate the association between African American ethnicity and presence of lacunar infarction adjusting for age and gender. ApoE4 allele number and African American ethnicity then were examined jointly for their association with lacunar infarction, also adjusting for age and gender.
Results
See table for population characteristics. In a model adjusting for age and gender, African American ethnicity was associated with increased odds of lacunes (OR 2.2, p 0.0375). Number of ApoE4 alleles then was added to the regression model and was significant (OR 2.2, p 0.009)

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

while the association with African American ethnicity decreased (OR 1.8, p 0.135).

	African American n = 233	Non African American n = 293 (239 Caucasian, 46 hispanic, 8 other)
Female Gender	142 (60.9%)	174 (59.4%)
Age at MRI	61.2 ± 5.5	61.2 ± 4.6
ApoE4 allele frequency	23.8%	12.0%
Lacunar Infarct Prevalence	20 (8.58%)	12 (4.1%)

Conclusion
African American ethnicity was associated with increased odds of lacunar infarction. When the relative contribution of ApoE4 was evaluated in conjunction with African American ethnicity, it was associated with significant increased odds of lacunar infarction and lessened the association with African American ethnicity. This suggests increased ApoE4 allele frequency may underlie some of the association between African American ethnicity and increased prevalence of lacunar infarction.

Calcified Cerebral Emboli, A "Do Not Miss" Diagnosis: Seventeen Proven Cases and Meta-Analysis of the World Literature

Walker, B. S.·Shah, L. M.·Osborn, A. G.
University of Utah
Salt Lake City, UT.

Purpose
Calcified emboli are a rarely reported but potentially devastating cause of stroke and may be the first manifestation of vascular or cardiac disease. Proper identification can guide treatment towards preventing future embolic events. This study identifies the source, risk factors, and imaging findings of calcified cerebral emboli.
Materials & Methods
A MEDLINE search for calcified AND emboli AND stroke identified 37 cases with imaging findings. Our institutional radiology information system also was searched retrospectively for all noncontrast head CT scans performed between 2001 and 2012 using keywords "calcified" and "emboli." Seventeen cases of calcified cerebral emboli were identified.

Results
A total of 54 cases (61% male and 39% female) were available for analysis. Mean patient age was 64 years. Mean embolus density was 166 HU. Average diameter was 2.5 mm (range 1.0-5.5 mm). Emboli were equally distributed in both hemispheres with 17% bilateral and 35% multiple. Eighty-one percent occurred in the middle cerebral artery distribution. The anterior (9%) and posterior (9%) cerebral arteries were the next most common sites. Presumed embolic sources were aortic stenosis (37%), carotid atherosclerotic plaque (20%), calcific mitral valve (17%), unidentified (9%), and miscellaneous (18%). Repeat imaging demonstrated distal migration of emboli in 11% of cases. Of our 17 cases, 71% were identified correctly as calcified emboli. Twenty-nine percent were misdiagnosed on initial interpretation as hemorrhage or infectious, traumatic, or vascular calcification. Twelve percent were overlooked on preliminary interpretation by the on-call radiology resident.

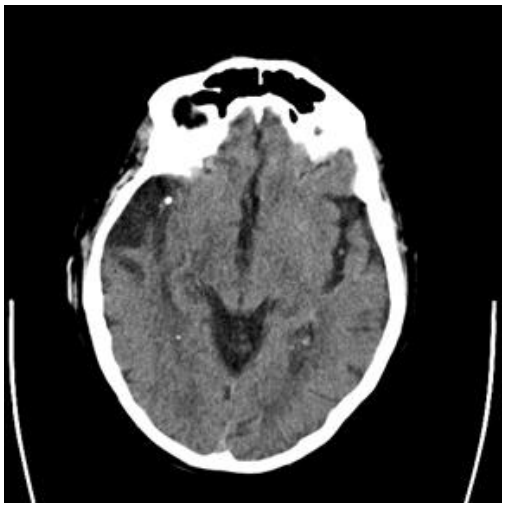

Figure 1. NECT scan in an 81-year-old female shows a calcified embolus in the right MCA with right temporal lobe encephalomalacia from a prior infarct. CT angiography demonstrated a calcific plaque with 70% stenosis of right ICA.
Conclusion
Proper identification of calcified emboli is important for appropriate patient management. Over 60% of calcified cerebral emboli are cardiac in origin. Nearly one quarter of all patients subsequently received aortic valve replacement to prevent further stroke. It is therefore crucial that all patients with calcified cerebral emboli should receive cardiac and extracranial carotid evaluation. Multiple emboli and distal migration suggest that repeat embolization may occur without proper intervention. Of those identified at our institution, nearly one in four initially was overlooked or misdiagnosed. It is imperative that radiologists correctly identify this manifestation of potentially treatable disease.

Computed Tomography Perfusion Parameter to Predict Cerebral Hyperperfusion Phenomenon following Carotid Artery Stenting

Takahashi, Y.·Mori, T.·Iwata, T.·Miyazaki, Y.·Nakazaki, M.
Shonan Kamakura General Hospital Stroke Center
Kamakura, JAPAN.

Purpose
Although SPECT is useful for predicting and finding cerebral hyperperfusion phenomenon (CHP) following carotid artery stenting (CAS), there are few institutions that could perform SPECT during peri-CAS period. The purpose of our study is to evaluate whether or not parameters derived from CT perfusion (CTP) used widely can predict CHP.
Materials & Methods
Patients who underwent CTP before elective CAS and SPECT before and immediately after elective CAS in our institution from December 2010 to November 2012. We defined CHP as post-CAS increase of more than 10% of the ratio of cerebral blood flow (CBF) in the territory of the affected middle cerebral artery (MCA) divided by CBF in the ipsilateral cerebellum (MCA/CE ratio) measured by SPECT. We assessed the correlation of pre-CAS CTP's parameters' ratio to MCA/CE ratio change between pre-CAS and post-CAS SPECT. The CTP's parameters' ratio was calculated as (parameters in the affected side divided by in the unaffected side) x 100. CT perfusion parameters we assessed are as follows: time-to-peak (TTP), mean-transit-time (MTT), cerebral blood volume (CBV) and CBF.
Results
Sixty-five patients were analyzed. Pre-CAS TTP ratio ($r = 0.323$, $p = 0.009$) and MTT ratio ($r = 0.317$, $p = 0.010$) showed a significant positive correlation with MCA/CE ratio change. Other parameters (CBV and CBF) had no significant correlation. The cut-off value of pre-CAS TTP and MTT ratio was 1.08 (AUC = 0.81, Sensitivity 85.7%, Specificity 70.0%), 1.05 (AUC = 0.74 Sensitivity 64.3%, Specificity 44.7%) to predict CHP respectively.
Conclusion
Increase of pre-CAS TTP ratio or MTT ratio is probably correlated with CHP following elective CAS.

Improved Agreement of Mismatch Classification in Acute Stroke of Arterial Spin Labeling and Bolus Perfusion-Weighted Imaging at 3T

Zaharchuk, G.·Zun, Z.·Bammer, R.·Moseley, M. E.·Albers, G. W.
Stanford University
Stanford, CA.

Purpose
Arterial spin labeling (ASL) has been proposed as a noncontrast alternative to bolus perfusion-weighted imaging (PWI) for acute stroke patients, enabling perfusion imaging in patients who cannot receive contrast. Studies also suggest that it can assess collateral flow and provide quantitative CBF measurements. However, a prior study at 1.5T showed that ASL overestimates tissue at-risk in patients with mild arterial delays, due to conventional ASL's known sensitivity to slow flow. Signal-to-noise ratio increases and errors due to slow flow decrease at 3T compared to 1.5T. Accordingly, the purpose of this study is to assess the agreement between PWI and ASL for mismatch status at 3T using both pseudocontinuous ASL (pcASL) and a transit-delay insensitive labeling method, velocity-selective ASL (vsASL).
Materials & Methods
This prospective study included all patients scanned at 3T for the evaluation of acute stroke within 48 hours of last seen normal with a positive diffusion-weighted imaging (DWI) lesion. Arterial spin labeling was performed with two separate scans: pseudocontinuous ASL (TR/TE/TL/post-label delay 4400/10/1500/2000 ms) and vsASL (TR/TE/TI 5000/14/1100 ms). Diffusion-weighted imaging and PWI scans were assessed automatically using RAPID software, and patients classified into reperfusion, no mismatch, or mismatch groups based on the DEFUSE-2 criteria. Arterial spin labeling DWI mismatch was assessed by a neuroradiologist blinded to patient history, clinical symptoms, and other imaging. Linear-weighted kappa for agreement between modalities was calculated. After rebinning ASL cases into mismatch versus no mismatch, sensitivity and specificity were determined using PWI as the reference standard.
Results
Thirty-two patients (age: 72 ± 14 years, range 39-105 years, M/F 9/23) were enrolled over a three-month period. Mean DWI and PWI lesion sizes were 11 ± 21 and 17 ± 29 ml, respectively. Twenty-nine and 18 patients received pcASL and vsASL, respectively. Linear-weighted kappa for agreement with PWI-DWI was 0.87 (95% confidence interval: 0.69-1.0) for pcASL and 0.62 (0.24-1) for vsASL. For mismatch versus no mismatch, sensitivity and specificity was 1 (0.46-1) and 0.92 (0.72-0.99) for pcASL; and 0.5 (0.09-1) and 1 (0.73-1) for vsASL. Velocity-selective ASL demonstrated less sensitivity to arterial delay, as predicted theoretically and observed in a prior study in chronic ischemia. Agreement (93% for pcASL and

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

89% for vsASL) with PWI was significantly higher than in a prior study performed at 1.5T, presumably due to reduced arrival time effects and higher SNR at 3T.

Agreement of Mismatch Classification by ASL DWI and PWI DWI

	PWI DWI Classification			
pcASL DWI Classification	Reperfusion	No Mismatch	Mismatch	Total
Reperfusion	3	0	0	3
No Mismatch	0	19	0	19
Mismatch	0	2	5	7
Total	3	21	5	29
vsASL DWI Classification	Reperfusion	No Mismatch	Mismatch	Total
Reperfusion	1	1	0	4
No Mismatch	0	12	2	14
Mismatch	0	0	2	2
Total	1	13	4	18

Conclusion

Arterial spin labeling and PWI agree significantly for the determination of mismatch in acute stroke patients at 3T. Velocity-relective ASL is feasible and demonstrates reduced sensitivity to slow flow in ischemic regions compared with pcASL. 3T ASL is a reasonable alternative to PWI as a perfusion modality to determine mismatch status in acute stroke patients.

Novel Technique for Oxygen Extraction Fraction Measurement Using PARSE MR Imaging

Menon, R. G.[1]·Walsh, E. G.[2]·Twieg, D. B.[3]·Carroll, T. J.[1]
[1]Northwestern University, Chicago, IL, [2]Brown University, Providence, RI, [3]University of Alabama at Birmingham, Birmingham, AL.

Purpose

Oxygen extraction fraction (OEF) is shown to be an independent predictor of stroke. There is an unmet clinical need for a robust MRI technique to quantify OEF in the brain. A novel, fast, and noninvasive MRI technique to measure OEF is being reported here.

Materials & Methods

We implemented the parameter assessment by retrieval from signal encoding (PARSE) sequence on a clinical 3T MR scanner. Parameter assessment by retrieval from signal encoding uses a more accurate MR signal model and allows the simultaneous estimation of M0, R2* and OEF related frequency changes. We performed sensitivity analysis and numerical simulations and concluded that the technique is sensitive to frequency changes of 4Hz and higher. In a series of five normal volunteers (M/F 3/2, age = 26 ± 10 years) and one arteriovenous malformation (AVM) patient we acquired single slice, 5.0 mm thick, 220 mm x 220 mm FOV, 64 x 64 matrix, resolution = 3 x 3 x 5.0 mm3 2D PARSE data. The frequency change maps calculated from the PARSE reconstruction were processed using ICA analysis to separate static components from the dynamic OEF components.

Results

The mean frequency change for normal subjects was in the range of 15.49 Hz ± 2.77. The mean calculated OEF for the five normal subjects was 36.87 ± 6.60%. The AVM patient exhibited an area of elevated OEF (84.05 ± 4.54%). Figure 1 shows the plot of OEF for normal subjects and the AVM patient, compared to published positron emission tomography (PET) literature.

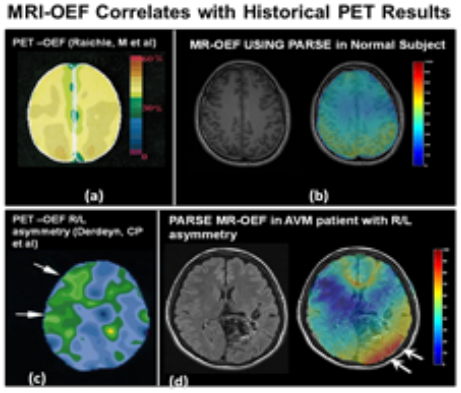

Figure 1: PARSE based MR-OEF images acquired in 5 sec are referenced to anatomic MPRAGE (5:00 min scan) and overlaid (b, d), correlate with expectations based on previously published PET data (a,c)

Conclusion

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

The mean OEF for the normal subjects are in close agreement to literature values of PET OEF studies of normative values from Carpenter (35 ± 7%), Yamauchi (42 ± 5%), Diringer (41 ± 6%) and Raichle (40 ± 9%). The AVM patient exhibits elevated OEF proximal to the AVM and "steal" in the distal part of the slice, suggesting that the surrounding tissue may be in distress due to the AVM. The data from PARSE-based studies on our cohort suggest a potential MRI OEF measurement technique. Further patient studies are required to validate the efficacy of this technique as related to assessing the risk in stroke patients.

Use of CT- and CBV-ASPECTS in Predicting Clinical Outcomes of Endovascularly Treated Acute Ischemic Strokes

Psychogios, M.·Schramm, P.·Frölich, A. M.·Knauth, M.
University Medicine Goettingen
Goettingen, GERMANY.

Purpose
Patient selection is crucial in the endovascular treatment of acute ischemic stroke patients. Baseline CT images, evaluated with the Alberta Stroke Program Early CT Scale (ASPECTS), are considered significant predictors of outcome. In this study we evaluated CT images and perfusion parameters, analyzed with ASPECTS, as final outcome predictors after endovascular stroke treatment.
Materials & Methods
A previously published cohort of endovascularly treated patients was analyzed. Patients with an occlusion of the M1 segment and multimodal CT imaging were included. CT perfusion data were reconstructed using commercial software. Two experienced neuroradiologists separately reviewed and scored CT and CT perfusion images with the ASPECTS score. Parameters were compared between patients with poor follow-up outcome and with favorable follow-up outcome. Significantly different variables were analyzed further by forward stepwise logistic regression.
Results
Fifty-one patients were included in our study. Baseline characteristics did not differ between patients with favorable and poor outcomes. No significant difference in recanalization status, the various times or CT ASPECTS was demonstrated between the two groups. Significant differences between the two groups were demonstrated for age (P = 0.0049), cerebral blood volume (CBV) ASPECTS (P = 0.0007) and the difference between CBV and cerebral blood flow (CBF) ASPECTS (P = 0.0045). Cerebral blood flow ASPECTS >7 demonstrated the highest sensitivity and specificity for good outcome with 84% and 79%, respectively.
Conclusion
CT perfusion parameters, evaluated with ASPECTS, are significant predictors of outcome and are more sensitive and specific than CT ASPECTS in the prediction of favorable outcome. Use of these parameters in treatment decisions could lead to a reduction of futile recanalizations.

Correlation between Leukoaraiosis Volume and Diabetes

Saba, L.[1]·Raz, E.[2]·Suri, J. S.[3]·Piga, M.[1]
[1]AOU Cagliari, Cagliari, ITALY, [2]University of New York, New York, NY, [3]Biomedical Technologies, Pocatello, ID.

Purpose
The association between diabetes mellitus and leukoaraiosis is uncertain, while the association with hypertension, age and carotid artery stenosis is widely demonstrated. We aim to evaluate the association of white matter hyperintense lesion volume and diabetes in a cohort of patients who underwent an MRI of the brain at our Institution.
Materials & Methods
Fifty-four consecutive patients (mean age 72 ± 9 years, males 42) were recruited prospectively at our Institution before undergoing carotid endarterectomy. The patients were assessed for the presence of vascular risk factors, including diabetes mellitus, hypertension, hyperlipidemia. The patients underwent an admission MRI of the brain which included T2-FLAIR, T2-SE and DWI sequences. FLAIR-leukoaraiosis lesion volume was performed by a neuroradiologist, blinded to the presence of risk factors, using a semi-automated segmentation technique (Jim, Xinapse System, Leicester, UK). Receiver operating characteristic (ROC) analysis was performed to evaluate the AUC of FLAIR-leukoaraiosis lesion volume and number of lesions with respect to the vascular risk factors.
Results
The ROC curve analysis showed an AUC of 0.725 (SE = 0.082 and 95% CI from 0.593 to 0.873) with a statistically significant p value of 0.002 between the presence of diabetes mellitus and the FLAIR-leukoaraiosis lesion volume. In the ROC curve analysis between the presence of diabetes mellitus and number of lesions the AUC was 0.715 (SE = 0.085 and 95% CI from 0.553 to 0.845) with a p value of 0.0119.
Conclusion
Our data demonstrate an association between diabetes mellitus and the volume of the cerebral white matter abnormality.

Low B-Value Diffusion-Weighted Imaging in Cerebral Ischemia: An Initial Experience

Besachio, D. A.·Rassner, U.
University of Utah
Salt Lake City, UT.

Purpose
Diffusion-weighted imaging (DWI) is routine in the evaluation of stroke patients. Signal changes on DWI are caused not only by self-diffusion of water, but also by water movement in vessels. Our purpose is to determine whether low B-value DWI may have some utility in identifying altered perfusion and may allow to identify "tissue-at-risk" in the setting of cerebral ischemia through our understanding of the principle of intra-voxel incoherent motion (IVIM).
Materials & Methods
We retrospectively reviewed six months of inpatient and emergency department brain magnetic resonance images (MRIO where low b-value MRI diffusion sequences (B = 50 s/mm^2) were performed in the setting of stroke evaluation. Low b-value apparent diffusion coefficient (ADC) maps were compared to perfusion imaging when available and with areas of infarct on follow-up imaging.
Results
Our data indicate that low b-value imaging ADC maps are mostly perfusion maps. A larger low b-value ADC abnormality compared to high b-value ADC can indicate tissue at risk beyond classic DWI imaging and correlates with site of infarct on follow-up CT images (Figures 1 and 2). In cases where tissue perfusion is re-established, low b-value ADC map abnormalities normalize. Low b-value images can predict sites at risk of future infarction on follow-up imaging.
Conclusion
Our limited experience with low B-value imaging suggests that decreased ADC values in a low b-value DWI sequence may act as an effective surrogate for cerebral tissue perfusion and can identify tissue at risk as well as normalization of blood flow. Further research with the use of intra-operative MRI during angiography for acute stroke is ongoing.

Fast 3D Arterial Wall Imaging Using Variable Flip-Angle, Ultralong Echo Train T1 FLAIR

Mazura, J. C.[1]·Fullerton, H. J.[1]·Banerjee, S.[2]·Koon, P. D.[2]·Barkovich, A. J.[1]·Hess, C. P.[1]
[1]University of California San Francisco, San Francisco, CA, [2]GE Global Applied Sciences Laboratory, Menlo Park, CA.

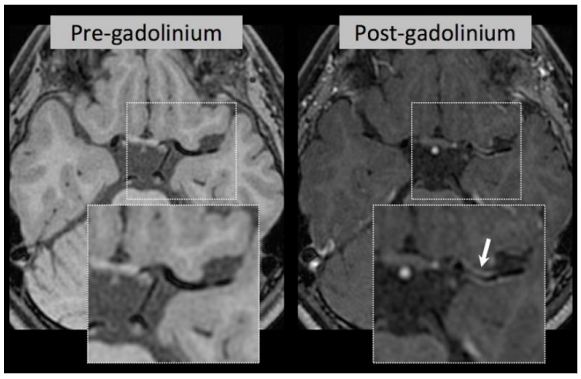
Purpose
Catheter angiography, CTA and MRA permit accurate evaluation of the arterial lumen, but are typically unable to identify abnormalities within the arterial wall. Mural thickening and enhancement on 2D T1 FLAIR arterial wall imaging (AWI) may improve the ability to differentiate among different types of intracranial arteriopathy. However, long scan times and flow artifacts have limited this approach. In this work, we developed a variable flip angle, ultra-long echo train 3D T1 FLAIR FSE pulse sequence for fast, clinically feasible AWI with isotropic 1 mm resolution and applied the technique to patients with various intracranial arterial lesions.
Materials & Methods
A fat-suppressed, pre and postgadolinium 3D T1 CUBE FLAIR imaging protocol was developed and deployed on two 3T GE MR750 scanners for the evaluation of adult and pediatric patients with suspected neurovascular disease. Using parallel acquisition and a variable flip angle schedule optimized for T1 contrast, scan time to achieve 1 mm resolution with whole brain coverage was 4.5 minutes per

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

acquisition (TR/TE=600 ms/MIN, ETL=20, ARC acceleration=2, NEX=1). Pre and postgadolinium 2D T1 FLAIR (TR/TE/TI=860/12/2100 ms, ETL=8, ASSET acceleration=2, total scan time = 30 minutes) also was performed in select patients for comparison. Unenhanced images were reviewed for dissection and concentric or eccentric mural thickening and compared to gadolinium-enhanced sequences to detect mural enhancement in five patients with transient childhood arteriopathy (TCA), four with stroke, two with vasculitis, and one with suspected intracranial dissection.

Results

The figure shows one representative positive AWI study, in which mild luminal narrowing on MRA was accompanied by concentric mural enhancement in a 13-year-old with a left lateral lenticulostriate infarct presumed due to TCA. Arterial wall imaging was performed successfully in all patients, and showed unilateral focal arterial enhancement in the supraclinoid ICA and/or MCA in three cases (1 TCA, 1 embolic infarct, and one dissection). Compared to 2-plane 2D T1 FLAIR, the 3D CUBE T1 FLAIR technique reduced imaging time from 30 minutes to under 10 minutes, allowed reformatting in any plane, showed fewer CSF pulsation and vascular pulsatility artifacts, and was less sensitive to cortical venous enhancement.



Conclusion

High-quality volumetric AWI can be performed with 1 mm isotropic spatial resolution in under 10 minutes using 3D T1 CUBE FLAIR in order to reveal intracranial arterial wall dissection, thickening and/or enhancement with higher fidelity than 2D T1 FLAIR. This technique shows promise for distinguishing between inflammatory, infectious and other types of intracranial arteriopathy.

Ultra-High Resolution 0.4 mm Isotropic Structural Imaging of the Human Hippocampus in vivo Utilizing Phase-Cycled bSSFP at 7.0T

Zeineh, M. M.·Parekh, M.·Su, J.·Rutt, B.
Stanford University
Stanford, CA.

Purpose

The hippocampus plays a central role in memory formation and disease entities such as Alzheimer disease and temporal lobe epilepsy. However, it is a complex and intricate structure with many components tightly wrapped and folded, particularly in the anterior hippocampus, or hippocampal head. Hippocampal microstructure is identified best with T2-weighted contrast. However, achieving isotropic high-resolution T2-weighted images is quite difficult, so most hippocampal acquisitions are anisotropic. This complicates segmentation, and has resulted in a myriad of attempts to label the hippocampal head consistently and accurately. This stands in contradistinction to specimen MRI, in which full hippocampal head segmentation is possible at a resolution on the order of 0.2 mm isotropic. Here, we report using balanced steady-state free precession (bSSFP) at 7.0T to achieve 0.4 mm in vivo isotropic resolution with contrast that reveals hippocampal microstructure in clinically achievable scan times.

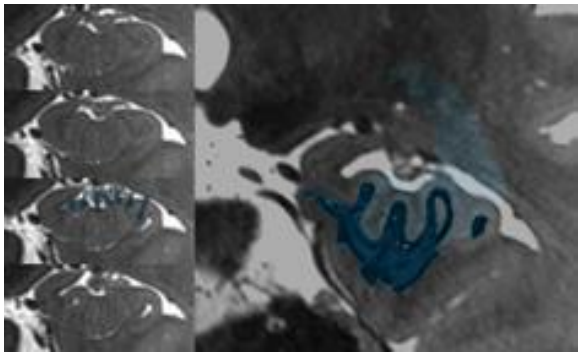
Materials & Methods

Four subjects provided informed consent in accordance with the IRB for scanning with a GE 7.0T Discovery MR950 scanner using a Nova coil (quadrature transmit, 32-channel receive). After performing high-order B0 shimming to approximately 20 Hz r.m.s. uniformity, we acquired six-eight increments of phase-cycled bSSFP (FIESTA, coronal, BW 62, FOV 17, 420x420, FA 25, TR 8.2 ms, TE 4.1, 0.4 mm slice thickness, 480 slices, 0.5NEX, ARC 1.75x1.75, 5:11 per phase cycle, several seconds of rest between phase cycles). Individual phase cycle images were reconstructed and combined into an initial sum-of-squares (SOS-1). FSL's flirt then was used to coregister each phase cycle to the SOS-1, after which we recombined into a second SOS (SOS-2), and this procedure was repeated once to produce SOS-3. Images were visualized and the hippocampal cell layer stratum radiatum lacunosum moleculare (SRLM) was segmented using itk-SNAP.

Results

The images demonstrated contrast comparable with T2-weighted FSE images with gray-white contrast-enhanced by a significant component of iron contrast. In all subjects, fields CA3 and CA1 of the hippocampal head were readily discernible and separable in coronal section, and the entirety of SRLM could be segmented (Figure 1). Three to four hippocampal digitations were observable in coronal section with fluid in the adjacent hippocampal sulcus. Gray-white contrast in the remainder of the brain was similar to 3D T2 FSE acquisitions.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Conclusion
Balanced steady-state free precession provides extremely detailed visualization of hippocampal microstructure only previously possible with ex vivo imaging. This may have applications to and beyond diseases of the medial temporal lobes.

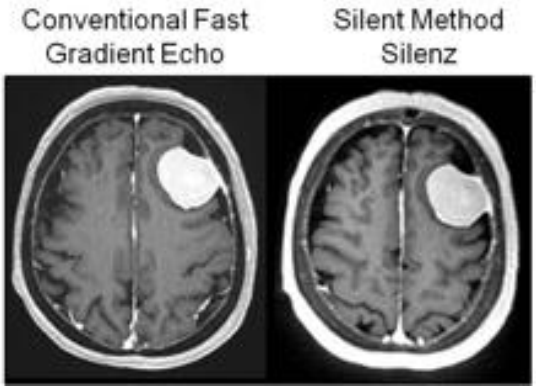
Silent MR Image Acquisition: Initial Clinical Experience and Assessment of Image Quality

Korosec, F. R.[1]·Rowley, H. A.[1]·Holmes, J. H.[2]·Wang, K.[2]·Thornton, F. J.[1]·Vigen, K. K.[1]·Mckinnon, M. C.[3]·King, K. F.[3]·Akao, J. H.[3]·Wei, S.[3]·Turski, P. A.[1]
[1]University of Wisconsin Madison, Madison, WI, [2]GE Healthcare, Madison, WI, [3]GE Healthcare, Waukesha, WI.

Purpose
Two concerns often expressed by patients undergoing MRI exams are the confined space and the loud noise. The confined space is being addressed by wider bore scanners. Recently, a prototype T1-weighted silent scanning sequence (Silenz, GE Healthcare) has been provided to our institution for internal evaluation in patient volunteers presenting for clinical neurologic MR exams. The goal of this work is to assess the quality and diagnostic capability of images obtained with the T1-weighted Silenz method.
Materials & Methods
Fourteen patients were enrolled in this IRB-approved study. Patients underwent a standard-of-care neurologic MR exam, including a postcontrast, T1-weighted fast gradient-echo scan (BRAVO, GE Healthcare), followed by a T1-weighted Silenz scan. The Silenz scan is a 3D radial acquisition method, in which the gradients are changed minimally during the acquisition in order to minimize the traditional gradient "banging" sounds. Imaging was performed on a 1.5T wide-bore scanner with a 24-channel GEM head-neck coil (Optima MR 450w, GE Healthcare). Imaging parameters for the Silenz scan were: TI=450ms, TE=0.016ms, flip=4°, RBW=±31.3kHz, FOV=256 mm2, matrix=256×256, 1.0 mm isotropic acquisition resolution, and scan time=6:11. Scan times were reduced by using parallel imaging in the conventional acquisition, and moderate radial undersampling in the Silenz acquisition. During the Silenz scan, the sound of the scanner had been measured previously to be slightly (<3dB) above the ambient noise levels in the room.
Results
Example axial images from a patient volunteer with an enhancing meningioma (Figure 1) show similar image quality with both the Silenz acquisition and the conventional method. Quality of the Silenz images was scored by two board-certified neuroradiologists using a scale of 1 to 5 (1=no useful diagnostic information, 2=limited diagnostic value but visible structures, 3=fair/marginal image quality, 4=good image quality but visibly lower SNR or contains artifacts, 5=excellent image quality with minimal if any artifacts). The combined average score from the two radiologists was 3.6. Additionally, the diagnostic capability of the Silenz and conventional fast gradient-echo images was compared (1=conventional more diagnostic, 2=same, 3=Silenz more diagnostic). Both radiologists noted that the images were comparable and this was reflected in their scores (combined average score of 2.0 for the two radiologists). Each acquisition method exhibited unique artifact properties and different signal-to-noise ratios.



Conclusion
Preliminary results indicate that the T1-weighted Silenz images exhibit good image quality, and diagnostic capabilities similar to those of a conventional T1-weighted fast gradient-echo method, while offering the advantage of silent acquisition.

Sinogram Affirmed Iterative Reconstruction for Head CT: Effects on Radiation Dose and Image Quality

Rivers-Bowerman, M. D.·Shankar, J.
Dalhousie University
Halifax, NS, CANADA.

Purpose
Iterative reconstruction has been reported to reduce radiation dose in CT, while preserving and even improving

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

image quality. The purpose of this study was to evaluate the effects of a commercially available iterative reconstruction algorithm, sinogram affirmed iterative reconstruction (SAFIRE), on radiation dose reduction and quantitative and qualitative measures of image quality for noncontrast head CT.

Materials & Methods

Institutional review board approval was obtained for this retrospective analysis of head CT datasets. For direct comparison of filtered back-projection (FBP) and SAFIRE image reconstruction techniques, fifty consecutive adult patients who underwent noncontrast head CT with SAFIRE were age-matched (± 5 years) with 50 patients who previously underwent noncontrast head CT with FBP. All CT scans were performed on a SOMATOM Definition Flash unit (Siemens Medical Solutions, Germany). Images were reconstructed axially with an H37s medium smooth kernel for FBP and with a J37s medium smooth kernel for SAFIRE. Dose-length products (DLP) were obtained from scanner-generated CT dose reports to estimate patient dose. One reader blinded to reconstruction technique measured gray matter (GM) and white matter (WM) attenuation in each patient with a region-of-interest (ROI) tool. Gray matter-WM signal-to-noise ratios (SNR) and GM-WM contrast-to-noise ratios (CNR) then were calculated from these values. Intra-observer variation was analyzed with a repeatability coefficient. Two readers blinded to reconstruction technique independently evaluated CT datasets for motion, noise, scatter-related artifact, GM-WM differentiation, small structure visibility, and image sharpness with an ordinal scale. Interobserver agreement was evaluated with the kappa statistic. Significance testing of quantitative and qualitative numerical data was performed with the independent samples t-test. Alpha was set at 0.05.

Results

The mean (standard deviation, range) age of the patient population was 57 (20, 21-92) years. With respect to the FBP control group, mean DLP in the SAFIRE test group was significantly reduced from 951 (59, 849-1144) mGy to 803 (77, 654-959) mGy ($P < 0.0001$). The mean ROI area for attenuation measurements was 22.8 (0.8, 18.3-26.3) mm^2 with a repeatability coefficient for ROI attenuation measurements of 1.8 HU. Gray matter SNR significantly increased from 10.0 (1.5, 7.1-15.1) in the FBP group to 15.6 (2.4, 11.1-22.6) in the SAFIRE group ($P < 0.0001$). Similarly, WM SNR increased from 7.3 (1.0, 5.1-9.4) in the FBP group to 10.2 (1.6, 7.4-14.5) in the SAFIRE group ($P < 0.0001$). There was also a significant improvement with SAFIRE for GM-WM CNR which rose from 1.7 (0.3, 0.9-2.5) to 3.1 (0.5, 2.1-4.1) ($P < 0.0001$).

Conclusion

Iterative reconstruction for noncontrast head CT reduces patient radiation dose by 15% for the SAFIRE settings employed at our institution, while significantly reducing image noise and improving contrast resolution.

Phantom Validation of MR Thermometry Using Proton Resonance Frequency Chemical Shift for Clinical High Field Applications

Dehkharghani, S.[1]·Wei, L.[2]·Pate, K. S.[1]·Magrath, R. P.[3]·Tong, F. C.[1]·Mao, H.[1]·Oshinski, J. N.[1]
[1]Emory University Hospital, Atlanta, GA, [2]Georgia Institute of Technology, Atlanta, GA, [3]Northwestern University, Chicago, IL.

Purpose

Brain temperatures lie at the intersection of complex metabolic and hemodynamic phenomena. The augmentation of ischemic neuronal injury during modest *hyper*thermia, and the well-known neuroprotective effects of *hypo*thermia highlight the importance of brain temperature in CNS disease. Traditional techniques aimed at brain thermometry are restricted by their costly and invasive nature, as well as their highly spatially constrained data collection. Physiologic models of cerebral thermoregulation have thus met with considerable controversy. Noninvasive measures of spatially varying cerebral temperatures represent a crucial step towards the elucidation of cerebral thermoregulation under normal and pathologic conditions, and during thermal therapies. Several nuclear magnetic resonance phenomena show sensitivity to temperature, and have been proposed as means of noninvasive MR thermometry. We report the results of a series of temperature-controlled phantom experiments investigating the sensitivity of single-voxel, point-resolved MR spectroscopy (SVS) as a means of thermometry in a brain cytosol phantom under clinically relevant parameters.

Materials & Methods

An aqueous metabolite solution titrated to physiologic concentrations of neuronal N-acetylaspartate (NAA), lactate (Lac), creatinine (Cre) and choline (Cho) was composed in-house for all phantom studies. The solution was secured within the bore of a 3T Siemens TimTrio whole-body clinical system (Siemens Medical Solutions, Erlangen, Germany); system temperature control and modulation was achieved through a circulating water bath custom designed for the following study, and experimentally validated in an independent series of experiments to ±0.1°C control. ^{1}H-MRS was acquired at static room temperatures (~18.8°C) with partially water-suppressed SVS (Tr=3000ms; Te=30ms; NEX=128; 1.5cc) following manual shimming, with eight repeated measures. Subsequently, in separate experimental sessions, sequential SVS were acquired with similar parameters during modulated temperatures. Spectra were first collected simultaneously during dynamic temperatures between 5-20°C, and in a second experiment between 20-45°C. Metabolite reference

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

temperatures from within the solution were collected simultaneously in all experiments at 3-second temporal update from a 4-channel, MR-compatible fiber-optic thermometry system (OpSens OTG-MPK5). Single-voxel spectroscopy thermometry was derived from the known temperature sensitivity of the water-NAA chemical-shift (ΔδH20-NAA), related to the temperature-dependent fluctuation in populations of bound and unbound water species, and approximated at 0.01ppm/°C. Spectra chemical shifts were assigned in java-version magnetic resonance user interface V4.0 (http://www.mrui.uab.es) and LCModel V6.3 (http://s-provencher.com/pages/lcmodel.shtml).

Results

Static MR thermometry sessions acquired by SVS at ambient room temperature (~18.8°C) demonstrated excellent stability and agreement (computed temperature=19.0°C on each of eight repeated measures). Collected spectra were of excellent quality (water line width=8Hz), facilitating frequency assignments and ΔδH20-NAA determination. Single-voxel spectroscopy thermometry acquired across 18 observations during modulated temperatures 20-45°C in two hours demonstrated a linear relationship (R^2=0.95; alpha=0.01±0.0007; RMSE=0.02ppm). Single-voxel spectroscopy thermometry session acquired during temperatures 5-20°C across 19 observations was best approximated by two-parameter model by linear regression (R^2=0.99; alpha=0.01±0.0003; RMSE=0.078ppm).

Conclusion

Noninvasive probes of brain temperature may be of tremendous utility for characterization of cerebral temperatures during ischemia or thermal therapy. Our results validate the accuracy and reproducibility of a simple SVS sequence acquired on a clinical whole body system for accurate, reproducible, and timely brain temperature estimation, and determination of cerebral thermal gradients.

Intra-Arterial Mannitol-Induced Blood-Brain Barrier Disruption in a Rabbit Model: Implications for Chemotherapeutic Drug Delivery in Brainstem Tumors

Pearl, M. S.[1,2]·Janowski, M.[1,3]·Airan, R.[1]·Walczak, P.[1]
[1]The Johns Hopkins University School of Medicine, Baltimore, MD, [2]Children's National Medical Center, Washington, DC, [3]Mossakowski Medical Research Centre, Polish Academy of Sciences, Warsaw 02-106, POLAND.

Purpose

One of the main challenges in brainstem tumor treatment is the poor penetration of chemotherapeutic drugs through an intact blood-brain barrier. This study describes a rabbit model of mannitol-induced blood-brain barrier disruption (BBBD).

Materials & Methods

This protocol was approved by our Institutional Animal Care and Use Committee. Four-French sheaths were placed in the right femoral arteries of 4-kg New Zealand white rabbits. Using a hybrid MRI angiography suite (Miyabi, Siemens), a 4-French catheter was used placed in the left vertebral artery. Through this catheter, a 1.7-French microcatheter was advanced over a 0.014-inch microwire into the left V4 segment or basilar artery under roadmap guidance. All catheters were continuously flushed with heparinized saline. The rabbits were transported to a 3T (Magnetom Trio, Siemens) MRI for dynamic injection and postmannitol administration images of the brain. Coronal T2 (TE/TR = 105/1500), T1 (TE/TR = 9.1/300), and GE-EPI (TE/TR = 30/3000; 60 measurements) images were obtained prior to intra-arterial (IA) mannitol injection. Dynamic EPI images were obtained during IA injection of feraheme (iron oxide nanoparticles, ~20 nm). Intra-arterial mannitol (25%, 0.26 ml/sec for 30 seconds) was delivered in the left V4 segment. After five minutes, gadolinium (Magnevist) was injected intra-arterially (0.5 molar, 0.01ml/sec for 1minute), Evans blue (EB) (2%, 2 ml/kg), known for rapid binding with albumin, was injected intravenously, and coronal T1 postgadolinium images were acquired. The EB staining was evaluated postmortem on brain slices.

Results

Dynamic EPI depicted the perfusion territory following contrast agent injection via the vertebral or basilar artery. Manipulation of the injection rate resulted in differential brain parenchymal coverage. Intra-arterial mannitol produced visible BBBD: diffuse bilateral enhancement of the brainstem, cerebellum and the PCA territory on gadolinium-enhanced T1-weighted images. Necropsy revealed unilateral EB uptake within the brainstem notably smaller than the degree of T1 enhancement.

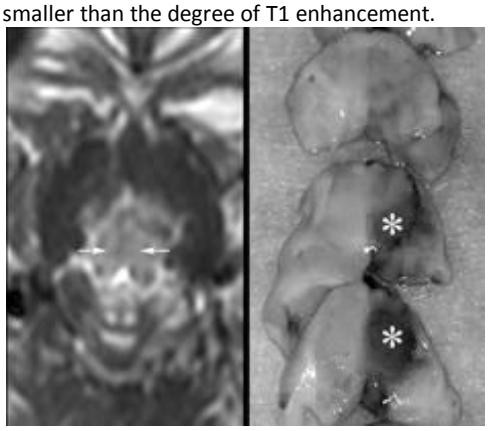

Figure 1. A) Coronal post-gadolinium T1-weighted image demonstrates diffuse bilateral enhancement of the brainstem (arrows). The unenhanced supratentorial brain is seen surrounding the brainstem. B) Selected brain slices show left-sided EB extravasation (asterisks) in the brainstem.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Conclusion
A transfemoral approach for IA microcatheter delivery of mannitol to the vertebrobasilar system in rabbits is feasible and efficient in producing BBBD. Assessment of BBBD for chemotherapy should consider the size of the therapeutic agent, as differential extravasation across the BBB was seen with gadolinium versus EB.

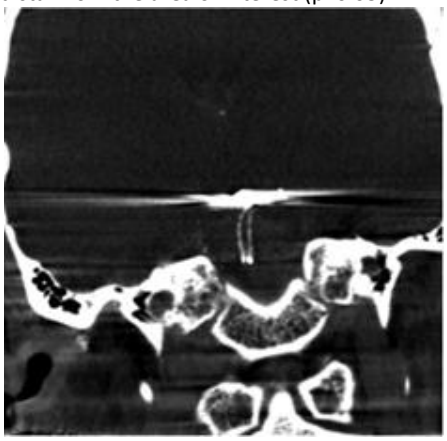
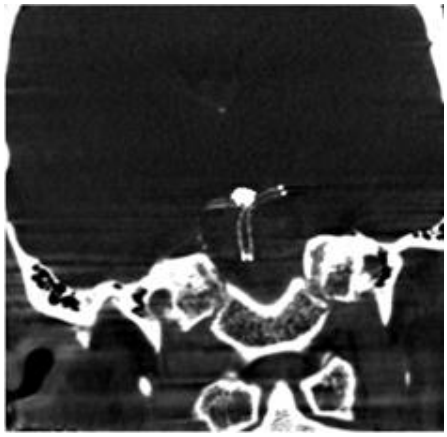
Cone Beam CT Metal Artifact Reduction in the Clinical Evaluation of Stent-Assisted Aneurysm Coiling

Radvany, M. G.[1]·Gundlack, F.[2]·Katz, Z.[1]·Kaminsky, I.[1]·Obrzut, M.[1]·Ehtiati, T.[2]
[1]Johns Hopkins University School of Medicine, Baltimore, MD, [2]Siemens, Princeton, NJ.

Purpose
Cone beam CT (CB CT) imaging is a useful technique for evaluation of intracranial stents. However, after aneurysm coiling there can be a significant amount of metal artifact precluding evaluation of the stent patency as well as residual filling at the base of an aneurysm. This study evaluates a modified reconstruction algorithm to reduce metal artifact and improve stent visualization.
Materials & Methods
We prospectively selected 11 consecutive cases in which patients underwent stent-assisted coiling and CB CT. Using the original data set from the diagnostic angiogram we reconstructed the data using the modified algorithm. The stent/vessel visibility, evidence of artifacts both near and far from the area of interest and overall image quality were evaluated by four interventional neuroradiologists.
Results
In eight of 11 cases there was improved visibility of the parent vessel/stent ($p < 0.01$). In all cases the overall image quality was improved ($p < 0.05$). In all cases there was a reduction in artifact near the area of interest ($p < 0.01$) and in 10 or 11 cases there was decrease in artifact distal from the area of interest ($p<0.05$).





Conclusion
Using a modified reconstruction algorithm to reduce metal artifact can improve image quality and evaluation of stents in stent-assisted coiling of aneurysm.

Evaluation of Cerebral Perfusion Parameters on CT Perfusion Associated with Global Cerebral Edema in Aneurysmal Subarachnoid Hemorrhage

Fodera, V.·Sanelli, P.·Gupta, A.·Baradaran, H.
New York Presbyterian-Weill Cornell
New York, NY.

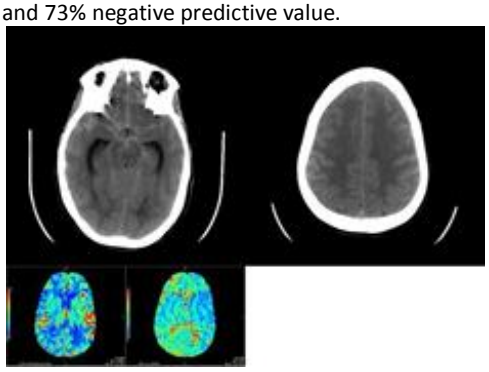
Purpose
Aneurysmal subarachnoid hemorrhage (SAH) is a devastating disease with severe complications including global cerebral edema (GCE) contributing to functional and cognitive disability. It is well known that GCE occurring during the early stage (day 0-3) independently leads to poor outcomes. However, little is known about mechanisms underlying the development of GCE and its effects on cerebral perfusion. Our aim was to evaluate cerebral perfusion parameters on CTP associated with GCE in aneurysmal SAH.
Materials & Methods
A retrospective study of consecutive SAH patients with CTP performed on admission (day 0-3) admitted from 2008-2010. Presence of GCE was determined on the noncontrast CT (performed concurrently with CTP) by two independent neuroradiologists blinded to all other clinical and imaging data using Claassen's definition: (1) complete or near-complete effacement of the hemispheric sulci and basal cisterns and (2) bilateral disruption of the hemispheric gray-white matter junction at the level of the centrum semiovale. Global cerebral edema was considered present if there was more than 75% sulcal effacement or more than 75% of gray-white matter disruption. CT perfusion was postprocessed into cerebral blood flow (CBF), cerebral blood volume (CBV) and mean transit time (MTT) data using a standardized method.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Qualitative analysis of CTP maps were performed by two independent blinded neuroradiologists to determine presence of global CTP deficits, defined as diffuse reduction in CBF and/or elevated MTT. Adjudication was performed by a third neuroradiologist. Test characteristics of CTP were calculated and statistical significance was determined by Fisher's exact test.

Results

A total of 45 patients were included in the statistical analysis. There were 42.2% (19/45) patients classified as GCE and 57.8% (26/45) as no GCE. Global perfusion deficits were seen in 52% (10/19) patients with GCE and 7.7% (2/26) without GCE. There is a statistically significant difference in the global perfusion in GCE ($p = 0.0014$) manifesting as diffusely reduced CBF and/or elevated MTT. Figure 1 demonstrates a patient with GCE and global perfusion deficit. Global perfusion deficits had a 53% sensitivity, 92% specificity, 83% positive predictive value and 73% negative predictive value.



Conclusion

Global perfusion deficits on CTP were statistically increased in GCE patients compared to patients without GCE. CT perfusion has a high specificity and positive predictive value. These initial results support further work in this field to evaluate the effects of GCE on cerebral perfusion and its association with poor outcomes.

Noninvasive Cerebral MR Thermometry Using Proton Resonance Frequency Chemical Shift in the Nonhuman Primate: Initial Experience and Validation

Dehkharghani, S.[1]·Wei, L.[2]·Oshinski, J. N.[1]·Mao, H.[1]·Magrath, R. P.[3]·Pate, K. S.[1]·Tong, F. C.[1]·Zhang, X.[4]·Howell, L. L.[4]

[1]Emory University Hospital, Atlanta, GA, [2]Emory University, Atlanta, GA, [3]Northwestern University, Evanston, IL, [4]Yerkes National Primate Research Center, Atlanta, GA.

Purpose

Cerebral thermoregulation remains a poorly understood phenomena, due primarily to the costly, invasive, and spatially limited nature of traditional techniques utilizing implanted brain temperature probes. The augmentation of neuronal injury during *hyper*thermia, and the neuroprotective effects of *hypo*thermia highlight the importance of brain temperature in CNS diseases. Among temperature-sensitive NMR phenomena, chemical shift difference between water and the N-acetylaspartate (NAA) methyl resonance ($\Delta\delta_{water\text{-}NAA}$) may be specifically well suited to characterization of cerebral gradients. We report the use of single and multivoxel MR spectroscopy (SVS/MVS) for noninvasive thermometry in the nonhuman primate (NHP) brain under clinically relevant conditions.

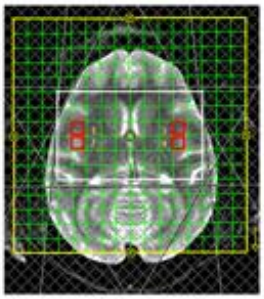
Materials & Methods

Imaging was performed on a 3T clinical system (Siemens Tim/Trio). Healthy Rhesus monkeys were obtained from the breeding program of our national primate research center with IAUCAC approval. Rhesus monkeys were selected for their recognition as an excellent surrogate for the modeling of human cerebrovascular diseases. Imaging included SVS collected by point-resolved spectroscopy with partial-water suppression (TR=2500 ms; TE=30 ms; Avg=128). A 10 x10x10 mm^3 voxel was placed juxtacortically near the right operculum, reflecting the anatomical vicinity of ischemic injury imposed by a NHP stroke model under investigation at our institution. Six repeated measurements were acquired successively under identical conditions for determination of $\Delta\delta_{water\text{-}NAA}$. In a separate experimental session, 2D-MVS (TR=2500; TE=84) with 6 repeated measurements was acquired with a 16x16 matrix placed to span the bilateral hemispheres from the sylvian region to the angular gyrus, with outer-volume suppression bands to mitigate lipid contamination. Physiologic monitoring, including rectal thermometry, was maintained on the anesthetized monkey throughout the protocol. Chemical shifts were assigned and analyzed in *j-mrui (http://www.mrui.uab.es)* and LCModel V6.3 *(http://s-provencher.com/pages/lcmodel.shtml)*.

Results

Systemic temperatures were maintained at ~37°C as indicated by rectal thermometry. MR thermometry derived following manual postprocessing of SVS yielded a temperature range 36.7-37.2°C (mean±sd=36.94±0.22). In MVS, separate $\Delta\delta_{water\text{-}NAA}$ values across two adjacent voxels assigned symmetrically in the right/left hemisphere (Figure) were derived from the MVS grid, with systemic temperatures again at ~37.0°C. Adjacent right hemispheric voxels acquired across six observations yielded cerebral temperatures 37.6°C±0.08 and 37.5°C±0.06 and an averaged 37.3°C±0.31 and 38.0°C±0.24 in left hemispheric voxels.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Placement of chemical shift imaging 2D-multi-voxel 16x16 grid for $\Delta\delta_{water\text{-}NAA}$ thermometry. 8 saturation bands placed for suppression of lipid resonance

Temp ($\Delta\delta_{water\text{-}NAA}$) °C

1: 37.5967±0.083	3: 37.2867±0.306
2: 37.5167±0.060	4: 37.9983±0.238

Conclusion
The validation of a noninvasive MR technique for brain temperature monitoring may facilitate the elucidation of complex metabolic and hemodynamic phenomena underlying neuronal injury. Our findings suggest that chemical shift thermometry offers a feasible and reproducible technique of brain thermometry with the potential to probe cerebral thermal gradients noninvasively.

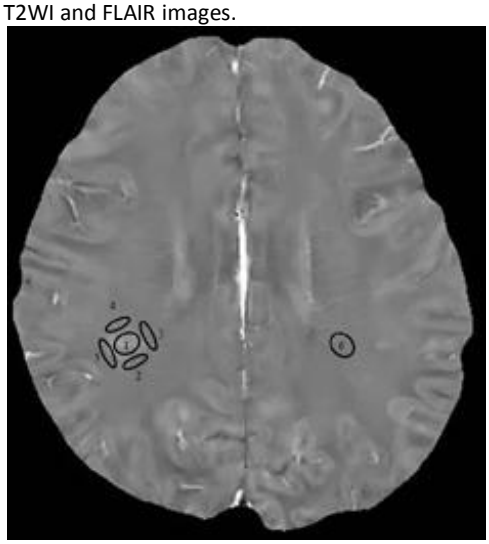
Evaluation of Normal-Appearing White Matter in Multiple Sclerosis Using Quantitative Susceptibility Mapping

Moriya, J.[1]·Kakeda, S.[1]·Ueda, I.[1]·Watanabe, K.[1]·Murakami, Y.[1]·Ide, S.[1]·Ogasawara, A.[1]·Futatsuya, K.[1]·Sato, T.[1]·Ohnari, N.[1]·Okada, K.[1]·Tsuji, S.[1]·Liu, T.[2]·Wang, Y.[2]·Korogi, Y.[1]
[1]University of Occupational and Environmental Health School of Medicine, Kitakyushu, JAPAN, [2]Weill Cornell Medical College, Ithaca, NY.

Purpose
The recent evidence from histologic studies has shown that the disease processes of multiple sclerosis (MS) involve not only the plaques seen on conventional MR images but also the white matter regions that appear to be normal on such studies. Quantitative susceptibility mapping (QSM) is a novel technique which allows determining the bulk magnetic susceptibility distribution of tissue in vivo from gradient echo magnetic resonance phase images. The purpose of this study was to determine whether the normal-appearing white matter (NAWM) regions surrounding and remote from MS plaques have abnormal magnetic susceptibility value.
Materials & Methods
Conventional MR and QSM imaging examinations were performed in 10 patients with MS and in 10 age-matched control subjects. Quantitative susceptibility mapping was performed for various ranges of echo time by using both the magnitude and phase components in the morphology-enabled dipole inversion method. We evaluated 60 MS plaques larger than 10 mm in diameter in the white matter. Uniform regions of interest (ROI) were placed on the plaques, periplaque white matter (PWM) regions, NAWM regions in the contralateral side of the brain, and WM regions in the control subjects, to obtain QSM values, which were compared across the WM regions (Figure). For ROI placement, PWM was defined as the white matter that was closest to and surrounding the plaque and that did not have abnormal signal intensity on coregistered T2WI and FLAIR images.



Results
In 50 of 60 plaques, the area of abnormal signal intensity on the QSM images was larger than the size of the corresponding plaque at qualitative visual evaluation of coregistered T2WI and FLAIR images. The mean QSM value was 150.3 ppb for plaques, 132.6 ppb for PWM, 120.3 ppb for NAWM, and 120.3 ppb for WM of control subjects. Significant differences in mean QSM values were observed among all WM regions ($P < .001$ for all comparisons, except QSM value in NAWM versus control subject WM).
Conclusion
The QSM values were abnormal in the periplaque regions in the patients with MS. Quantitative susceptibility mapping may be more accurate than T2WI or FLAIR for assessment of disease burden.

KEYWORDS: Multiple sclerosis plaques, Advanced MR imaging, QSM

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Evaluation of a Bayesian Expert System for Aiding Neuroradiology Diagnoses: A Pilot Study

Tanwar, M.·Herskovits, E. H.·Nasrallah, I. M.·Kundel, H.·Mohan, S.·Li, C.·Lynch, M. C.·Bryan, R.
University of Pennsylvania
Philadelphia, PA.

Purpose
Recently, there has been an explosive growth of digital imaging data, resulting in challenge and opportunity. Contemporary computational techniques can analyze immense amounts of complex data and are being incorporated into decision-support applications. We have developed a prototypical Bayesian expert system that takes input key features (KFs) detected in images and outputs a differential diagnosis (DDx) ranked by posterior probability. We hypothesize that the idealized KFs upon which the model was based and those extracted by radiologists at different levels of training and the DDx lists produced by the model and human readers are similar.
Materials & Methods
Eleven neuroradiological entities (abscess, cerebritis, craniopharyngioma, glioblastoma, hematoma, infarct, metastasis, multiple sclerosis, rhombencephalitis, toxoplasmosis, xanthogranuloma) and normal, were evaluated by a senior neuroradiologist to identify characteristic and idealized imaging KFs and approximate conditional probabilities of these features. These features and probabilities were used to build a Bayesian expert system for differential diagnosis. Two attending neuroradiologists selected a test set of 60 diagnosis-proven MR examinations from our PACS: 5 for each entity. Three diagnosis-blind readers -- attending neuroradiologist, neuroradiology fellow and PGY-3 radiology resident -- reported the KFs and their rank ordered DDx after reviewing each case. We entered each reader's KFs into our model, obtaining a posterior probability ranked DDx list for each case-reader combination. We compared reader's observed KFs to each other and to the ideal disease features, and we compared readers' DDx to those of the model and to each other. We also compared DDx lists to the clinically proven diagnosis. Percentage agreement, kappa statistics, and ROC analysis were used to evaluate human and computer reader performance.
Results
For individual extracted KFs, there was moderate to excellent agreement between the different human readers (57-91%), which was similar to agreement between individual reader KFs and the idealized KFs for the various diseases (42-94%). Inter-reader agreement for each feature was similar to agreement between readers and the model system KFs. The model, using ideal cases (i.e., cases with "classic" features, as determined by a senior neuroradiologist), was in 100% agreement with the known diagnosis. These indicate that the KFs upon which the model system was based are concordant with actual clinical cases. The primary diagnoses of the human readers versus the proven diagnoses showed percent agreement of 77-92% and K = 0.74-0.91. ROC analysis of DDx for human readers (AUC 0.91-0.93) and model output diagnoses based on human extracted KFs (AUC 0.66-0.82) all demonstrated excellent performance.
Conclusion
A prototype neuroradiological decision-support application was developed and evaluated using a small set of clinical neuroradiological MR examinations. Readers selected similar KF values regardless of experience level, probably reflecting our use of readily noticeable findings. There was excellent agreement between each readers' most likely diagnoses and the known diagnosis, with the resident manifesting slightly lower accuracy, probably because our 12 entities are fairly distinct. Further development might render this software suitable for reducing the variability of radiology reports, improving report quality, and increasing the efficiency of practicing radiologists.

Time Delayed Contrast-Enhanced MR Imaging Improves Detection of Brain Metastases

Kushnirsky, M.·Katz, J. S.·Knisely, J. P. S.·Schulder, M.·Rosen, L.·Steinklein, J.·Warshall, C.·Nguyen, V.
Hofstra North Shore-LIJ School of Medicine
Manhasset, NY.

Purpose
Contrast-enhanced magnetic resonance imaging (MRI) is the preeminent diagnostic test for brain metastases (BM). Brain metastases detection for stereotactic radiosurgery (SRS) planning may improve with a time delay following administration of a high-relaxivity agent for 1.5T and 3T imaging systems. Metastasis detection with time-delayed MRI was evaluated in this study.
Materials & Methods
Fifty-three volumetric MRI studies from 38 patients undergoing SRS for BM were evaluated. All studies used 0.1 mmol/kg gadobenate dimeglumin (MultiHance®), immediately after injection, followed by two more axial T1 sequences after five minute intervals (final image acquisition commenced 15 minutes after contrast injection). Two studies were motion-limited and excluded. Twu hundred eighty-seven BM were identified. The studies were randomized and examined separately by three radiologists, who were blinded to the temporal sequence. Each recorded the number of BM detected per scan. A Wilcoxon signed-rank test compared BM numbers between scans. One radiologist determined the scan on which BM were defined best.
Results

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

The interclass correlations for scans 1, 2, and 3 were 0.7392, 0.7951 and 0.7290, respectively, demonstrating excellent inter-rater reliability. At least one new lesion was detected in the 2nd scan as compared to the 1st in 35.3% of subjects (95% CI: 22.4%-49.9%). The increase in BM numbers between scans 1 and 2 ranged from 1 to 10. At least one new lesion was detected in the 3rd scan as compared to the 2nd in 21.6% of subjects (95% CI: 11.3%-35.3%). The increase in BM numbers between scans 2 and 3 ranged from one to nine. Between scans 1 and 3 additional tumors were seen on 41.2% of scans (increase range 1 to 14). The median increase in tumor number for all comparisons was one. There was a significant increase in number of BM detected from scan 1 to scan 2 ($P < 0.0367$), and from 1 to 3 ($P < 0.0264$). In 34 of the 51 studies (66.7%), the radiologist selected the 3rd scan as providing the clearest tumor definition.

Conclusion

In patients who are being prepared for SRS of brain metastases, delayed MRI after contrast injection revealed an increased number of targets that need treatment. To avoid missing tumors that could be treated at the time of planned SRS, and resultant "treatment failures", we recommend that postcontrast MRI be acquired between 10 and 15 minutes after injection in patients undergoing SRS for treatment of metastatic brain tumors.

Reducing Artifacts in Patients with Implanted Spinal Hardware at 1.5 and 3T Using WARP

Safriel, Y.[1,2]·Dale, B.[3]·Padua, A.[3]
[1]University of South Florida, Belleair Beach, FL, [2]Radiology Associates of Clearwater, Clearwater, FL, [3]Siemens Medical Solutions, Inc., Morrisville, NC.

Purpose

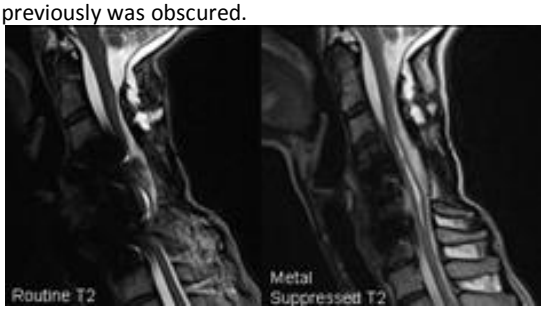
Implanted spinal hardware can create significant artifacts on MRI images due to the change in susceptibility between metal and tissue. This artifact can be particularly severe at 3T as compared with 1.5T. Clinically, the signal loss and distortion may obscure pathology resulting in additional invasive tests. WARP is a work-in-progress designed to reduce these artifacts but has not been evaluated on the spine or at 3T.

Materials & Methods

The study was IRB approved and HIPPA compliant. The WARP sequence is a turbo-spin echo (TSE) sequence that utilizes increased transmit and receive bandwidth and either view angle tilting (VAT) or slice-encoding metal artifact correction (SEMAC) in order to reduce sensitivity to susceptibility variations. All patients with implantable spinal hardware had a routine lumbar MRI and at least one WARP sequence. Routine sequences included a sagittal and axial T2 TSE with restore sequence and T1 TSE sequence.

Results

Twenty-four patients were scanned. The cohort included subjects with lumbar or cervical instrumentation (pedicle screws, disk arthroplasty and plates) scanned on 1.5T or 3T platforms (Siemens, Germany). Hardware composition included stainless steel, titanium, and composites. Sagittal T2 images showed qualitatively greater improvement with the application of metal suppression. Fat-suppressed images showed least improvement. View angle tilting images were superior to SEMAC images. In six patients, the metal suppression improved visualization of pathology. In two patients, metal suppression changed the diagnosis or revealed pathology that was not seen otherwise. In one of those, metal suppression revealed a syrinx that was incompletely seen with the standard sequences. In the other, the metal suppression revealed a small disk fragment and severe central stenosis that previously was obscured.



Conclusion

WARP sequences have potential to improve imaging in patients with implanted hardware on both 1.5T and 3T platforms. It also may improve diagnostic confidence possibly reducing the need for invasive procedures such as myelography. Further work is needed to better define the parameters prior to commercial release.

KEYWORDS: Metal artifact, Spinal imaging, 3T

Single Voxel MR Spectroscopy in Nonherniated Painful, Herniated Painful, and Nonpainful Lumbar Disks

Tanenbaum, L.[1]·Hu, S.[2]·Gornet, M.[3]·Berven, S.[2]·Peacock, J. C.[4]·Lotz, J.[4]·Bradford, D.[4]·Claude, J.[4]·Kane, P.[4]·Schranck, F.[3]·Stewart, D.[5]
[1]Mount Sinai School of Medicine, New York, NY, [2]University of California San Francisco, San Francisco, CA, [3]Orthopedic Center of Saint Louis, Saint Louis, MO, [4]Nocimed, LLC, Redwood City, CA, [5]MRI Partners of Chesterfield, Saint Louis, MO.

Purpose
To evaluate noninvasive in vivo single voxel MR spectroscopy (SVS) via two leading commercial 3T scanners in lumbar disks in diskogenic low back pain (LBP) patients receiving provocative diskography (PD) and asymptomatic volunteers (ASY), and correlate to nonherniated painful (NHP), herniated painful (HP), and nonpainful (NP) disks.
Materials & Methods
Single voxel spectroscopy exams were conducted via CHESS/PRESS SVS pulse sequences on commercial GE Signa and Siemens Verio 3T scanners, each single center, per custom investigational acquisition/postprocessing configurations and protocols developed for each platform. Two hundred twelve of 82 (disks/subjects) acquisitions from both platforms were conducted during the study(79/42 GE; 133/39 Siemens). Developmental technique refinements yielded 167 disk spectra meeting criteria for deterministic diagnostic correlations (74 of 79 disks, GE; 93 of 133 disks Siemens): 14 PD positive(PD+) NHP disks (13 GE; 1 Siemens); 7 PD+ HP disks, including six with significant leg pain(Siemens only); and 146 NP disks(61 GE; 85 Siemens), comprising PD negative (PD-) disks in pain patients and ASY disks. Provocative diskography was performed generally per ISIS guidelines. Proteogylcan(PG), lactic acid (LA), and alanine(AL)-related spectral measures were used for diagnostic algorithm development to correlate to disk types - which was performed independently for disk spectra subgroups acquired via each MR platform, with combined results assessed.
Results
Single voxel spectroscopy-based algorithms using PG and LA measures for both MR platforms resulted in 99.4% overall accuracy in correlating with 159 of the 160 NHP and NP disks, including 13 of 14 NHP disks, and all 146 of the NP disks with no false positives(12/13 NHP and 61/61 NP disks, GE; 1/1 NHP and 85/85 NP disks, Siemens). Of the 93 Siemens-based disk spectra evaluated, SVS signatures for the 7 PD+ HP disks did not differ significantly from the 85 NP disks. However, all 92 Siemens-based HP and NP spectra had a PG/LA ratio > 1, versus a PG/LA ratio < 1 for only the one Siemens-based PD+ NHP disk evaluated. Prior 11T ex vivo analysis of surgically removed disks also demonstrated PG/LA ratios were significantly lower for NHP disks versus NP disks. Nociceptor in-growth into disk nuclei has been observed in NHP disks, but not typically in NP disks - potentially related to inflammation and PG reduction. Increased LA in disks may irritate such intradiskal nociceptors to cause diskogenic LBP. However, annulus fibrosus disruptions of HP disks can irritate external nerves instead, and may allow extradiskal fluid interaction to neutralize intradiskal acidity.
Conclusion
PG and LA-related biomarkers via noninvasive SVS acquisitions in 160 lumbar disks on two commercial 3T scanners differentiated NHP from HP and NP disks with 99.4% accuracy in this study, with 100% positive predictive value and specificity (0 false positives in 146 NP disks), and failing to predict only 1/14 PD+ NHP disk. Quantitative disk SVS may provide a valuable radiology platform for chemical differentiation between these different disk types and pain profiles, and which may help guide clinical management of LBP patients in the future. Further study is warranted to confirm these encouraging findings.

Comparison of in vivo Quantification of T1ρ in Lumbar Spine Disk Spaces at 3T in Middle-Aged Elite Athletes versus Middle-Aged Sedentary Controls: Initial Findings

Filippi, C. G.[1,2]·Duncan, C. T.[2]·Schlobohm, K.[2]·Gonyea, J. V.[3]·Hipko, S.[3]·Andrews, T.[4]·Watts, R.[3]
[1]Columbia University College of Physicians and Surgeons, New York City, NY, [2]University of Vermont School of Medicine, Burlington, VT, [3]University of Vermont School of Medicine-FAHC, Burlington, VT, [4]Philips Health Care, Cleveland, OH.

Purpose
T1 is an emerging, quantitative MR imaging modality that has been shown to correlate with proteoglycan content. Recent studies at 3T with parallel transmission have shown significant negative correlations of T1 with age at all disk space levels in the lumbar spine in normal controls supporting a potential role for T1 as a biomarker of disk degeneration. Studies have shown higher rates of disk degeneration in elite athletes particularly at L5/S1. The purpose of this study was to compare standard T2-weighted sequences and T1 quantification in middle-aged elite athletes to sedentary age-matched controls to determine if T1 would detect proteoglycan changes between these two groups.
Materials & Methods
Eleven male sedentary subjects (age range 44 to 59 years, mean 49.8 years) and six elite male athletes (age range 48 to 56 years, mean 51.4 years) with no history of chronic back pain or surgery had T1 imaging of the lumbar spine at 3T with parallel transmission. All athletes are marathoners considered elite level by national USA Track and Field parameters for age. For T1, sagittal 3D gradient-echo

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

sequence (TR 3.35/TE 1.76) with flip angle 10, matrix 240 mm, 3 mm slice thickness, 18 slices, and five spin lock times of 1/25/50/75/100 msec respectively with a spin lock frequency of 350Hz. Mean T1 values of all lumbar spine disk space levels were quantified. For quantitative analysis, ROIs were placed centrally within the disk space compartments on 100 msec spin lock time sequences. Average and standard deviations of T1 values were calculated using a monoexponential curve fit with baseline correction based on noise values (air). Sagittal T2-weighted images were performed with TR 2800/TE 110 with 240 mm FOV, 3 mm thickness, 18 slices, flip angle 90. From these images, Pfirrmann scores of degenerative grade were determined at all lumbar disk space levels. Student two tail t-test was used to analyze these measures at all disk space levels with significance set to $P < .05$. One neuroradiologist with CAQ and two medical students performed quantification, all blinded. Interobserver and intra-observer variability was determined for T1 with Spearman rank correlation and for Pfirrmann scores with Cohen Kappa statistic.

Results

There were no statistically significant differences in Pfirrmann scores between these groups at any disk space level. Kappa statistic .675 indicated good interrater agreement. Regarding T1, there was a statistically significant lower T1 value in elite athletes at L5-S1 level ($P < .05$). T1 at L5/S1 for elite athletes is 48. 54 +/- 14.74, T1 for sedentary controls was 89.67 +/- 23.42. Spearman correlations for T1 values ranged from .62 to .99.

Conclusion

T1 was significantly lower at L5/S1 in elite athletes, which supports clinical studies, and no significant differences detected on Pfirrmann scores derived from T2-weighted images at this L5-S1 level such that T1 may be a more sensitive biomarker for disk degeneration. Larger studies will be needed to corroborate this preliminary work.

Comparison of Contrast-Enhanced Time-Resolved MR Angiography and Digital Subtraction Angiography for Evaluation of Spinal Vascular Malformations

Boddu, S.·Saindane, A. M.·Dehkharghani, S.·Tong, F.·Dion, J.
Emory University School of Medicine
Atlanta, GA.

Purpose

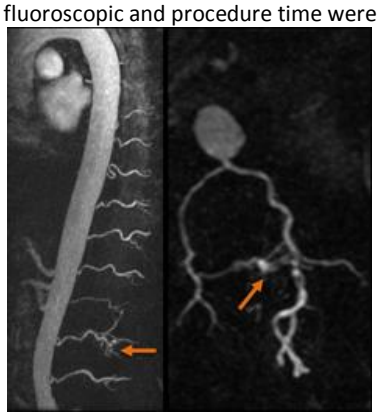
Spinal vascular malformations (SVMs) can pose a challenge in diagnosis and exact localization. Spinal digital subtraction angiography (DSA) is the gold standard for diagnosis, but can be intensive in time, radiation dose, and contrast dose. Conventional spinal MRI has limited sensitivity for evaluation of SVMs. We hypothesize that multiphasic contrast-enhanced time-resolved MRA (CE-TR-MRA) will have utility for noninvasive diagnosis and pre-angiographic localization of SVMs.

Materials & Methods

Thirty-one consecutive patients who underwent CE-TR-MRA for suspected SVMs presenting over a 24-month period were reviewed. Of these, 17 patients [14 males; median age 65 years (30-80 years)] underwent both CE-TR-MRA and DSA, with DSA performed a median of 11 days (0 - 41 days) after the CE-TR-MRA. Subjects underwent MRA on a 1.5T GE unit using both 3D TOF-MRA and CE-TR-MRA using yime resolved imaging of contrast kinetics (TRICKS) with intravenous administration of a standard dose gadolinium-based contrast agent. Both the CE-TR-MRA and DSA images were evaluated for presence or absence of SVM and location of feeding arterial supply. Contrast-enhanced TR-MRA was evaluated against DSA as the reference standard. Digital subtraction angiography also was evaluated for number of vessels catheterized, contrast volumes, fluoroscopic and procedure time.

Results

Thirteen of 17 CE-TR-MRA studies were of diagnostic quality; four patients had suboptimal MRA from motion artifact. Of the 13 diagnostic studies, six patients were positive for SVM both on CE-TR-MRA and DSA, six patients were negative for SVM on both CE-TR-MRA and DSA and one patient was a false positive on CE-TR-MRA (a nonspecific hypervascular blush from the right L1 level with no shunt pathology on DSA). The sensitivity, specificity, positive and negative predictive values of TR MRA were 100%, 86%, 86% and 100%, respectively. One patient negative on both CE-TR-MRA and DSA had a cavernous malformation on MRI. One patient with an initially negative DSA had a positive CE-TR-MRA for dAVF, confirmed on repeat targeted DSA. The localization of SVM arterial supply on CE-TR-MRA was within one vertebral level on DSA for all patients. Compared to patients with confirmed SVM on CE-TR-MRA, patients with negative and suboptimal CE-TR-MRA had significantly increased number of vessels catheterized (p=0.001) and larger contrast volumes (p=0.0009). No significant difference in fluoroscopic and procedure time were found.



Conclusion

Contrast-enhanced TR-MRA is a reliable noninvasive investigation for the diagnosis and localization of SVMs,

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

and is useful prior to DSA to reduce the number of catheterized vessels and contrast volume.

Novel Semi-Automatic Algorithm for Spinal Cord Cross-Sectional Area Analysis in Multiple Sclerosis

Bakshi, A. C.·Winston, L.·Saad, Z.·Jacobson, S.·Reich, D. S.·Nair, G.
National Institutes of Health
Bethesda, MD.

Purpose
To quantify spinal cord atrophy in multiple sclerosis (MS) by using a novel semi-automated algorithm that determines cross-sectional area from noninvasive imaging techniques.
Materials & Methods
MR imaging was performed on seven MS patients (two secondary progressive, one primary progressive, three relapsing-remitting, one clinically isolated syndrome, age 43.3 ± 9.2 years, EDSS between 0 and 6.5, five women and two men) and seven healthy controls (44.4 ± 7.5 years, age-matched to MS, five women and two men) on a Siemens 3T Skyra system equipped with a spine array coil. Volumetric images of the cervical and thoracic cord were obtained using a T1-weighted MPRAGE sequence with TR = 3000 ms, TE = 4.5 ms, TI = 750 ms, FA= 8 degrees, and 1 mm isotropic resolution. Cross-sectional area of the cord was calculated by detecting the edge of the spinal cord from slices reformatted perpendicular to the cord at each point between the C1 and C7 vertebral body segments. Total postprocessing time was <5 minutes with minimal user input. Multiple sclerosis patients also underwent disability tests including the Expanded Disability Status Scale (EDSS) and the 9-hole peg test.
Results
The average cross-sectional cervical cord area for MS patients (69.4 ± 12.0 mm2) was significantly lower than that for healthy controls (84.2 ± 10.9 mm2) (t-test, $p < 0.001$). The average cross-sectional area at each point along the cord was also lower for MS patients (Figure). In the MS group, there were negative correlations between the average cross-sectional cervical spinal cord area and the corresponding EDSS score ($r = -0.90$, $p = 0.003$) and 9-hole peg test times ($r = -0.73$, $p = 0.03$), suggesting that cord measures determined through this novel algorithm may be associated with clinical disability.

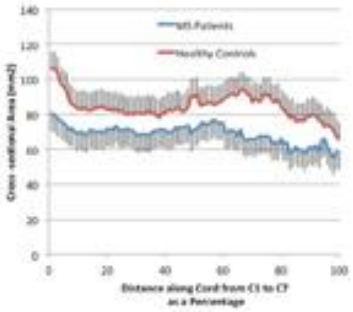

Figure: Cross-sectional cord area for 7 MS patients and 7 healthy controls as a percentage of distance from C1 to C7.

Conclusion
Cross-sectional area measurements acquired through this algorithm correlated inversely with clinical disability scores. These measurements therefore may prove useful as imaging biomarkers of MS progression both in the clinic and in clinical trials. Testing of additional patients as well as expanding these measures to the thoracic spinal cord is underway.

Oxaliplatin-Induced Neuropathy Can Be Demonstrated by Imaging: Molecular Neurography in a Mouse Model

Le Roux, L. G.·Bredow, S.·Schellingerhout, D.
M. D. Anderson Cancer Center
Houston, TX.

Purpose
The purpose of our study was to utilize a new imaging technology, neurography, based on the retrograde transport of a molecular imaging agent, to determine if oxaliplatin neurotoxicity affects retrograde axonal transport.
Materials & Methods
Female adult BALB/c mice (n = 8) were treated with oxaliplatin to a cumulative dose of 30 mg/kg by giving 10 divided intraperitoneal doses using a five days of treatment, five day rest, five day treatment administration paradigm. Animals were imaged at baseline and weekly for 149 days after commencement of therapy. Control animals (n = 8 from 8 to 28 days, n = 4 from 35 to 65 days)) were mock treated with saline and were imaged similarly out to 65 days. All animals received fluorescently labeled TTc-Alexa790 (15 ug in 20 uL) via intramuscular injection into the calf muscles at every imaging session. Fluorescent imaging (Xenogen IVIS 200) was used to image the distribution of TTc over 60 minutes, with ROI measurements taken from the thoracic spine to quantitate fluorescent uptake. Region of interest measurements had background activity subtracted, and were normalized to the signal intensity at time = 0.
Results

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

With sham treatment, TTc transport through the sciatic nerve and spinal cord causes the fluorescent signal intensity over the thoracic ROI to gradually increase (Figure, legend indicates number of days after start of study). At 60 minutes the grouped mean normalized fluorescence was 562% (+/-210% SD). With oxaliplatin treatment, transport is abruptly and severely impaired with baseline values of 836%+/-375% falling to 396%+/-140%, 247%+/-63%, 213%+/-58%, 162%+/-46%, 147%+/-63% with each successive week and stabilizing around 175% (+/-45%) for grouped means from 6 weeks out to the end of the study. The difference between normalized fluorescence grouped mean values from 6 weeks after oxaliplatin treatment to the end of study, and control animals is highly statistically significant (T-test $p<0.0001$).
Conclusion
Oxaliplatin causes a rapid and apparently irreversible (to our current followup of 149 days) decrease of retrograde axonal transport in the sciatic nerves and spinal cord, as demonstrated with a neurographic molecular imaging agent.

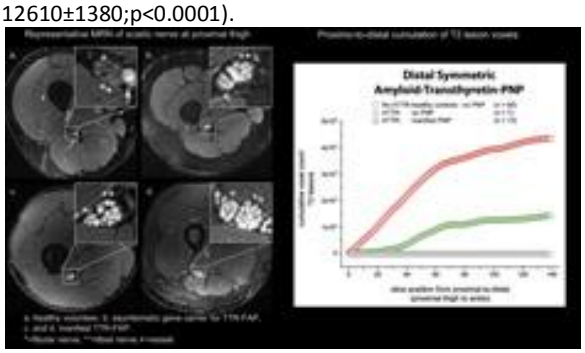
Hereditary Transthyretin Familial Amyloid Polyneuropathy: In vivo Detection of Lower Limb Nerve Injury Using High-Resolution MR Neurography

Kollmer, J. C.·Hund, E.·Hornung, B.·Schönland, S.·Hegenbart, U.·Kimmich, C.·Bendszus, M.·Pham, M.
University of Heidelberg
Heidelberg, GERMANY.

Purpose
Transthyretin-familial-amyloid-polyneuropathy (TTR-FAP) is an autosomal-dominant transmitted hereditary disease leading to misfolding and extracellular deposition of the protein transthyretin. It is endemic (e.g., in certain regions of Portugal and Sweden) but very rare in other parts of Europe and the U.S. Clinically, it is a life-threatening multisystemic disorder, presenting mainly with an axonal, distal-symmetric-sensory-motor, small-fiber-polyneuropathy (PNP) in addition to autonomic/cardiac manifestations. Concerning the pathomechanisms of TTR-FAP it is unclear whether the deposited amyloid leads to direct toxic effects or indirect ischemic nerve injury. For the first time, we investigated in vivo amyloid-related nerve-injury by large coverage and high-resolution T2-weighted imaging.
Materials & Methods
We prospectively examined a large sample of 20 patients with genetically confirmed TTR-FAP {13 with manifest PNP [measurements included: complete neurologic examination, scoring for NIS-LL (Neuropathy-Impairment-Score-Lower-Limbs), NDS (Neuropathy-Deficit-Score), NSS (Neuropathy-Symptom-Score), detailed neurographic measurements], and seven neurologic/electrophysiologic asymptomatic-gene-carriers}. These subjects were compared to 60 healthy volunteers, age/gender-matched. Imaging was done on a 3T-MR-scanner (Magnetom/Trio/Siemens) with high-resolution T2-weighted fat-suppressed-sequences separately for each leg and lumbar plexus: 1) axial T2-TSE-fs-sequences from proximal thigh to distal ankle (140 slices/leg; TE/TR 55/5970ms, voxel-size 0.4x0.3x3.5mm); 2) 3D-T2-IR-SPC sequence with axial reformation (50 images) for the lumbar plexus/spinal nerves (TE/TR 202/3000, voxel-size 1.0x1.0x1.0). Manual segmentation of the lumbar plexus/sciatic/tibial/fibular/sural nerve as nerve-tissue-voxels was performed on each axial imaging slice (320/subject). Lesion-voxels then were classified fully automated and operator-independent. Statistical analysis was performed by using nested-two-way-ANOVA and pairwise-contrast-analysis.
Results
Quantitative evaluation of lesion-voxels and pairwise-contrast-analysis showed with strong statistical significance that lesion-voxel-number was markedly higher not only in symptomatic TTR-FAP (28948±5035;$p<0.0001$) but also in asymptomatic gene-carriers (18119±4162;$p=0.02$) compared to healthy controls. Differences in lesion-voxel-number between symptomatic and asymptomatic TTR-FAP also were highly significant ($p<0.0001$). Nested-two-way-ANOVA revealed for lesion-voxel-count a predominant proximal focus (thigh) of nerve lesions (proximal 35290±3275 versus distal 12610±1380;$p<0.0001$).



Conclusion
We could show for the first time, that in TTR-FAP, nerve lesions were detectable in vivo by using high-resolution MRN not only in patients with manifest PNP, but also in asymptomatic gene carriers in whom imaging detection precedes clinical/electrophysiologic manifestation. This suggests that MRN can serve as a novel and highly sensitive diagnostic marker even of early asymptomatic stages of TTR-FAP. Furthermore, we found proximal nerve lesions to be more severe than distal lesions in all 20 TTR-FAP subjects. This finding is surprising because symptoms prevail distally (not proximally), pointing towards ischemia rather than metabolic toxicity as major pathomechanism of TTR-induced nerve damage.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

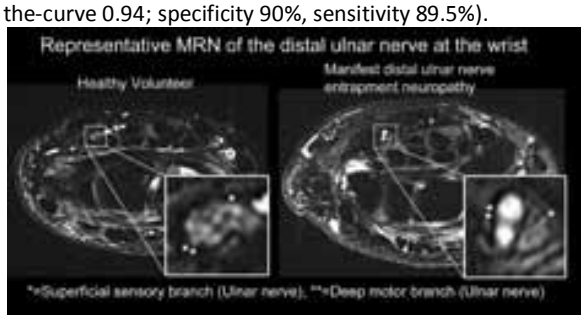
MR Neurography versus Electric Nerve Conduction in Distal Ulnar Nerve Entrapment

Kollmer, J. C.[1]·Dombert, T.[2]·Staub, F.[2]·Bäumer, P.[1]·Bendszus, M.[1]·Pham, M.[1]
[1]University of Heidelberg, Heidelberg, GERMANY, [2]Center for Peripheral Neurosurgery, Dossenheim/Heidelberg, GERMANY.

Purpose
In patients with a suspected peripheral neuropathy it is essential to determine the presence of an underlying nerval lesion, especially if surgical decompression is indicated. The current diagnostic goldstandard are electrophysiologic measurements of nerve function, but even then, the exact localization and detection of nerve entrapment often remains unclear. The clinical relevance and validity of MR neurography (MRN) in determining a neuropathic lesion is still subject of controversial discussions, especially because the underlying histopathologic processes leading to an increased intraneural T2-signal, the major diagnostic sign of MRN, are not completely understood. In this study, we correlated intraneural T2-signal with motor-nerve-conduction, which has never been performed before in any human or experimental study.
Materials & Methods
We prospectively examined 11 patients with confirmed rare ulnar nerve entrapment neuropathy at the wrist and 11 asymptomatic volunteers, matched for age and gender. Imaging was done on a 3T MR-scanner (Magnetom/Verio/Siemens) applying axial T2-weighted fat-suppressed-sequences (TR/TE 3830/60ms, voxel-size 0.2x0.2x2.0mm). Intraneural T2-weighted-signal was evaluated by manually delineating nerve circumference as intraneural region-of-interest (ROI) on each axial imaging slice. To determine contrast-to-noise-ratios (CNR), additional ROIs were placed in the thenar muscles and in the air. Electrophysiologic examinations included distal motor-nerve-conduction of the ulnar nerve measured as distal-motor-latency (dml) to first dorsal-interosseus (IOD I) and abductor digiti minimi muscle.
Results
Electrical-nerve-conduction of the deep motor branch measured as dml to IOD I shows a significant nonlinear correlation with ulnar motor branch T2-signal (mean dml IOD I in patients 5.85 +/-0.66ms (range 3.0-10.3 ms), mean dml IOD I in volunteers 3.28+/-0.10ms (range 2.7-3.8; pathologic if >4.4ms); R^2 = -0.8; p<0.001). T2-weighted-CNR values increase steeply within the range of beginning deceleration of electrical-conduction (up to 5ms) until reaching a plateau within the range of severe conduction slowing (>5ms). Furthermore, ROC-analysis revealed increased nerve T2-signal of the deep motor branch to be a sign of excellent diagnostic performance (area-under-the-curve 0.94; specificity 90%, sensitivity 89.5%).



Conclusion
MR neurography serves as an excellent diagnostic test in determining even distal nerve entrapment with involvement of smallest distal nerve branches at the limit of current structural resolution. The strong nonlinear correlation between nerve T2-signal and motor-nerve-conduction with an exponential asymptotic growth underlines that MRN is particularly sensitive for the detection of early stages of focal entrapment neuropathy, whereas nerve conduction during this stage shows only slightly subnormal deceleration. Furthermore, our results support that an increased intraneural T2-signal reflects an underlying clinically relevant pathology.

MR Neurography: Anterior Interosseus Nerve Syndrome Is Not a Neuropathy of the Anterior Interosseus Nerve

Pham, M.[1]·Baeumer, P.[1]·Kollmer, J.[1]·Kele, H.[2]·Bendszus, M.[1]
[1]Heidelberg University Hospital, Heidelberg, GERMANY, [2]Center for Peripheral Nerve Disease, Neuer Wall, Hamburg, GERMANY.

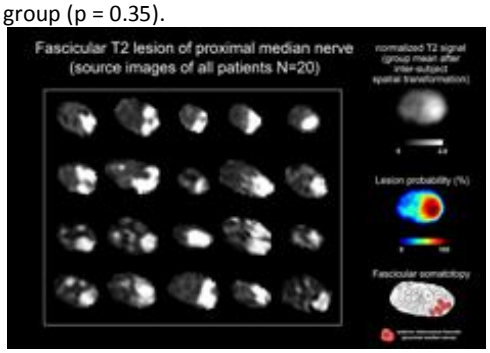
Purpose
Anterior-interosseus-nerve-syndrome (AINs) is conceived as entrapment-neuropathy of the anterior-interosseus-nerve trunk (AIN) at mid-forearm level, distal to its exit from median nerve (MN). MR imaging has been used so far to rule out mass lesions compressing AIN and to confirm muscle injury/denervation by increased intramuscular T2-weighted-signal. However, precise determination and localization of the nerve lesion itself by MR-neurography or any other test including electrophysiology has failed so far.
Materials & Methods
In a large prospective cohort of 20 consecutive patients (45.6 ± 10.4 years,15m,5f) the rare AINs was confirmed by standard criteria: acute weakness of terminal thumb and index finger-flexion. All patients and additional 20 healthy controls matched to age/gender underwent extended high-resolution MR-neurography of upper

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

arm/elbow/forearm level (15Ch/Transmit-Receive extremity coil, 3x41 slices 2D-T2-TSE, TE/TR 55/5970ms, in-plane resolution/slice thk. 0.3mm/3mm). AIN (forearm) and median nerve (elbow+upper-arm) signal was rated qualitatively as "normal" versus "increased/lesion". Quantitative evaluation was performed after normalization of nerve T2-weighted-signal with respect to adjacent intramuscular T2-weighted-signal (long head/biceps muscle). Three different regions-of-interest were read-out: MN-controls-all-fascicles, MN-patients-lesion-fascicles, MN-patients-normal-fascicles. Predominant lesion focus was determined from maximum intensity of normalized T2-weighted-signal and referenced to humeroradial joint space.

Results

In all AINs patients but none of controls (sensitivity/specificity 100%) proximal lesions of MN-trunk at upper arm (14.4 ± 5.5 cm proximal to humeroradial joint) and not of distal AIN-trunk were found. In all patients proximal lesions involved selectively only certain fascicles at dorsal and ulnar aspect within MN cross-section (Figure). This cross-sectional/fascicular distribution corresponded exactly to the somatotopic organization of the fascicle group destined to become AIN further distally but is not equivalent to AIN itself(Figure). Additionally, multifocality of lesions was observed in the majority of patients. Quantitative evaluation showed that normalized T2-weighted-signal intensity within affected fascicles was increased strongly in all patients (> 1.7 of normalized T2-weighted-signal corresponding to >2SD of controls;p<0.0001) and was normal in other fascicles within MN cross-section not corresponding to AIN fascicle group (p = 0.35).



Conclusion

MR neurography could accomplish to determine precise localization of nerve lesions in AINs, which before has not been possible neither by attempts of physical nor electrophysiologic localization. Findings of selective injury to certain but not all fascicles within upper-arm MN trunk and of lesion multifocality rule out entrapment as pathomechanism and saves these patients from inappropriate surgical exploration of AIN. The observation of lesion multifocality in the majority of patients suggests immune-mediated inflammation and not mechanical entrapment as cause.

Early Diabetic Nerve Injury Detected in vivo by Large Coverage Sampling of Nerve T2 Signal

Pham, M.·Hornung, B.·Oikonomou, D.·Weiler, M.·Baeumer, P.·Kollmer, J.·Nawroth, P.·Bendszus, M.
Heidelberg University Hospital
Heidelberg, GERMANY.

Purpose

Distal symmetric diabetic polyneuropathy (DPN) is a very frequent complication of diabetes and the most prevalent neuropathy. DPN causes considerable long-term morbidity. Its pathogenesis remains unclear with two theories competing to explain nerve injury: direct/toxic metabolic injury to distal fibers versus indirect/secondary ischemic injury. To detect in vivo spatial patterns of early DPN would improve differentiation because experimental work indicates that toxic/metabolic effects result in diffuse-distal, whereas ischemia results in proximal injury. Few studies investigated spatial patterns of diabetic nerve injury only analyzing ex vivo samples. We showed previously that severe DPN is detectable in vivo by MR neurography (MRN). Now, with refined image acquisition, data analysis and coil technology, we show the spatial distribution of even early DPN in vivo.

Materials & Methods

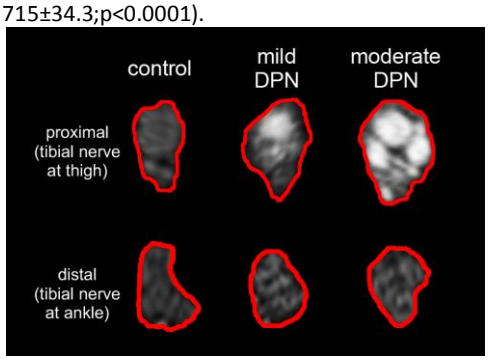
Sixty patients confirmed with DPN (59.5±12.2 years. 25f/35m) by physical and electrophysiologic examinations were graded as nonsymptomatic/mild/moderate according to national guidelines. These groups were compared to 60 nondiabetic, age/sex-matched controls. Participants underwent extended MRN acquiring nerve-T2-signal with high spatial resolution and at same time ample anatomical coverage (spinal nerve to ankle,TA 57 min.): 140 axial slices per leg (2D-T2-TSE, TE/TR 55/5970ms, in-plane resolution/slice-thk. 0.3mm/3mm, 15Ch/Tx/Rx Coil), +50 axial slices for spinal nerve and plexus coverage reformatted from 3D-T2-SPC sequence (TE/TR 200/1000). Manual segmentation of nerve tissue voxels (spinal nerves/plexus/sciatic/tibial/fibular/sural) was performed slice-by-slice (320 slices per subject). Lesion voxels were classified in fully automated, operator-independent manner: first, normative distributions of T2-signal was calculated in controls for each slice and nerve. Lesion voxels were identified in patients as statistical outliers at 1.5 of normalized T2-signal which separated best patients from controls.

Results

Nested two-way ANOVA showed strong significance for increasing lesion-voxel count with increasing DPN severity (main effect GROUP:p<0.0001), with proximal (thigh) not distal (ankle) position (main effect POSITION:p<0.0001), and for interaction GROUPxPOSITION (p=0.0003) indicating a proximal-to-distal gradient of injury

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

dependent on DPN severity (Figure). Pairwise contrasts for GROUP showed that lesion voxel number in moderate (2527±631,p<0.0001), even in mild (1991±291;p=0.0039) and even in nonsymptomatic DPN (1749±284;p=0.29) were higher than in controls (1518±151,Figure), for POSITION that lesions occurred with predominant proximal not distal focus (proximal:3262±92 vs. distal: 715±34.3;p<0.0001).



Conclusion

We report for the first time that nerve injury is detectable in vivo by MRN not only in severe but also early/mild DPN; and further, that spatial injury pattern is proximal rather than distal-diffuse suggesting ischemia rather than direct toxicity to nerve as predominant pathomechanism.

DT Imaging Can Detect Even Subclinical Peripheral Nerve Injury

Baumer, P.·Heiland, S.·Weiler, M.·Ruetters, M.·Bartsch, A.·Bendszus, M.·Pham, M.
University of Heidelberg
Heidelberg, GERMANY.

Purpose

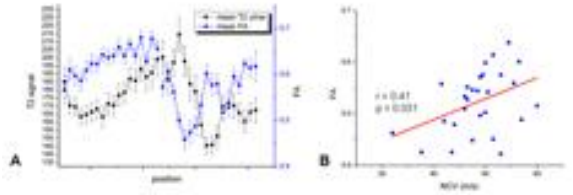
Diffusion tensor imaging (DTI) is a promising technique in MR neurography (MRN) for the evaluation of the peripheral nervous system. The main functional parameter obtained by DTI for peripheral nerves is fractional anisotropy (FA). Previous experimental and clinical works have explored the potential of FA as a sensitive parameter for the detection of neuropathy in carpal tunnel syndrome and inflammatory diseases . Fractional anisotropy was shown to correlate with electrophysiologic parameters of distal motor latency and amplitude of action potential in a small number of patients. It is hitherto unclear how sensitive FA is in the detection of neuropathy. We set out to investigate the ability of DTI to detect subclinical nerve injury at the ulnar nerve.

Materials & Methods

MR neurography exams were performed on elbows and wrists (Magnetom Trio, Siemens, 15Ch Tx/Rx Coil) in 30 healthy subjects without a history of peripheral nerve injury. Sequences included a PD/T2-weighted relaxometry (TR 3000ms, TE 13/52ms, slices 18, averages 2, spectral fat-suppression, in-plane-resolution 0.39x0.39x4mm^3, TA 6:23 min) and DTI (TR 3800ms, TE 87ms, b-value 800s/mm^2 encoded in 19 directions, slices 18, averages 2, in-plane-resolution 1.17x1.17x4mm^3, TA 2:43 min). DTI postprocessing was performed on a Siemens Syngo MMWP version VE32B station. Nerves were segmented manually slice-by-slice to obtain nerve T2 and FA values. All subjects also underwent electrodiagnostics including nerve conduction velocities(NCV) for ulnar and median nerves, distal motor latency (dmL), and motor compound action potentials.

Results

Across all subjects, ulnar FA values showed a nadir (minimum 0.46±0.02, mean 0.55±0.02) in the proximal ulnar sulcus where T2 values showed a peak (maximum 197.9±9.4, mean 174.6±7.9)(Figure A). Ten subjects (33%) had decreased NCV across the elbow segment. These exhibited significantly decreased FA values (0.40±0.10, p=0.043) as well as increased T2 values (183.8±60.0, p=0.037) at this position. T2 values did not correlate significantly to NCV. In contrast, both minimum and mean FA values correlated with proximal ulnar NCV (minimum FA r=0.57, p=0.0016, mean FA r=0.41, p=0.031; Figure B). Similar results were obtained for the median nerve in the carpal tunnel with increased T2 signal and decreased FA. Again, T2 values did not correlate with electrophysiologic parameters at the carpal tunnel, but mean FA significantly correlated with dmL (r=-0.41, p=0.029).



Proximo-distal course of T2 and FA at upper arm and elbow

Correlation between FA vs. NCV at ulnar sulcus

Conclusion

Changes in nerve FA correspond already to subclinical nerve injury. DTI demonstrates stronger correlations to electrodiagnostic parameters and therefore might be even more sensitive than T2-weighted nerve signal in the detection of neuropathy.

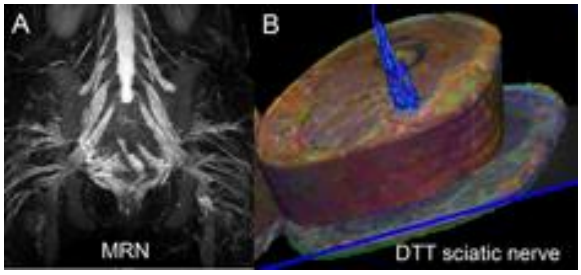
Diffusion Tensor Imaging and Tractography of the Sciatic Nerves in Chronic Inflammatory Demyelinating Polyradiculoneuropathy

Gasparotti, R.·Todeschini, A.·Filosto, M.
University of Brescia Medical School
Brescia, ITALY.

Purpose
Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) is an acquired peripheral neuropathy of presumed autoimmune etiology. The diagnosis rests upon a combination of clinical, electrodiagnostic and laboratory features. MR imaging showing bilateral hypertrophy of brachial and/or lumbar plexuses may assist the diagnosis. Diffusion tensor imaging (DTI) recently has been proposed as a noninvasive technique to evaluate the peripheral nerve microstructure in vivo. We hypothesized that diffusion tensor tractography (DTT) and measurements of fractional anisotropy (FA) along the sciatic nerves can differentiate patients with CIDP from controls.
Materials & Methods
We performed a 1.5T MRI (Aera, Siemens, Germany) on 10 patients affected by CIDP (mean age 50.2) and 10 age- and sex-matched healthy volunteers (mean age 48.7 years) using the following imaging protocol: a) 3D magnetic resonance neurography (3D MRN) of brachial and lumbosacral plexuses, b) 2D MRN and c) DTI of sciatic nerves at the level of thigh. Diffusion tensor tractography of the sciatic nerves was guided by color-coded FA maps overlaid on high-resolution MRN. The FA values of the tracked segments of the sciatic nerves were compared between the two groups. The sciatic nerve cross-sectional area (CSA) also was measured at the level of mid-thigh on the axial 2D MRN sections. The CSF protein concentration was available for nine patients. T-test and Pearson correlation test were utilized for the statistical analysis. Threshold for significance was defined as $p<0.05$.
Results
In the patient group, plexus hypertrophy and increased signal intensity were detected in 13 out of 20 plexuses (65%) on 3D MRN. Sciatic nerve CSA was increased significantly in CIDP patients (mean 58.50 ± 3.41 mm^2) compared to controls (mean 86.20 ± 22.07) ($p = 0.04$). The sciatic nerve FA values were significantly lower in CIDP patients (mean 0.404, 95% C.I 0.378-0.427) than in healthy volunteers (mean 0.466, 95% C.I. 0.443-0.490) ($p = 0.001$) and inversely correlated with the CSA values ($r = -0.708$, $p = 0.033$). The association between the CSF protein concentration and FA values reached statistical significance ($r = 0.67$, $p = 0.52$).



Conclusion
Our preliminary data suggest that a noninvasive DTI assessment of the sciatic nerves may provide clinically useful information in addition to MRN in patients with CIDP. The quantitative assessment of FA can help further characterizing the effects of the disease processes on the structural integrity and directional coherence of the nerve fibers.

(8) General Programming: Reversible Brain Syndromes: PRES, Reversible Cerebral Vasoconstriction Syndrome and Cerebral Venous Thrombosis (SAM) (AR)

O-77 **1:15 PM - 1:40 PM**

Posterior Reversible Encephalopathy Syndrome (PRES)

Bartynski, W. S.
Presbyterian University Hospital
Pittsburgh, PA.

Presentation Summary
Posterior reversible encephalopathy syndrome (PRES) is a unique neurotoxic state. Typically the clinical presentation is nonspecific with altered mentation, headache, visual symptoms and seizures most common. The toxicity has been identified most commonly in patients following allogeneic bone marrow or solid organ transplantation, women experiencing preeclampsia or eclampsia, patients with autoimmune conditions such as Lupus, patients with significant infections, sepsis or shock and patients following cancer chemotherapy. The imaging pattern of PRES generally demonstrates vasogenic edema with a

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

characteristic distribution in the parietal, occipital and frontal lobes, primarily reflecting the brain watershed areas. The areas of vasogenic edema usually reverse and resolve, hence the concept of "Reversible Encephalopathy". Evidence of vasculopathy can be identified on imaging studies including MRA and catheter angiography and pathophysiology obtained in the acute phase of the process demonstrates evidence of endothelial activation and immune cell trafficking and up-regulation of vascular endothelial growth factor (VEGF) suggesting brain hypoxemia. Clinically, approximately 25-30% of patients have a normal blood pressure at the time of toxicity with mild BP elevation (MAP 105-115 mmHg) seen in approximately 15% and more severe hypertension (MAP>120 mmHg) in approximately 50%. Evidence of systemic inflammatory response syndrome (SIRS) and multi-rgan dysfunction syndrome (MOD) commonly is noted including thrombocytopenia, liver dysfunction, renal dysfunction, pulmonary dysfunction and BP instability (most frequently noted in patients with infection and eclampsia). This talk will review the clinical and imaging features of PRES, focusing on the likely biological factors responsible for the toxicity.These features are important for initial recognition of the toxicity as well as understanding the probable causes of the condition.

O-78 **1:40 PM - 2:00 PM**

Reversible Cerebral Vasoconstriction Syndrome

Gandhi, D.
Johns Hopkins University Hospital
Baltimore, MD.

Presentation Summary
RCVS represents a group of clinical syndromes characterized by severe "thunderclap" headache with or without neurologic deficits and multifocal segmental areas of cerebral arterial narrowing or vasoconstriction that usually resolve within weeks. RCVS is being recognized increasingly as a cause of isolated convexity subarachnoid hemorrhage (cSAH) and must be differentiated from other etiologies of cSAH such as amyloid angiopathy, cortical vein thrombosis and PRES. Several specific clinical, laboratory and neuroimaging findings can assist in differentiating RCVS from SAH-related vasospasm or primary angiitis of CNS (PACNS); diseases with which RCVS often is confused. Acute relapsing thunderclap headaches with or without neurologic deficits, presence of cortical SAH over the convexity, diffuse vasoconstriction involving the distal intracranial vessels (out of proportion to the amount of SAH), near normal CSF analysis and short-term reversibility of vasoconstriction (<3 months) are typical of this entity and help differentiate it from other conditions causing thunderclap headaches. This presentation will summarize the clinical and imaging criteria for the diagnosis of RCVS and review the current literature on this entity.

O-79 **2:00 PM - 2:20 PM**

Cerebral Venous Thrombosis

Spampinato, M.
Medical University of South Carolina
Charleston, SC.

Presentation Summary
Cerebral venous thrombosis is an infrequent but serious disorder accounting for 0.5% of all cerebrovascular accidents. Several predisposing factors have been identified, including congenital and acquired prothrombotic states, while infection remains the most common underlying cause in developing countries. The clinical diagnosis of cerebral venous thrombosis can be difficult because signs and symptoms of this condition are frequently vague and nonspecific, including signs of intracranial hypertension, focal neurologic deficits, seizures, and/or cavernous sinus syndrome. As a result, neuroimaging can be of paramount importance in establishing an early diagnosis of cerebral venous thrombosis, which in turn can significantly decrease the risk of serious complications including stroke or death. Cerebral venous thrombosis should be considered in the differential diagnosis when confronted with unexplained brain edema, especially in young or middle-age patients, in the setting of atypical or unusual headache or stroke-like symptoms, and in the absence of cardiovascular risk factors. The diagnosis of cerebral venous thrombosis usually is established with the use of contrast-enhanced brain MRI and MR venogram, although unenhanced brain CT can sometimes demonstrate findings concerning venous thrombosis. CT venogram also is used increasingly in the emergency setting because it can be performed quickly and offers improved visualization of small venous structures when compared with MR venography. Parenchymal abnormalities seen in cerebral venous thrombosis can include parenchymal swelling, vasogenic and cytotoxic edema, hemorrhage, or gyral enhancement. Even large areas of nonhemorrhagic brain signal abnormality can resolve completely. The radiologist may play an important role in the diagnosis of cerebral venous thrombosis and in monitoring treatment response. Understanding the pathophysiology and imaging characteristics of reversible and nonreversible MR imaging abnormalities can improve patient management and prognosis prediction.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

O-80 **1:15 PM - 1:35 PM**

fMRI and DTI

Young, R. J.
Memorial Sloan-Kettering Cancer Center
New York, NY.

Learning Objectives
Upon completion of this presentation, participants will be able to:
1) Review the roles of BOLD fMRI and DTI in the treatment of patients with brain tumors.
2) Present representative motor and language cases where fMRI and DTI impact preoperative planning.
3) Discuss the limitations of fMRI and DTI.
4) Discuss the advantages and disadvantages of tractography.
Presentation Summary
Surgery is an effective treatment for many brain tumor patients with improvements possible in both the length and the quality of patient survival. Blood oxygen level dependent (BOLD) functional MRI (fMRI) and diffusion tensor imaging (DTI) allow the in vivo noninvasive evaluation and mapping of eloquent brain areas. These may provide useful information to facilitate patient counseling, and assist preoperative planning to maximize tumor resection and minimize potential neurologic complications. This lecture will describe the complementary roles of fMRI and DTI and present illustrative motor and language cases. The practical limitations of both techniques also will be discussed, including the unique advantages and disadvantages manifested by tractography

O-81 **1:35 PM - 2:00 PM**

Genomics and Genetics in Gliomas

Colen, R. R.
M.D. Anderson Cancer Center
Houston, TX.

Learning Objectives
Upon completion of this presentation, participants will be able to:
1) understand the field of imaging genomics.
2) understand the application of imaging genomics in brain tumors.
3) understand the use of MRI as a biomarker for underlying genomic composition.
4) understand the role of MRI in personalized medicine for target discovery of therapeutic targets.
5) understand the use of MRI in drug development.
6) understand the research available in imaging genomics.
Presentation Summary
The objective of this course is to introduce the recently emerged field of imaging genomics (radiogenomics) in brain tumors, specifically glioblastoma (GBM). Emphasis will be on the use of imaging in relation to underlying tumor genomics, how to use MRI as a biomarker, surrogate and correlate of tumor genomics as well as the use of MRI as a genomic target discovery tool and its application in therapeutic discovery and drug development.

O-82 **2:00 PM - 2:20 PM**

Nanotechnology

Provenzale, J. M.
Duke Medical Center
Durham, NC.

Presentation Summary
The intent of this presentation is to inform the audience of recent advances of nanotechnology to the central nervous system (CNS). Nanotechnology provides important and interesting new methods to diagnose CNS disease, determine disease extent, deliver therapy, monitor therapeutic response and re-engineer tissue. *Diagnosis.* A number of investigators have used nanoparticles as contrast agents for more sensitive diagnosis of CNS diseases. As an example, presently this author and collaborators at Emory University are studying the use of magnetic iron oxide nanoparticle clusters to identify medulloblastoma cells in the cerebrospinal fluid (CSF) of medulloblastoma patients. The nanoparticles used in this study are coated with a ligand that binds to epidermal growth factor receptor (EGFR), which is highly expressed by medulloblastoma cells. After lumbar puncture to obtain CSF, the nanoparticles are immersed in small quantities of CSF. After the magnetic nanoparticles bind to cells, the nanoparticles can be isolated by application of a magnetic field, thereby allowing identification of tumor cells. *Determination of Disease Extent during Surgery.* One of the major applications of nanotechnology is intra-operative determination of tumor extent, in an attempt to improve surgical margins after tumor removal. Paramagmetic iron-oxide nanoparticles have been used for approximately a decade for intra-operative imaging. These nanoparticles appear to accumulate in intratumoral macrophages and reactive astrocytes; they can be detected on MR imaging for a period of days after intravenous infusion. Using intra-operative MR imaging, the neurosurgeon can assess adequacy of brain tumor resection in real-time. Working with collaborators at

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Emory University and Georgia Institute of Technology, this author has examined the use of a handheld imaging device for detection of fluorescent dyes within tumors. This technique at once offers an alternative to the use of large, stationary imaging devices in the operating room and an alternative to the use of nanoparticles. The process involves the intravenous infusion of the fluorescent marker indocyanine green (ICG) a few hours prior to surgery. Indocyanine green is approved by the FDA for retinal angiography. Workers in our laboratory have found that ICG passively leaks into tumors but not into normal tissue. By using ICG in an off-label manner to assess tumor margins, we have successfully used a handheld laser that emits near-infrared light to identify tumor margins in approximately 12 types of non-CNS tumors during surgery on naturally occurring tumors in canine patients at the University of Georgia, College of Veterinary Medicine. Other types of fluorescent dyes are being explored for use in brain tumors. *Nanoparticles for Drug Delivery.* Another highly promising application of nanoparticles for treating brain tumors is delivery of chemotherapy. Advantages of nanoparticles in this setting include the potential for highly localized deposition of chemotherapy within the tumor as opposed to systemic delivery using standard chemotherapy formulations. For instance, even intravenous administration of nanoparticles could provide a means of specific delivery of the agent by allowing nanoparticles to be preferentially deposited within tumor. A major impediment has been development of nanoparticles that will readily cross the blood-brain barrier, which has been addressed successfully by a number of investigators. The major advantages include the potential for incorporating relatively large amounts of chemotherapy into nanoparticles as well as for delivery of hydrophobic substances that normally might have very limited access to brain tumors because of the blood-brain barrier. By avoiding delivery of chemotherapy to nontarget organs outside the CNS, toxic effects might be minimized and lower doses might be possible. As an example, intravenous use of the chemotherapeutic agent camptothecin has been limited by high rates of systemic toxicity. However, intravenous infusion of camptothecin within polymeric micelles (one form of nanoparticle) allowed the drug to be delivered in amounts sufficient to decrease tumor volumes without development of toxicity. *Tissue Engineering.* Nanoparticles offer the prospect of restructuring the CNS microenvironment and, in some cases, repair damage caused by CNS tissues. For instance, one form of nanoparticle termed a carbon nanotube has been shown to be capable of improving responsiveness of neurons. Nanotubes placed within cultured neuronal networks can affect the collective electrical properties of such networks by promoting electrical “shortcuts” between the proximal and distal components of neurons. Carbon nanotubes also have been shown to be capable of serving as a scaffold for neuronal cell adhesion and growth. Functionalized nanotubes can modulate neuronal growth in a graded manner; positively charged nanoparticles have been shown to promote neurite outgrowth of hippocampal neurons in culture. Finally, nanofiber scaffolds have been developed which can self-assemble within the CNS to promote growth of neuritis. These devices promote formation of a gel-like material which encapsulates neural progenitor cells and promotes differentiation of these cells into mature neuronal cells. Such mechanisms may eventually allow regeneration of CNS tissue in such diseases as multiple sclerosis and neurodegenerative diseases. In summary, a wide range of potential applications of nanotechnology for assessment and therapy of CNS diseases are available. The exact forms in which these possibilities will come to fruition in humans are undetermined at present. However, it appears highly likely that at least some of the initiatives outlined here will play a role in human CNS diseases in one form or another.

O-83 **2:20 PM - 2:45 PM**

Neuro-Oncology Trials

Barboriak, D. P.
Duke University Medical Center
Durham, NC.

Presentation Summary
Clinical trials have a key role in the process of translating advances in imaging into clinical practice. There is increasing demand for "strong evidence" in order to incorporate advanced imaging techniques into clinical practice guidelines and to justify reimbursement from payers. Depending on the maturity of the imaging technology, a variety of trial designs can be justified in order to advance an imaging application toward clinical acceptance. Ultimately, however, a multicenter trial frequently is necessary to provide the strength of evidence needed to change clinical practice. In this talk, possible pathways to translation of imaging technology to clinical practice through a series of trials will be discussed, with a focus on the types of data generated in single center trials that are most helpful in justifying validation in a multicenter trial. Because of the high costs of these trials, there is increasing interest in imaging techniques with proven utility for guiding therapeutic decision-making that leads to improvements in patient outcomes such as quality of life and survival. Not surprisingly, diagnostics (although not necessarily imaging) and treatments have become much more closely linked, and there is increasing emphasis on performance of practice-altering trials that validate the diagnostics and treatment in tandem. This talk also will review the role of imaging for brain tumor evaluation in the current clinical trials environment. The importance of specifying use cases for imaging such as differentiation of pseudoprogression from true progression, differentiation of pseudoresponse from true response, better prediction of patient response to specific treatments, and early identification of treatment success or failure will be discussed. The evolution of imaging assessment from Macdonald criteria to the RANO criteria,

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

and future directions for these assessments will be examined. Because of the centrality of treatment as providing the context of advanced imaging assessments, the talk will review current thinking for possible treatment modalities and associated trials, including the use of treatment de-escalation strategies, anti-angiogenic therapies, immunotherapies, and tumor vaccines, among others. In addition, imaging has a central role in target localization for anatomically guided therapies, and current ideas for the use of imaging to delineate tumor volumes for surgical planning and for radiation therapy will be reviewed.

(10) General Programming: Arterial Dissections: Extra- and Intra-Cranial Diagnosis and Treatment (SAM) (AR)

O-84 **1:15 PM - 1:40 PM**

Diagnosis: MR verses CTA?

Zaharchuk, G. G.
Lucille Packard Children's Hospital at Stanford
Stanford, CA.

Presentation Summary

Cervical arterial dissection is the most common cause of ischemic stroke in the young (patients under 45 years of age). Despite this, it often is not initially suspected due to the sometimes subtle presenting signs, overall infrequent occurrence of stroke in this age group, and the lack of routine neck imaging as part of the stroke workup. However, given the delayed and sometimes devastating presentation of large vessel embolic stroke in these patients, establishing the diagnosis early can have a big impact. Digital subtraction angiography (DSA) traditionally has been the reference standard for diagnosis of cervical artery dissection. However, because of its risk and expense, it has been largely supplanted by noninvasive modalities, including ultrasound, CT/CT angiography, and MRI/MR angiography. Each of these tests has its strengths and limitations. Ultrasound is contrast- and radiation-free, but results are sensitive to technologist skill and there is poor conspicuity of the vertebral arteries. CT/CTA can be acquired rapidly and has high spatial resolution, but involves both radiation and contrast; radiation in particular is a limitation in the widespread use of this technique, as many patients are young. MRI/MRA can document both small amounts of acute ischemia and the pathognomonic "methemoglobin" crescent sign, but suffers from motion-sensitivity and poor accuracy in the vertebral arteries. This talk will review the relative advantages and disadvantages of each of these modalities.

O-85 **1:40 PM - 2:00 PM**

Extracranial Vascular Dissections: Endovascular Treatment

Pride, G.
University of Texas Southwestern Medical Center
Dallas, TX.

Presentation Summary

As a common cause of stroke in young and middle aged individuals[1], Extracranial neurovascular dissection presents an important opportunity for diagnostic and interventional neuroradiologists to positively impact patient care. Timely diagnosis and precise imaging evaluation allows the institution of appropriate therapy that may substantially decrease stroke risk and maximize patient outcomes. Awareness of the etiology, pathophysiology, clinical presentation, imaging findings, prognostic features and multiple treatment options is thus extremely important. Treatment paradigms for Extracranial neurovascular dissections generally lack guidance from large clinical trial data. First line therapy is most commonly medical with interventional or surgical approaches being reserved to select cases. Multidisciplinary approaches often offer the best promise for optimal outcomes. This talk will review treatment paradigms for Extracranial vascular dissections, focusing on endovascular treatment options.

Extracranial cervical dissections may account for 5-22% of ischemic strokes in the young, representing a significant health problem[2]. Most have a high chance for complete healing and are as thus often best managed medically with antithrombotic therapy to prevent thromboembolism. Both antiplatelet and anticoagulant therapies prevent stroke during the healing process[2,3]. Non-randomized studies fail to show superiority of one approach over the other[3]. Randomized comparison trials are currently underway. Imaging and clinical follow-up is critical to document healing. Endovascular treatment for Extracranial dissection may be done as part of acute stroke therapy for tandem lesions or acute occlusion when appropriate[4,5]. More frequently, it is reserved for ongoing neurological ischemic symptoms despite medical therapy, either due to hemodynamic insufficiency or resistant thromboembolism[5]. Other potential indications are persistent significant stenoses on follow-up with limited collateral opportunity or enlarging/ruptured pseudoaneurysms[2]. Treatment strategies include stenting with or without angioplasty, coil embolization, covered stent placement, vascular sacrifice and flow diversion. We will conclude with a discussion of future directions in the endovascular treatment of Extracranial neurovascular dissections and dissecting aneurysms.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Same Disease, Different Pathology: The Special Case of Intracranial Disssecting Aneurysms - Diagnosis and Treatment

Derdeyn, C. P.
Mallinckrodt Institute
St. Louis, MO.

Presentation Summary
Acute intracranial arterial dissections, particularly distal vertebral or basilar dissections, often present with ischemic symptoms related to thrombo-emboli in the distal circulation or local branch vessel occlusion. In a subset of these patients, the entire wall may be damaged by the dissection and hemorrhage into the subarachnoid space ensues. Dissecting aneurysms are an uncommon but extremely important cause of subarachnoid hemorrhage (SAH): they may be difficult to diagnose, difficult to treat, and carry a very high risk for recurrent hemorrhage. It is important to consider dissecting aneurysms as a cause for SAH if no saccular aneurysm is identified. Dissecting aneurysms often appear as an irregular, nonsaccular aneurysmal enlargement of an intracranial artery. In some cases this is accompanied by focal narrowing. The most common location is the distal vertebral artery at the origin of the posterior inferior cerebellar artery. The supraclinoid carotid or basilar arteries are less commonly affected. Imaging findings may be very subtle, with only minimal irregularity of the arterial contour. This is particularly true of internal carotid “blister” aneurysms. Close angiographic follow up of indeterminant cases is imperative, as these lesions may grow quickly prior to rerupture. The imaging diagnosis requires high-resolution angiographic imaging. Catheter angiography, particularly with 3 dimensional reconstruction, is important if the diagnosis cannot be made with noninvasive imaging. Treatment can be challenging. The most definitive treatment is sacrifice, open surgical or endovascular, of the diseased vessel segment. This is not feasible in some locations without complex bypass procedures. More recently, stents and flow diverters have been used in selected cases with some success. The need for aggressive anti-platelet medications in this setting remains an issue, however.

(11) General Session: Scientific Publishing Update

O-87 **1:15 PM - 1:45 PM**

Peer Review Systems

Castillo, M.
University Of North Carolina School Of Medicine
Chapel Hill, NC.

Presentation Summary
Journal scientific peer review (PR) as we know it started in the mid 1950s with the invention of the photocopier. Peer review can be un-blinded or blinded and in AJNR we use the double-blinded method. However, this method has been significantly criticized, especially by editors themselves. With the advent of Web 2.0 the possibility of open PR arose and by adding this step one may increase or decrease time to publication. Postpublication open PR does not affect publication schedules and keeps articles fresh by self-renewal due to revisions. Unfortunately, journals have experienced mixed results with these new methods. Parallel to the journal’s efforts, many third party postpublication PR websites have appeared and these commercial for profit sites take advantage of recycling already published material for their own purposes. This lecture reviews these aspects and proposes solutions to the most pressing issues of PR. The lecture will be divided into three parts: historical aspects of PR, open PR, and postpublication PR including blogs and Facebook.

Resonance in Medicine, and on the Editorial Board of many professional journals. Dr. Kressel's major interests are magnetic resonance imaging of the abdomen and pelvis with particular interests in prostate, liver and pancreas. In 1993 Dr. Kressel was appointed Radiologist-In-Chief of the Department of Radiology at the Beth Israel Hospital in Boston, and Miriam H. Stoneman Professor of Radiology at the Harvard Medical School. In February 1998 Dr. Kressel was appointed Chief Medical Officer at Beth Israel Deaconess Medical Center, and continued to serve as Radiologist-in-Chief. In August 1998 Dr. Kressel was appointed President and CEO of Beth Israel Deaconess Medical Center. In January 2000, Dr. Kressel returned to the Radiology Department at Beth Israel Deaconess Medical Center and resumed his role as Radiologist-in-Chief. In 2007, Dr. Kressel was appointed Editor Designate for Radiology, and assumed the role of Editor in January 2008. In 2011 he was awarded the RSNA's Gold Medal.

Presentation Summary
Over the past several decades, concerns have been raised increasingly as to the validity and ability to generalize from published scientific articles. The causes of this problem appears to be multifactorial but include ethical issues, including conflict of interest and redundant publication, and issues relating to the quality of the science and the tendency to over-interpret or "spin" the findings that are being reported. The rate of retraction of scientific manuscripts has grown ten-fold in the past decade. Nearly half of the retractions, unfortunately, are due to some form of misconduct, including plagiarism, redundant publication, and data falsification. There is ample evidence that conflict of interest particularly as it relates to industry sponsored research also contributes to the problem. Despite recent efforts in mandating trial registration before the study begins, and in making the primary data available for review, these commercially driven problems appear to persist. Scientifically, the validity of a result is largely dependent on the statistical power of the study, and the many sources of bias, including publication bias, the apparent desire of journals to publish positive results. Smaller studies, testing multiple variables, and within study flexibility as to designs, outcomes and analyses are all sources of potential problems. Recently a number of investigators have begun to look at "spin" in scientific publications. In a study reviewing over 126 articles on diagnostic performance, a variety of journals with impact factors of 4.0 or greater, 31% had some form of over-interpretation and a much larger number, perhaps as high as 89%, had some evidence of potential over-interpretation including lack of a sample size calculation, lack of a clear test hypothesis, and failure to report confidence intervals in accuracy measurements. To deal with these issues we will need a multifaceted approach including restructuring the incentives in science, encouraging the publication of high quality studies with negative results, promoting Meta-analysis and creating a culture of ethical scientific research throughout the research community.

O-89 **2:15 PM - 2:45 PM**

Metrics: Now and Future

Wilms, G. E.
UZ-Gasthuisberg
Leuven, B-3000, BELGIUM.

Presentation Summary
Publication metrics such as the impact factor (IF) are used to evaluate and rank journals. They are obtained from dividing citations received in one year by the number of papers published in the two previous years. Some influencing of the IF by the editor is possible by encouraging self-citation, choice of article types, open access and publication of themed issues but these are considered as caretaking for the journal rather than manipulation. Disadvantage of the IF as a measure of a journal importance are, besides discipline and language dependence, that the IF is based on high citations of a minority of articles and the absence of evaluation of the real impact on medical practice. Major criticism concerns the use of the IF in the decision of appointment, promotion, tenure and awarding of research grants to individual researchers, since the IF does not apply to a single article nor one author. The h-index, based on the set of the scientist's most cited papers and the number of citations of other publications, seems a more appropriate way of evaluating a scientist or a scientist group. The index is used widely with possible local modifications. Newer indices seem mandatory taking into account the influence of online citation counting such as Google Scholars or CrossRef, online first publications, open access journals and frequency of downloads.

Neuropsychologic Deficits and Structural Brain Damage after Aneurysm Treatment in Patients with Good Clinical Outcome

Friedrich, B.·Wostrack, M.·Hammer, K.·Harmening, K.·Meyer, B.·Ryang, Y.·Förschler, A.
Klinikum Rechts der Isar, Technische Universität München
Muenchen, GERMANY.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Purpose
Despite good neurologic outcome after treatment of cerebral aneurysm with or without preceding subarachnoid hemorrhage (SAH) many patients are complaining about mood disorders and chronic headaches. We aimed to investigate whether the history of SAH or treatment modality are crucial for neuropsychologic deficits and if any specific brain changes are associated with these disorders.
Materials & Methods
Fifty case-matched pairs of patients with or without previous SAH treated by surgical clipping or endovascular coiling are intended to be assessed prospectively by a test battery including Hospital Anxiety and Depression Scale (HADS), Beck depression inventory (BDI) and Headache Impact Test (HIT-6). Additionally, brain MRI including H1-MR spectroscopy and volumetry of the hippocampus as well as DTI measurement are performed. So far, 37 consecutive patients were enrolled: n = 17 with preceding SAH, n =10 incidental, n = 23 with first treatment by clipping, n = 14 first treatment by coiling; MRI was performed in 29 cases.
Results
No substantial differences were found between patients with and without previous SAH in respect of depression, anxiety and headaches. However, we observed significantly higher mean scores in all tests in patients treated surgically versus patients treated by coiling: HADS 13.9 versus 9.7; BDI 13.57 versus 11.26; HIT-6 52.57 versus 48.26, respectively. HADS score significantly increased in patients with multiple aneurysms resulting in multiple treatments: 13.18 versus 9.7 in those with single treatment. Spectroscopy revealed slight reduction of hippocampal Glx in patients with previous SAH: 0.013 versus 0.0109 in non-SAH subjects. All surgically treated patients showed lower mean concentrations of hippocampal NAA (0.00479 versus 0.00946), Glu (0.0065 versus 0.00835) and Glx (0.011 versus 0.013) compared to those treated by coiling. Hippocampal atrophy could be detected in both patients who suffered SAH or were surgically treated, but surgical treatment resulted in a significantly aggravated atrophy. In the DTI measurement the FA values in the hippocampal area were reduced significantly in patients treated by surgical approach compared to endovascular coiling.
Conclusion
Aneurysm surgery seems to be associated with higher morbidity in respect of mood disorders and headaches compared to endovascular treatment independently of preceding SAH. Additionally surgical aneurysm clipping seems to induce a much severe structural damage to the depression-associated hippocampal area than endovascular coiling.

Long-Term Risks of Re-Bleeding and Death after Coiling and Clipping of Ruptured Aneurysms: Results of Followup 10 to 18 Years after Subarachnoid Hemorrhage of Patients Enrolled in the International Subarachnoid Aneurysm Trial

Molyneux, A. J.·Sneade, M.·Birks, J.·Yarnold, J.·Clarke, A.·Kerr, R.
Oxford University
Oxford, UNITED KINGDOM.

Purpose
To report the long-term risk of recurrent subarachnoid hemorrhage and the causes of death in patients enrolled in the International Subarachnoid Aneurysm Trial (ISAT), after coiling or clipping of a ruptured cerebral aneurysm.
Materials & Methods
Two thousand one hundred forty-three patients enrolled in ISAT were followed as a whole cohort for five years. The UK cohort of 1644 patients has been followed up since enroment for between 10 and 18 years based on annual patient questionnaires. All UK patients were flagged with the Office for National Statistics (ONS) and all UK deaths were notified direct to the Trial office together with cause of death. Recurrent SAH was notified by patient questionnaire, direct from the hospital concerned or via ONS cause of death notification.
Results
UK patients alive at one year have been followed for a minimum of 10 years and for a maximum of 18 years after enrollment, with a mean of 14 years. A total of 37 recurrent subarachnoid hemorrhages have occurred between one year and the date of final followup. The total number of follow-up years is now in excess of 20,000 person years. Twenty-one recurrent SAHs have occurred from the original treated target aneurysm, 16 in the patients allocated coiling and five in the patients allocated clipping. Sixteen were from another aneurysm, of these six were from pre-existing aneurysms, one of which had been clipped previously and five that had not been treated. Nine were from new aneurysms and in one patient the source of hemorrhage was unknown. Of the 37 patients with recurrent SAH 16 died within 30 days as a result of the re-bleed. All the causes of death after one year were categorized and the most common causes of delayed mortality were due to cancer and cardiovascular disease unrelated to SAH or its treatment.
Conclusion
The risk of delayed recurrent subarachnoid hemorrhage from the ruptured aneurysm in patients treated by coiling and clipping between 1994 and 2002 is very low. Re-bleeding is more common after coiling than clipping but this risk is of the order of between one and two per thousand per year. The significant initial clinical benefit observed after coiling will never be lost at this rate of aneurysm re-bleeding at any age of presentation.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

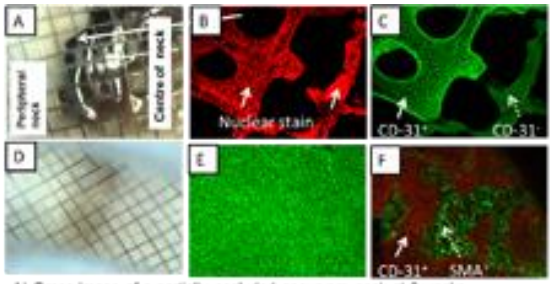
Molecular and Cellular Mechanisms of Aneurysm Occlusion following Flow Diverter Treatment

Kadirvel, R.·Ding, Y.·Dai, D.·Rezek, I.·Lewis, D.·Kallmes, D.
Mayo Clinic College of Medicine
Rochester, MN.

Purpose
Uncertainty regarding the relative importance of flow disruption, thrombus formation in the dome, and endothelialization across the neck impedes our ability to design improved flow diversion devices. The objective of this study was to characterize the progression of healing across aneurysm necks following flow diverter treatment.
Materials & Methods
Rabbit saccular aneurysms were treated with flow diverters. On days one, three, and seven (n=3 at each time point), and at eight weeks (n=9) after implantation, angiography was performed and the aneurysm along with the device-implanted vessel was harvested. Gross examination and histology were performed. *En face* staining was performed for CD-31 (endothelial cells), CD-34 (endothelial progenitor cells), SMA (smooth muscle cells) and inflammatory cells.
Results
Aneurysms remained patent in all subjects at days one and three and remained incompletely occluded at seven days. At eight weeks, complete, near-complete, and incomplete occlusion was noted in four, two, and three aneurysms, respectively. The parent artery segments covered by the flow diverters were completely devoid of endothelial cells at one and three days, but had re-endothelialized by seven days. The struts along the aneurysm necks at one, three, and seven days harbored scattered tissue islands comprised exclusively of inflammatory cells; similar findings were present in the patent areas of the incompletely occluded eight-week samples. Translucent tissue was present along the occluded segments of the aneurysm necks at eight weeks (Figure A). Most of the scattered tissue islands at all-time points consisted of inflammatory cells. However, some tissue islands in the periphery were made up of endothelial cells, which were in continuity with endothelial cells along the parent artery wall (Figures B&C). Histological analysis showed the incompletely occluded aneurysm domes harbored primarily unorganized thrombus. The necks of the completely occluded aneurysms were covered with a thin layer of endothelial cells (Figures D&E). A few, localized, nonendothelialized areas covered with smooth muscle cells were noted (Figure F). The domes were filled with organized thrombus. We did not observe any CD-34$^+$ cells in any aneurysm to suggest that circulating-progenitor cells were the cell of origin in and around the aneurysm neck.



A) Gross image of a partially occluded aneurysm neck at 8 weeks demonstrating scattered tissue islands in the center of the neck. B) Nuclear staining of Figure A confirms the presence of nucleated cells covering the device struts that are in close proximity to the vessel wall. C) Peripheral cells stained CD-31+ (solid arrow) and CD-31- in the neck center (dotted arrow), indicating that endothelial cells are growing from parent vessel out over the aneurysm neck. D) Gross image a completely occluded aneurysm at 8 weeks showing the thick, translucent membrane covering the aneurysm orifice. E) The neck area is mostly endothelialized with CD-31+ cells. F) Smooth muscle cells (SMA+, dotted arrow) reside under both the endothelialized (solid arrow) and non-endothelialized areas.

Conclusion
The initial event following flow diversion treatment is adherence of clusters of inflammatory cells across the aneurysm neck. Endothelialization is relatively delayed and is derived exclusively from cells in the adjacent parent artery. Concurrent with centripetal endothelialization, thrombus formation in the dome and gradually extends down toward the aneurysm neck.

Cerebral Aneurysm Treatment Is Beginning to Shift to Low Volume Centers

Brinjikji, W.·Lanzino, G.·Kallmes, D. F.·Cloft, H. J.
Mayo Clinic
Rochester, MN.

Purpose
A recent expansion of the neurointerventional workforce in the United States could lead to a trend toward cerebral aneurysms being treated increasingly at low volume centers. Such a trend could have a negative impact on patient care because higher volume centers are known to have better outcomes than low volume centers.
Materials & Methods
Using the Nationwide Inpatient Sample, we evaluated trends in aneurysm treatment in the United States from 2001 to 2010. We assessed the following outcomes: 1) number of subarachnoid hemorrhage (SAH) and unruptured aneurysm (UA) patients treated annually by treatment modality from 2001-2010, 2) trends in the proportion of SAH and UA patients treated at high volume centers (≥50 cerebral aneurysms treated per year) from 2001-2010, and 3) the percentage of aneurysm treatment centers treating <50 cerebral aneurysms per year from 2001-2010. Chi-squared testing was used to compare categorical variables.
Results

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

The number of SAH patients treated per year increased from 7680 in 2001 to 10970 in 2003. From 2003 to 2010 the number of ruptured aneurysms treated per year has fluctuated between 9291 and 12237. The number of UA patients treated per year increased steadily from 4474 in 2001 to 10720 in 2006, but then has fluctuated between 8304 and 11897 cases from 2006 to 2010. The percentage of SAH patients treated at high volume centers rose from 22% in 2001-2002 to 68% in 2007-2008 and then dropped to 58% in 2009-2010 (P<.0001). The percentage of UA patients treated at high volume centers rose from 38 percent in 2001-2002 to 73% in 2005-2006 and then dropped to 65% in 2009-2010 (P<.0001). The percentage of aneurysm treatment centers with <50 cases/year steadily declined from 99% in 2001 to 85% in 2008 (P<.0001). Since 2008, there has been an increase in the percentage of low volume treatment centers to 91% (P<.0001).

Conclusion

A trend toward fewer cerebral aneurysms being treated in high volume centers in 2009 and 2010 is worrisome, as high volume centers are known to tend to have better outcomes than low volume centers. This trend is likely due to recent expansion of the neurointerventional workforce.

Timing and Nature of Immediate Postoperative Events following Elective Endovascular Aneurysm Treatment: Is Routine Intensive Care Unit Observation Necessary?

Patel, B.·Arias, E. J.·Cross, D. T.·Moran, C. J.·Derdeyn, C. P.
Washington University in St. Louis School of Medicine
St. Louis, MO.

Purpose

Patients with asymptomatic intracranial aneurysms treated with endovascular methods are observed in the postprocedure period for complications, including ischemic and hemorrhagic stroke, cardiac dysfunction and groin access complications. The purpose of this study was to analyze the timing, nature and rate of postoperative events in patients in whom the procedure was completed without apparent intraprocedural complications, and determine whether routine postprocedure monitoring in an intensive care setting is necessary for these patients.

Materials & Methods

Patients who underwent endovascular treatment of unruptured cerebral aneurysms from March 2002 to June 2012 were identified from a prospective case log. Hospital records were reviewed. Admissions for treatment of recurrent aneurysm were included. Postprocedure monitoring for all patients was in a neurologic intensive care unit or 24-hour postanesthesia care unit for a minimum of 24 hours. The presentation, patient characteristics, aneurysm size and location, and form of treatment of each cerebral aneurysm were analyzed. Endovascular procedures included coiling alone, stent-assisted coiling, balloon-assisted coiling, Onyx HD 500 occlusion, and pipeline embolization device with or without coiling. Patients with adverse intraprocedural events including perforation and embolic events were excluded from this analysis. Postprocedural events occurring during hospitalization included intracerebral hemorrhage, stroke, groin hematoma (if resulting in additional treatment or prolonged hospital stay), retroperitoneal hematoma, and cardiac events. The time from the completion of the procedure to event discovery was recorded.

Results

A total of 681 endovascular treatments of unruptured cerebral aneurysms were performed. Nine treatments were excluded from our analysis due to intraprocedural events. Twenty-seven treatments (4.0%) resulted in postprocedure complications: three hemorrhages (one intraventricular hemorrhage, one subarachnoid hemorrhage with intraventricular hemorrhage, and one intraparenchymal hemorrhage), six ischemic strokes, four cardiac events, five retroperitoneal hematomas and nine groin hematomas. The majority (20/27 or 74.0%) of these complications were detected within four hours from the procedure. These included one hemorrhage, four ischemic strokes, four cardiac events, two retroperitoneal hematomas, and nine groin hematomas. All cardiac events and groin hematomas were detected within four hours. In contrast, 14.8% (4/27) of the complications were detected between four to 12 hours, 3.7% (1/27) between 12 and 24 hours, and 7.4% (2/27) more than 24 hours after the procedure. Further analysis of the complications detected greater than four hours from the conclusion of the procedure revealed two minor hemorrhages detected on head CT due to headaches resulting in no permanent deficits, two ischemic strokes with minor deficits requiring inpatient rehab after discharge, and three asymptomatic retroperitoneal hematomas found due to falling hematocrit levels that required no further intervention or treatment.

Conclusion

Patients with uncomplicated endovascular aneurysm intervention require close monitoring for at least four hours. The nature and frequency of complications between four and 24 hours suggests continued in-patient monitoring is useful, but could be performed in a less resource-intensive environment.

Safety and Efficacy of a New Device for the Treatment of Wide Neck Bifurcation Aneurysms (pCONus): Preliminary Experience in Eighteen Patients

Aguilar-Pérez, M.[1]·Kurre, W.[1]·Felber, S.[2]·Donauer, E.[3]·Hopf, N.[1]·Bäzner, H.[1]·Henkes, H.[1]
[1]Klinikum Stuttgart, Stuttgart, GERMANY,
[2]Stiftungsklinikum Mittelrhein, Koblenz, GERMANY,
[3]MediClin Krankenhaus Plau am See, Plau am See, GERMANY.

Purpose
Wide neck intracranial bifurcation aneurysms are considered to belong to the subgroup of aneurysms with increased treatment difficulty and risks. The simultaneous use of two or more microcatheters and the use of one or two compliant balloons for temporary sealing of the aneurysm neck while introducing coils are known techniques for the endovascular treatment of these aneurysms. Also the use of intracranial self-expanding stents to create an artificial border between a vessel bifurcation and an aneurysm has shown during the last decade to be a safe and efficacious option. pCONus is a self-expanding, completely retrievable, electrolytically detachable device with a proximal shaft (similar to stents) and four distal petals and with a nylon cross in the distal end of the shaft (Figure 1). The device is made to bridge the orifice of wide neck bifurcation aneurysms in order to allow better control of the coil occlusion. It combines functional elements of “waffle cone” stent deployment and the no longer available TriSpan Neck Bridging Device. The purpose of this study was to evaluate the safety and efficacy of this new device for the treatment of intracranial wide neck bifurcation aneurysms.
Materials & Methods
Eighteen consecutive patients, deemed unsuitable for or refusing microsurgery, underwent an endovascular treatment of intracranial wide neck bifurcation aneurysms using the pCONus device between April 2011 and November 2012. pCONus was used by prescription in highly selected patients. Target vessels included the anterior circulation in 13 (72.3%) and the posterior circulation in five (27.7%). Six patients were treated in the setting of acute subarachnoid hemorrhage (33.3%) and five of the aneurysms showed reperfusion after previous coil occlusion (27.7%).
Results
No technical failure or major complication was encountered. Rupture did not occur during any of the procedures. No premedication was used in the patients with subarachnoid hemorrhage and no thromboembolic complications were observed. After the initial embolization procedure, a 90 to 100% occlusion rate was achieved in all cases but a neck remnant was evident in four patients. Initial follow-up angiography was available in 10 of 18 (55.5%) patients and demonstrated a 90 to 100% occlusion rate in eight (80%). Evident coil compaction was observed in one patient, who underwent a second treatment two months after the first therapeutic session.

Conclusion
The pCONus device allows a controlled coil occlusion of wide neck bifurcation aneurysms, both ruptured and unruptured. Major complications are rare.

Stent-Assisted Coiling versus Coiling Alone in Unruptured Intracranial Aneurysms in the MAPS Trial: Safety, Efficacy, and Mid-Term Outcomes

Hetts, S. W.[1]·Turk, A.[2]·English, J.[1]·Prestigiacomo, C.[3]·Nesbit, G.[4]·Mocco, J.[5]·Barnwell, S.[4]·Gobin, Y. P.[6]·Lopes, D.[7]·Ge, G.[8]·Jin, J.[8]·Carroll, K.[8]·Murayama, Y.[9]·Gholkar, A.[1]·Johnston, S. C.[1]·McDougall, C.[10]
[1]University of California San Francisco, San Francisco, CA,
[2]Medical University of South Carolina, Charleston, SC,
[3]University of Medicine & Dentistry of New Jersey, Newark, NJ, [4]Oregon Health and Science University, Portland, OR, [5]Vanderbilt, Nashville, TN, [6]Weill Cornell Medical School, New York, NY, [7]Rush University Medical Center, Chicago, IL, [8]Stryker Neurovascular, Fremont, CA,
[9]Jikei University School of Medicine, Tokyo, JAPAN,
[10]Barrow Neurological Institute, Phoenix, AZ.

Purpose
Stent-assisted coiling (SAC) may result in less aneurysm recanalization but more complications than coiling alone (CA). We evaluated outcomes of SAC in the prospective, multicenter MAPS Trial.
Materials & Methods
Three hundred sixty-one MAPS patients with unruptured intracranial aneurysms (UIAs) were treated per protocol by SAC or CA. Baseline patient and aneurysm characteristics, procedural details, neurologic outcomes, and safety data were analyzed post hoc. An independent core laboratory evaluated angiographic outcomes.
Results
One hundred thirty-seven of 361 patients received a Neuroform stent. Aneurysms treated with SAC had wider necks (62% of SAC versus 33% of CA with necks >4mm, P<0.0001) and lower dome-to-neck ratios (1.5 versus 2.1, p = 0.0001) necks, however. Although complete angiographic obliteration for SAC was similar to CA at 1 year (51.8% versus 44.4%, p = 0.22), angiographic

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

worsening was lower for SAC than CA (16.7% versus 33.3%, p = 0.002). The primary endpoint for the MAPS Trial was defined as target aneurysm recurrence (TAR), a composite clinical endpoint consisting of target aneurysm retreatment, delayed intracranial hemorrhage, or death from an unknown cause. At one year of followup, the TAR rate among all UIA was 12/137 (8.8%) for SAC and 19/227 (8.5%) for CA (p = 0.93). Among WNA at one year, the TAR rates were 12/85 (14.1%) and 10/73 (13.7%), respectively (p = 0.94). By two years of followup, 13/137 (9.5%) of SAC and 22/224 (9.8%) of CA patients had had a TAR event (p = 0.92) in the UIA cohort. Similarly, TAR event rates did not differ in the WNA groups at two years, with 13/85 (15.3%) of SAC and 11/73 (15.1%) of CA experiencing a TAR event (p = 0.97).
Conclusion
Stent-assisted coiling was effective in treating UIAs. Stent-assisted coiling correlated with better angiographic outcomes at one year without significantly higher rates of SAEs, death, or disability despite the stented aneurysms having more difficult morphology than coiled aneurysms. Increased ischemic events in SAC as compared to CA warrant attention as the trial continues. Primary clinical outcomes did not differ between the SAC and CA groups either among all UIAs or among WNAs at both one and two years.

Middle Cerebral Artery Aneurysms - Feasibility, Clinical and Anatomical Results of the Endovascular Treatment by WEB Flow Disruption: Preliminary Evaluation in a Multicenter Study

Pierot, L.[1]·Klisch, J.[2]·Cognard, C.[3]·Szikora, I.[4]·Mine, B.[5]·Kadziolka, K.[1]·Sychra, V.[2]·Gbucz, I.[4]·Januel, A.[3]·Lubicz, B.[5]
[1]Hopital Maison-Blanche, Reims, FRANCE, [2]Helios General Hospital, Erfurt, GERMANY, [3]Purpan Hospital, Toulouse, FRANCE, [4]National Institute of Neurosurgery, Budapest, HUNGARY, [5]Erasme University Hospital, Brussels, BELGIUM.

Purpose
The endovascular treatment of middle cerebral artery (MCA) aneurysms with unfavorable anatomy (wide neck, unfavorable morphology) frequently is challenging. Flow disruption using the WEB® is potentially an interesting endovascular treatment for this type of aneurysm. In this multicenter study we report our preliminary experience with this device.
Materials & Methods
Thirty-three patients with 34 MCA aneurysms were treated using the WEB in five European centers. The ability to successfully deploy the WEB, procedural and device related adverse events, morbidity and mortality of the treatment, and short-term angiographic follow-up results were analyzed.
Results
Most treated aneurysms (85.3%) were unruptured, had a size between 5 and 10 mm (85.3%), and a neck size greater or equal to 4 mm (88.2%). The treatment failed in 1/34 aneurysms (2.9%) due to the lack of appropriate size of the device. Treatment was performed exclusively with the WEB in 29/33 (87.9%). Additional treatment (coiling and/or stenting) was used in 4/33 (12.1%). Mortality of the treatment was 0.0% and morbidity 3.1% (intraoperative rupture with mRS 3 at one-month followup). In short-term followup (2 to 12 months), adequate occlusion (total occlusion or neck remnant) was observed in 83.3% of aneurysms.
Conclusion
Flow disruption seems to be a promising technique for the treatment of complex MCA aneurysms, singularly those with a wide neck or unfavorable dome-to-neck ratio. However the analysis of mid- and long-term anatomical results is still needed to confirm the value of this technique.

Safety and Long-Term Efficacy of Flow Diversion versus Standard Coiling in the Treatment of Unruptured Carotido-Ophthalmic Aneurysms: A Preliminary Analysis

Di Maria, F. I.[1]·Clarençon, F.[1]·Sourour, N. A.[1]·Bernat, A.[1]·Biondi, A.[2]·Jean, B.[3]·Chiras, J.[1]
[1]Pitié Salpêtrière Hospital, Paris, FRANCE, [2]CHU Besançon, Besançon, FRANCE, [3]CHU Clermont Ferrand, Clermont Ferrand, FRANCE.

Purpose
Carotido-ophthalmic aneurysms (COA) are challenging lesions often prone to recanalization after endovascular treatment. Flow diversion (FD) is emerging as a new endovascular strategy for the treatment of these aneurysms, its goal being virtually to achieve a stable aneurysm occlusion on a long-term basis. We sought to compare angiographic outcome and complication rates in two groups of patients treated by standard coiling (SC) or FD at our institution over six years.
Materials & Methods
From February 2006 to December 2011, 40 unruptured COAs were treated endovascularly in 38 patients, nine of which were symtomatic. Twenty-six COAs were treated by SC. Balloon-assisted technique was employed in eight cases, stent-assistance in five cases. Flow diverters were deployed in the 14 aneurysms starting June 2009. Additional coiling was performed in four cases. One treated aneurysm was a recurrence after previous standard coiling. Imaging followup was carried out by 3D TOF MRA and DSA at six months and at 12 months respectively, then 3D TOF MRA on a yearly basis.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Results
Mean followup was 59.2 +/- 35.6 months. No death or permanent morbidity was observed. One thromboembolic event (3.8%) causing transient neurologic motor deficit occurred in the SC group within six hours after the procedure. One homolateral intraparenchimal hemorrhage (7.1%) was observed 10 days after procedure in the FD group, causing transient aphasia and contralateral monoplegia. Clinical outcome was good in all patients. No statistical significance was found in terms of difference in complication rates (p = 0.08). No cases of rebleeding were observed during followup. Partial recanalization was observed during followup (mean 65.3 +/- 27.1 months) in 12 (46.3%) COAs treated by SC (six neck remnants and six residual sacs), leading to retreatment in five (19.2%). Of the five aneurysms coiled by stent-assisted technique, two recanalized at one year. One incompletely treated aneurysm didn't show any increase in the size of the circulating portion over 38 months. On the other hand, in the FD group (mean follow-up time 37.2 +/- 25.4), eight COAs showed complete thrombosis within six months, 13 within 12 months. No recanalization was observed after thrombosis had occurred. One small (5 mm) wide-necked aneurysm remained patent at 24 months and required retreatment by a second flow diverter. The difference in recanalization rate between the two groups in terms of recanalization at followup was statistically significant (p = 0.0004) even when considering only sac remnants and not neck remnants in the SC group (p = 0.002).
Conclusion
Though conducted on a small sample and in a particular subset of aneurysms, this retrospective analysis shows better stability of aneurysmal thrombosis after use of FD compared to SC. The introduction of flow diverters may probably increase the rate of long-lasting complete angiographic occlusion in COAs. However, larger samples and long term followup for FD are needed to better assess complication rates and stability of treatment results.

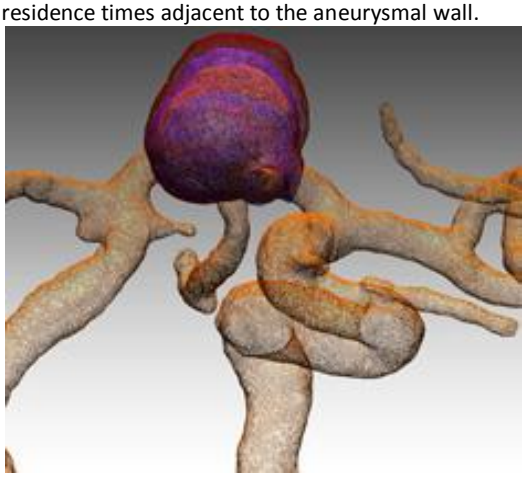
Luminal Expansion and Narrowing in the Progression of Intracranial Aneurysms

Saloner, D.[1]·Rayz, V.[1]·Lee, W. A.[1]·Faraji, F.[1]·Martin, A.[1]·Young, W. L.[2]·Ko, N.[2]·Lawton, M. T.[2]
[1]VA/University of California San Francisco, San Francisco, CA, [2]University of California San Francisco, San Francisco, CA.

Purpose
This study was designed to investigate changes in lumenal morphology in patients with untreated aneurysms who were imaged serially over time. The aim was to determine individuals who demonstrated outward remodeling of their aneurysms and those where the lumenal geometry narrowed, and to relate those changes to prevalent hemodynamics on patient-specific basis.
Materials & Methods
Eighty-three patients were recruited where a clinical decision was made not to attempt any interventional repair of their aneurysms. These subjects underwent serial MR imaging at intervals of six months on a 1.5T scanner. 3D contrast-enhanced MR angiography was performed to determine the lumenal geometry with 30 second acquisition and with a voxel size of 0.5 mm^3 . In addition, 3D balanced steady state imaging was performed on the identical volume with identical spatial resolution. In selected subjects, 4D MR velocimetry was acquired with 1 mm^3 spatial resolution. Serial studies were co-registered in a three-dimensional space and changes of the lumen were measured on the CE MRA studies, and changes in the outer wall were determined from the balanced steady state images. Numerical computational fluid dynamic simulations were performed to determine the time-varying velocity fields in the aneurysms using patient-specific geometries as determined by CE MRA and inlet flow velocities from the MR velocimetry.
Results
A total of 337 interval studies were performed over the 83 subjects, with each subject having received at least two studies and some as many as nine studies. The error of reproducibility averaged over all subjects was found to be 4.9%. In all subjects, the outer wall of the aneurysm either remained unchanged or demonstrated outward remodeling over time. Twelve percent of the aneurysms showed significant layering of intralumenal thrombus. Of the aneurysms that remained thrombus-free, 15% demonstrated lumenal growth(Figure: ACoA aneurysm). Computational fluid dynamics calculations indicated that locations of growth correlated with areas of the aneurysm that were subjected to low wall shear stress. Regions of thrombus layering were found to correlate with locations where there was low blood shear stress and long residence times adjacent to the aneurysmal wall.



Conclusion
MR imaging is an effective modality for monitoring the

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

temporal evolution of aneurysm morphology. These studies indicate that hemodynamics can play an important role in the rate of outward remodeling of the aneurysms and in the likelihood that regions of the anuerysm might layer clot. These studies could potentially lead to improved methods for stratifying patient treatment.

Effects of Circle of Willis Anatomical Variations on Angiographic and Clinical Outcomes of Coiled Anterior Communicating Aneurysms

Tarulli, E.[1]·Sneade, M.[2]·Clarke, A.[2]·Molyneux, A. J.[2]·Fox, A. J.[1]
[1]Sunnybrook Health Sciences Centre, Toronto, ON, CANADA, [2]Oxford Neurovascular and Neuroradiology Research Unit, Oxford, UNITED KINGDOM.

Purpose
To evaluate the effects of circle of Willis anatomical variations on angiographic and clinical outcomes of anterior communicating aneurysm coiling treatment.
Materials & Methods
Anatomical variations and contrast filling of anterior cerebral artery trunks (A1), pericallosal (A2), and anterior communicating (A-com) arteries showed a high rate of aneurysm occurrence for unilateral A1 dominance cases (AJNR 2010;31:186-191). The randomized Cerecyte Coiling Trial (CCT) provides a sub-group of 98 cases with A-com aneurysms compared with 335 cases with other aneurysm locations for analysis of clinical outcome and the stability of aneurysm packing (platinum coil or Cerecyte coil) from follow-up angiography for angiographic outcome (Stroke 2012; 43:2544-2550). Clinical outcomes were assessed categorically by the Modified Rankin Score (mRS) at six months. A-com aneurysm cases are analyzed to relate A1 vessel dominance for treatment results, seeking differences in coil packing stability between cases with balanced A1 pattern and for aneurysms in other locations. Post-coiling angiographic outcomes were categorized immediately after coiling and at delayed followup (five-seven months) determining treatment success as defined in the published CCT results.
Results
A1 dominance was seen in 70% (n = 72) of A-com aneurysms and 30% (n = 31) A1 co-dominant. Treatment success in the A1 dominant group was 56% (n = 39 of 69) compared with 55% (n = 16 of 29) for treatment success for A-com aneurysms with other configurations at five-seven months (five cases lost to followup). These results compare to 57% (n = 190/335) treatment success for other aneurysms in other locations. Using p = 0.05 as a cutoff for the one-sided Fisher exact test there was no statistically significant difference in immediate treatment success rate between any A-com aneurysm configurations versus aneurysms elsewhere (p>0.5). Yet Pearson Chi-square tests comparing the angiographic appearance at baseline and five-seven months followup for the A1-dominant, A-com group showed statistical significance (p = 0.048) with fewer neck remnants (comparing 53% with 38%, n = 38 to n = 26) and more incompletely treated aneurysms with sac filling (comparing 8% with 22%, n = 6 to n = 15) while the completely treated proportion was unchanged (40%, n = 28). There was no statistically significant difference in clinical outcomes between these groups at the five-seven month followup (p = 0.57). No difference was seen for the randomized platinum and Cerecyte coil groups.
Conclusion
A-com aneurysms with A1 dominant circle of Willis configurations with incomplete occlusion at baseline may be less stable at followup than other aneurysms and those with A1 co-dominance despite no difference in clinical outcome at this time point. This supports the hypothesis that the A1 dominant flow into termination aneurysms of the A-com artery contributes to aneurysm formation, growth, and instability of treatment with coil packing.

Hyperperfusion in Carotid Stenting Patients

Aralasmak, A.·Atay, M.·Toprak, H.·Ozdemir, T.·Asıl, T.·Goktekin, O.·Alkan, A.
Bezmialem Vakif University
Fatih/Istanbul, TURKEY.

Purpose
To define hyperperfusion by evaluating pre and poststent CT perfusion studies of carotid stenting patients.
Materials & Methods
Total 29 patients, referred for carotid artery stenting, were enrolled. Sixty-four-channel CT (Toshiba, Aquilion) was used. Prestent CT perfusion studies were performed within one week before stenting. Poststent studies were performed three days after stenting. For CT perfusion, 45 ml contrast agent was administrated after five sn of data acquisition. The injection was performed by automatic injector in the right arm at a rate of 5 ml/s. Following computation of CBV, CBF, MTT and TTP maps, measurements were performed from areas of perfusion

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

deficits and corresponding contralateral normal sides. Measurement from watershed regions and putamen were obtained irrespective of perfusion deficit. At least four areas were measured. For CBV, relative CBV (rCBV) were calculated by dividing ipsilateral (stent side) CBV to the contralateral CBV values. Pre and poststent rCBV were calculated separately. Similar calculations were performed for pre and poststent relative CBF (rCBF) and relative MTT (rMTT) values. Additionally for MTT, the different present MTT (dMTTpre) value was calculated by subtracting contralateral MTT from ipsilateral MTT values. Similar calculations were performed by using poststent values for poststent difference MTT (dMTTpost). Finally, average values of measurements were taken into consideration for comparison. Patients with clinical showing of one of the hyperperfusion syndromes except mild headache were accepted as a patient with hyperperfusion syndrome.

Results

Two of 29 (6%) showed clinical hyperperfusion of focal neurologic deficit and seizure after stenting. Their average values and comparing with average values of patients with no clinical hyperperfusion syndrome were given in the table. Only appreciable difference was noted in pre and poststent dMTT values. Six of 29 showed poststent radiologic hyperperfusion noted with increased CBF, increased or spared CBV and shortened MTT values. However, only one of them was symptomatic showing clinical hyperperfusion syndrome.

Hyperperfusion	rCBV pre	rCBF pre	rMTT pre	rCBV post	rCBF post	rMTT post	dMTT pre	dMTT post
-	1.00	1.13	1.28	1.09	1.10	1.16	**0.71**	**0.27**
+	1.09	1.30	1.28	1.00	1.41	1.11	**-0.08**	**-0.49**

Conclusion

After carotid stenting, revascularization of previously hypoperfused areas can cause symptoms such as ipsilateral headache, hypertension, seizure, focal neurologic deficit, brain edema, intracerebral or subarachnoid bleeding and death. Hyperperfusion mostly occurs within three-five days of revascularization. Due to dreadful consequences of hyperperfusion, to anticipate the possibility of hyperperfusion before stenting is critical. In our study, among the perfusion parameters, we found only appreciable difference between the patients with and without clinical hyperperfusion is MTT. Radiologic hyperperfusion does not match the clinical hyperperfusion.

Comparison of Vasoconstrictive and Vasodilatory Reserve in Patients with Stenosis of Brain-Supplying Arteries

Mandell, D. M.[1]·Poublanc, J.[1]·Pucci, O.[1]·Wong, T.[1]·Sam, K.[1]·Han, J.[1]·Crawley, A.[1]·Duffin, J.[2]·Fisher, J.[1]·Mikulis, D.[1]
[1]University Health Network, Toronto, ON, CANADA, [2]University of Toronto, Toronto, ON, CANADA.

Purpose

In patients with stenosis of brain-supplying arteries and reduced cerebral perfusion pressure, there is reduced capacity for vasodilator-induced augmentation of cerebral blood, that is, reduced cerebrovascular reactivity. Measurement of cerebrovascular reactivity can be useful for risk stratification. While the cerebral vasodilatory response is relatively well known in patient populations, the response of the cerebral vasculature to vasoconstrictive stimuli is less well known. The aim of this study was to compare the magnitude of vasoconstrictive and vasodilatory reactivity in patients with stenosis of brain-supplying arteries.

Materials & Methods

We measured vasoconstrictive and vasodilatory reactivity in 12 patients with arterial steno-occlusive disease using both hypocapnic (vasoconstrictive) and hypercapnic (vasodilatory) stimuli, and blood oxygen level-dependent (BOLD) MR to measure changes in cerebral blood flow. MR imaging was performed on a 3.0 T whole body scanner. Following a T1-weighted three-dimensional sequence for anatomical co-registration, CVR data was acquired with a T2*-weighted single-shot gradient-echo echo-planar sequence during a precisely controlled ramp waveform of end-tidal partial pressure of carbon dioxide (PETCO2) from 30 mm Hg to 50 mm Hg. CVR was calculated as percent change in BOLD MR signal intensity per mm Hg change in PETCO2 on a voxel-wise basis. We segmented the middle cerebral artery territory cortex using an automated algorithm, and calculated mean CVR for the combined MCA segments for each patient. We performed a paired t-test to determine whether there was a difference in magnitude of reactivity for hypocapnic (30 - 40 mm Hg) versus hypercapnic (40 - 50 mm Hg) stimuli. We also analyzed whether baseline (resting) PETCO2 was correlated with the difference between hypocapnic and hypercapnic reactivity.

Results

There was a (nearly significant) trend toward higher vasoconstrictive cerebrovascular reactivity than vasodilatory reactivity (0.17 versus 0.13; two-sided P = 0.052). There was no significant correlation between resting PETCO2 and the difference between hypocapnic and hypercapnic reactivity.

Conclusion

CO2 BOLD MR demonstrates greater vasoconstrictive than vasodilatory reactivity in patients with stenosis of brain-supplying arteries. Further investigation is required to determine whether this difference is due to a normal

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

physiologic difference in magnitude of vasoconstrictive and vasodilatory response, or due to the underlying steno-occlusive disease.

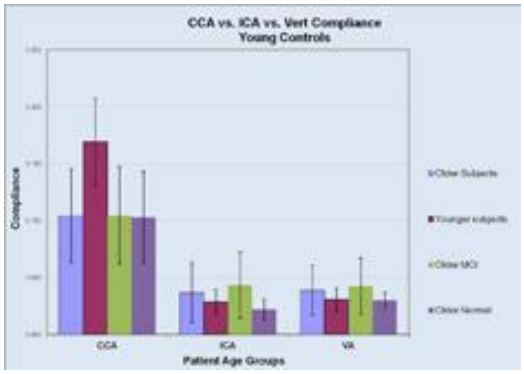
Comparison of Common Carotid, Internal Carotid and Vertebral Arterial Compliance in Young Healthy Controls and Elderly Subjects Directly Measured with 3D Time-of-Flight MR Angiography

Bert, R. J.[1]·Mihlon, F.[2]·Hildreth, K.[1]·Moreau, K.[1]·Schwartz, R.[1]
[1]Univerisity of Colorado Denver, Aurora, CO, [2]Duke University, Durham, NC.

Purpose
Common carotid artery (CCA) compliance decreases with aging and may affect CNS perfusion dynamics. Less is known about internal carotid artery (ICA) and vertebral artery (VA) compliance, as they are difficult to directly measure with ultrasound. We have used cardiac-gated 3D time-of-flight (CG 3D ToF) MRA to directly measure CCA, ICA and VA compliance changes in small cohorts of young and older males and compared these changes to vascular flow waveforms obtained with quantitative phase contrast MRA in the same vessels.
Materials & Methods
We measured CCA, ICA and VA compliance with CG 3D ToF MRA in 10 healthy young men and 10 older men (seven with mild cognitive impairment and three without) as previously described, with a 1.5T system. Comparison ultrasound compliance measurements of the CCA provided controls (3). Quantitative phase-contrast MRA, normal to the vessels, was used to obtain velocity and flow curves. Peak systolic velocity and peak blood flow curves were used to set gates for compliance measurements.
Results
Common carotid artery vascular distension from MRI and ultrasound were reasonably correlated (MRI 0.158 ± 0.049, US 0.125 ± 0.034); R2 = 0.41. There were pronounced compliance differences between CCA (0.171 ± 0.04) and ICA (0.029 ± 0.011) ≈ VA (0.031 ± 0.01) in young healthy controls. The pattern was the same but differences smaller in the 10 older subjects: CCA (0.104 ± 0.04), ICA (0.037 ± 0.026), VA (0.039 ± 0.02). Common carotid artery was reduced in older compared to younger subjects (p<.002) However, there were no differences in ICA (P = 0.71) and VCA (p = 0.17) between older and young adults. However, surprisingly, ICA compliance differences did reach significance between MCI and normal older subjects (p = 0.049), despite the low power. Common carotid artery flow curves broadened and peak flows decreased with age, as compliance decreased.



Conclusion
Internal carotid artery and VA are less compliant than CCA in both young healthy controls and older adults. Common carotid artery versus ICA-VA compliance differences narrowed significantly with aging and resulted from decreased CCA compliance alone. In our small sample, MCI and non MCI older subjects demonstrated significant differences in ICA, but not CCA or VA compliance. These results warrant further study to obtain greater statistical power for validation. Current findings suggest that CCA contractility decreases with age, broadening flow curves and decreasing peak flows.

Hemodynamic Alterations in Cerebral Blood Vessels after Carotid Artery Revascularization: Quantitative Analysis by Using 2-Dimensional Phase-Contrast MR Imaging

Youn, S.[1]·Kim, H.[1]·Lee, J.[2]·Lee, H.[2]
[1]Daegu Catholic University Medical Center, Daegu, KOREA, REPUBLIC OF, [2]Kyungpook National University Hospital, Daegu, KOREA, REPUBLIC OF.

Purpose
While the clinical benefits from carotid artery revascularization (CAR) gained consensus, the understanding of hemodynamic alterations in cerebral blood vessels are still limited. It is unclear whether and how collateral flow and total cerebral blood flow volume ($_{FV}$TCBF) would change after CAR. It also is unknown that the increased intracranial pressure (ICP) and/or cerebral hyperperfusion syndrome may be suggested by flow changes in cerebral veins and cerebrospinal fluid (CSF) in the ischemic brain with significant carotid artery stenosis. The purpose of this study was to evaluate comprehensively the effect of CAR on cerebral arterial and venous flow volume (FV) with 2-dimensional phase-contrast magnetic resonance imaging (2D PC MRI).
Materials & Methods
The 39 carotid artery stenoses in 37 patients (28 men; 70.00 ± 8.58 years old), who were treated by CAR including 32 stentings and seven endarterectomies, were included in this prospective study. From the 2D PC MRI acquired

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

before and after the revascularization, time-FV curves were generated with software (Reportcard, GE Healthcare, Milwaukee, WI). The FVs of the arteries, veins and CSF ($_{FV}$CSF) for before and after revascularization were compared with paired T-test. The relationships between the parameters of different locations were correlated with the Pearson correlation.

Results

After revascularization, the mean FV in the treated internal carotid artery ($_{FV}$TxICA; proportion of treated ICA among total FV) increased from 162.06 mL/min (25.80%) to 267.71 mL/min (37.21%; *P*<.001). The mean total FV of patients before revascularization was 638.66 mL/min. CAR increased the $_{FV}$TCBF of patients to 716.72 mL/min (*P*<.001). However, no significant changes were seen in the FV of the contralateral ICA and basilar artery after CAR. The FV of the internal jugular veins, superior sagittal and straight sinuses ($_{FV}$SS+SSS), and transverse sinuses increased after CAR (*P*<.05). Positive relationships were shown between the $_{FV}$TCBF and the $_{FV}$SS+SSS before and after revascularization (*r* = 0.584-0.741, *P*<.001). However, no significant changes were seen in the $_{FV}$CSF after CAR, and there was no patient with suspicion of hyperperfusion syndrome.

Conclusion

Carotid artery revascularization improves effectively the $_{FV}$TCBF by increasing the $_{FV}$TxICA without disturbing the collateral flows. The venous drainages are increased and closely linked to the increased $_{FV}$TCBF. The closed linkage of artery and vein, and interval constant $_{FV}$CSF may suggest our patients' condition with stable ICP. Based on these results, 2D PC MRI is recommended to evaluate the outcomes of CAR quantitatively.

Value of Noncontrast Time-Resolved MR Angiography Using Arterial Spin Labeling in the Diagnosis of Occlusive Disease of the Major Intracranial Arteries

Tsuchiya, K.·Gomyo, M.·Ohara, A.·Shimatani, N.·Nitatori, T.
Kyorin University
Tokyo, JAPAN.

Purpose

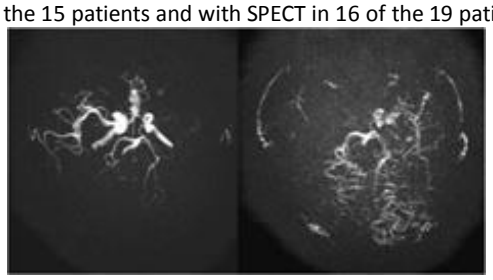
Our purpose was to assess the value of noncontrast time-resolved MR angiography developed based on the arterial spin labeling technique in the evaluation of the hemodynamic status of occlusive disease of the major intracranial arteries.

Materials & Methods

The study group comprised a total of 24 patients (16 men and eight women; age range, 15-76 years; mean age, 59 years). Their disease included stenosis or occlusion of the internal carotid artery (five patients), middle cerebral artery (five patients), anterior cerebral artery (one patient), and moyamoya disease (13 patients). Among them, 10 patients were in the status of postbypass surgery. Noncontrast time-resolved MR angiography was performed on a 3T system using a 3D fast field-echo sequence with parameters as follows: TR/TE/FA, 4.5 ms/2.1 ms/15 deg; FOV, 230 × 256 mm; imaging matrix, 256 × 256; slab thickness, 96 mm; and section thickness, 3 mm. As to magnetically label the blood as a tracer, we placed a tag pulse band of 200 mm thickness inferior to the scan slab placing an interval of 17 mm. No cardiac or peripheral pulse gating was used. Changing a labeling delay time by 300-500 ms, we performed three-six scans in the axial plane. Visual assessment regarding the visualization of the stenoocclusive lesion and collateral vessels was performed comparing with 3D time-of-flight (TOF) MR angiograms in all patients using a four-point grading system. Comparison also was done with digital subtraction angiography in 15 patients and brain perfusion single photon emission tomography (SPECT) in 18 patients.

Results

Noncontrast time-resolved MR angiography better depicted the stenoocclusive lesion and collateral vessels than 3D TOF MR angiography in 21 patients (84%) achieving a better result in the assessment by scoring (Wilcoxon rank-sum test, P<0.01). Its findings were comparable with digital subtraction angiography in 14 of the 15 patients and with SPECT in 16 of the 19 patients.



Conclusion

In assessing the hemodynamic status of occlusive diseases of the major intracranial arteries, noncontrast time-resolved MR angiography is superior to 3D TOF MR angiography, while it is equivalent to conventional digital subtraction angiography and SPECT.

Validation of Dynamic CT Perfusion Summary Maps in Suspected Hyperacute Middle Cerebral Artery Stroke Patients: Comparison to Early Diffusion-Weighted Images

McKinney, A. M.·Palmer, C.·Jaghadeesan, B.·Truwit, C.
University of Minnesota & Hennepin County Medical Centers
Minneapolis, MN.

Purpose

Accurate CT perfusion (CTP) maps of penumbra and infarct core have been elusive, and are quite variable between postprocessing vendors. Meanwhile, the relatively simple,

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

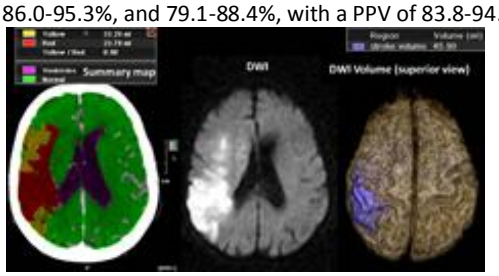
reproducible measurement of infarct volume on DWI MRI has been proposed as a means to select patients for thrombolytic therapy. Our goal was to evaluate the performance of one vendor's dynamic CTP "summary" (penumbra) maps in hyperacute MCA infarcts, as compared to DWI, and to compare the volume of infarct "core" between methods.

Materials & Methods

We identified 1087 64-slice emergent adult CTP examinations performed for stroke over 5.5 years, 244 of which were positive on DWI (DWI+), and 249 negative (DWI-). Forty-three of 244 DWI+ patients were performed <12 hours post-ictus/onset (>1.5 cm size), who were compared to 43/249 DWI patients, also <12 hours onset. Three reviewers separately evaluated both coregistered DWI and CTP "summary" (penumbra) maps, tabulating ASPECTS scores, and being blinded to other CTP parameters and noncontrast CT. The summary maps were generated automatically by a delay-corrected singular value decomposition ("SVD+") method, which automates comparison to contralateral and surrounding cerebrum via thresholds (CBV -40%, TTP>7.0sec., etc.); suspected infarct was colored red, ischemic penumbra yellow, and "normal" cerebrum green. Infarct volumes from the DWI and the CTP summary maps then were measured and correlated.

Results

The maximum diameter of MCA infarcts in the 43 DWI+ patients ranged from 16-142 mm (mean 46.2 mm). Regarding the three reviewers' ASPECTS scores, "interobserver" kappa for infarct "core" ranged from 0.930-0.969 ($p<0.0001$) on DWI, and from 0.943-0.963 ($p<0.0001$) on CTP summary maps; "intraobserver" kappa (comparing DWI to CTP scores) ranged from 0.645-0.737 ($p<0.0001$). The infarct "core" volume on DWI ranged from 1.5-215.6 cc (mean 34.5 cc), and on CTP summary maps was 0-184.5 cc (mean 28.7 cc). The volume of infarct "core" on CTP summary maps correlated excellently with DWI volume (Spearman's $r = 0.928$, $p<0.0001$), while the red+yellow "core+penumbra" region had less correlation($r = 0.766$, $p<0.0001$). Overall, the sensitivity, specificity, and accuracy of the summary maps ranged from 72.1-83.3%, 86.0-95.3%, and 79.1-88.4%, with a PPV of 83.8-94.3%.



Conclusion

The automated display and volume measurement of infarct "core" on "summary" (penumbra) maps were quite representative of the infarct volume on DWI, with reproducible ASPECT scoring between observers. However, automated penumbra visualization needs prospective validation, and future studies could validate whether infarct "core" volumes on such maps correlate with outcome, in order to augment patient selection for therapy.

Delayed MD CT Angiography Significantly Improves Detection of the Spot Sign and Increases Sensitivity for Prediction of In-Hospital Mortality following Intracerebral Hemorrhage

Ciura, V. A.[1]·Ortiz Lievano, J. C.[1]·Brouwers, H. B.[2,3,4]·Rosand, J.[2,3,5]·Goldstein, J. N.[2]·Pomerantz, S. R.[1]·Gonzalez, R. G.[1]·Romero, J. M.[1]
[1]Massachusetts General Hospital, Boston, MA, [2]Massachusetts General Hospital, Harvard Medical School, Boston, MA, [3]Center for Human Genetic Research, Massachusetts General Hospital, Harvard Medical School, Boston, MA, [4]J. Philip Kistler Stroke Research Center, Massachusetts General Hospital, Harvard Medical School, Boston, MA, [5]Hemorrhagic Stroke Research Group, Massachusetts General Hospital, Harvard Medical School, Boston, MA.

Purpose

To determine whether addition of 90 second delayed multidetector computed tomography angiography (MD CTA), in addition to routine first-pass MD CTA in patients with spontaneous intracerebral hemorrhage (ICH) improves detection of the spot sign and increases sensitivity for predicting in-hospital mortality. Previous trials have demonstrated that the spot sign is an independent predictor of hematoma expansion and death. Delayed imaging may capture additional patients at risk of death.

Materials & Methods

We performed a prospective study of consecutive patients enrolled over nine months at a single academic center. Patients were separated into two groups - those with a spot sign and those without. Spot sign positive cases were further subdivided into groups depending on the presence of the spot sign on first pass, delayed, or both CTA acquisitions. Uni- and multivariate logistic regression was performed to assess clinical and neuroimaging covariates (including the spot sign) for relationship with in-hospital mortality. Accuracy measures were calculated to compare first pass and delayed CTA performance.

Results

Of 55 consecutive patients, 16 patients (29%) had a positive spot sign; eight of 16 with spot sign on first pass and delayed CTA, and eight of 16 with spot sign on delayed CTA only. Median baseline hematoma volume for all patients was 43 mL (interquartile range 9 - 79 mL). Twenty-four of 55 (44%) patients died in hospital. Of the patients with a positive spot sign, 13/16 (81%) died in hospital. The odds ratio (OR) of in-hospital mortality if a spot sign was present on first pass CTA was 12.4 (95%

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

confidence interval (95% CI) 1.40 - 109.07, p = 0.02), whereas OR of in-hospital mortality if a spot sign was present on delayed CTA was 11.0 (95% CI 2.62 - 46.37, p = 0.0007). The sensitivity for predicting mortality increased from 0.29 to 0.52 with the addition of delayed CTA, while specificity marginally decreased from 0.97 to 0.90. The area under the curve (C-statistic) for the spot sign on first-pass CTA was 0.63 in predicting in-hospital mortality, improved to 0.72 with the addition of delayed CTA. In multivariate analysis, baseline ICH volume and the spot sign were predictive of in-hospital mortality; however, the effect of the spot sign was only significant if present on first pass CTA.

Conclusion

Addition of 90 second delayed CTA to the imaging workup of patients with spontaneous ICH captures additional patients with the spot sign and nearly doubles the sensitivity for predicting in-hospital mortality. This improved sensitivity makes the spot sign a more attractive selection tool for targeting patients that may benefit from early surgical or medical intervention. The spot sign is a dynamic entity that appears to change with time, thus supporting the theory that it represents active ongoing hemorrhage.

Presence of CT Angiography Spot Sign Depends on Scan Timing of CT Angiography

Tsukabe, A.･Watanabe, Y.･Tanaka, H.･Nishizawa, M.･Kunitomi, Y.･Yoshiya, K.･Tomiyama, N.
Osaka University Graduate School of Medicine
Suita City, Osaka Prefecture, JAPAN.

Purpose

Morbidity and mortality in spontaneous intracerebral hematoma (ICH) are correlated with hematoma expansion. Recently computed tomography angiography (CTA) spot sign has been reported to be correlated with hematoma expansion and patients' outcome. However, previous studies showed various predictive values, especially in sensitivity for hematoma expansion. One of the reasons for this discrepancy might be the difference of scan timing of CTA. So the purpose of this study is to assess the impact of scan timing on predictive value for hematoma expansion of CTA spot sign from two different arterial phases.

Materials & Methods

Fifty-one consecutive patients with primary ICH who underwent dual-arterial phase CTA within six hours symptom onset, as well as follow-up noncontrast CT (NCCT) before discharge or death between January 2009 and October 2012 were recruited. All CT examinations were performed with 64-detector CT scanner. CT angiography studies were obtained using automatic triggering technique at the level of hyoid with 100 cc contrast media (300 mgI/ml), injection rate of 4 cc/sec and two sequential arterial phases were obtained. Two neuroradiolists reviewed two arterial phases of CTA for spot sign independently. One neuoradiologist reviewed admission and follow-up NCCT for measuring hematoma volume using ABC/2 method in another session. Hematoma expansion was defined as volume increase of hematoma size >20% or >6 ml. Predictive values of CTA spot signs in each phase for hematoma expansion were statistically analyzed respectively.

Results

The number of patients whose hematoma expanded was 15 out of 51 patients. Time difference between two phases of CTA was 11.6 second on average. CT angiography spot sign was depicted in 11/51 patients (21.5%) in early arterial phase, and in 26/51 patients (51.0%) in late arterial phase. Table shows sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and accuracy for hematoma expansion of CTA spot sign in two different arterial phases. Sensitivity and NPV were much better and specificity was worse in late arterial phase than in early arterial phase. Positive predictive value and accuracy were almost not different. In both phases, CTA spot sign was associated with hematoma expansion (in early arterial phase: p = 0.039, in late arterial phase: p < 0.001, Pearson's chi-square test).

	sensitivity	specificity	PPV	NPV	accuracy
early arterial phase	40.0%	86.1%	54.5%	77.5%	72.5%
late arterial phase	93.3%	66.7%	53.8%	96.0%	74.5%

Conclusion

The sensitivity and specificity of CTA spot sign for hematoma expansion showed big difference between two sequential arterial phases. To evaluate the CTA spot sign properly, we must pay more attention to scan timing and scan timing should be coordinated especially when planning the multicenter studies.

KEYWORDS: Intracerebral hemorrhage, CTA, CTA spot sign

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

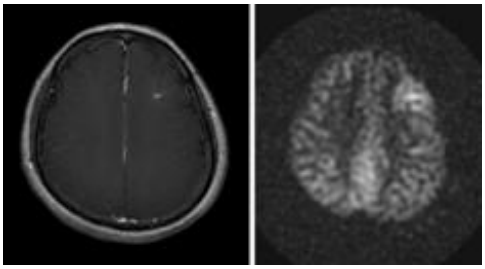
Association of Developmental Venous Anomalies with Perfusion Abnormalities on Arterial Spin Labeling and Bolus Perfusion-Weighted Imaging

Iv, M.·Fischbein, N. J.·Zaharchuk, G.
Stanford University Medical Center
Stanford, CA.

Purpose
While developmental venous anomalies (DVAs) are the most common CNS vascular malformation, how they arise and their relationship to other shunting lesions such as arteriovenous malformations is incompletely understood. Some DVAs are associated with abnormal perfusion parameters on arterial spin label (ASL) and bolus perfusion-weighted imaging (PWI). We investigated the frequency and characteristics of DVA-associated perfusion abnormalities and discuss their potential causes.
Materials & Methods
We reviewed official brain MRI reports to identify all cases of DVAs on studies performed between March 2009 and August 2012 at a single hospital. Developmental venous anomalies' location (infratentorial, supratentorial, deep gray) and perfusion abnormalities on PWI and/or ASL imaging were assessed. 3D FSE pseudocontinous ASL was performed (TR/TE/label time/post-label delay: 4400/10/1500/2000 ms). Perfusion-weighted imaging was acquired with gradient-echo EPI (TR/TE: 1800/40 ms) and 0.1 mmol gadolinium contrast with post-processing using RAPID software. For PWI, conspicuity on separate hemodynamic maps (CBV, CBF, MTT, Tmax) was evaluated. For ASL, abnormality in the DVA itself, adjacent parenchyma, or associated draining vein was recorded.
Results
Six hundred thirty-two cases of DVA were identified. Of these, 121 had both perfusion modalities,15 had PWI alone, and 127 had ASL alone. Most DVAs were located in the supratentorial brain (77%). For cases with ASL imaging, 21/248 (8%) showed abnormalities: abnormal venous signal within a draining vein adjacent to the DVA (2/21, 10%), high signal within the DVA itself (10/21, 47%), and abnormal signal within the parenchyma surrounding the DVA (9/21, 43%) (Figure 1). For PWI, 106/136 (78%) demonstrated abnormalities, typically elevated CBF and CBV and mildly delayed MTT and Tmax that was largely confined to the DVAs themselves



.
Conclusion
This study establishes an estimate of the incidence of perfusion abnormalities associated with DVAs. Perfusion abnormalities in DVAs were common on PWI but uncommon on ASL. Perfusion-weighted imaging findings of mild delay and high CBV are expected; they appear more prominent than the DVA itself likely due to the blooming effects of deoxyhemoglobin with gradient echo EPI acquisition. Developmental venous anomalies with intrinsic ASL signal or signal in draining veins ("venous ASL signal") may represent transitional lesions or small arteriovenous shunts and, as such, may warrant further evaluation with angiography and/or follow-up imaging. A prospective study would be needed to understand more fully the clinical significance of these findings.

Volume versus Hounsfield Unit of Thrombus: Which One Determines Hyperattenuated Artery Sign on 5 mm CT?

Kim, E. Y.[1]·Ahn, S. S.[2]·Shin, N. Y.[2]·Carneiro, F.[1]
[1]The University Hospital, Cincinnati, OH, [2]Severance Hospital, Seoul, KOREA, REPUBLIC OF.

Purpose
A recent study claimed that the hyperattenuated artery sign (HAS) on 5 mm nonenhanced CT reflects RBC content of thrombus. It also has been suggested that thrombi with lower HU on 2.5 mm nonenhanced CT are more resistant to pharmacologic lysis. The outcomes also may be affected by the thrombus volume, which is larger in patients with HAS than in those without. Therefore, determination of both the volume and HU of thrombus is important before thrombolytic treatment. As nonenhanced CT images are still reconstructed with 5 mm thickness for evaluation of acute stroke in many hospitals, it may be advantageous to predict both the HU and volume of thrombus on 5 mm nonenhanced CT. The purpose of this study was to assess the difference of HU and volume between thrombi with HAS and without on 5 mm nonenhanced CT using 1.25 mm helical nonenhanced CT.
Materials & Methods
We enrolled 85 patients who underwent both 5 mm sequential and 1.25 mm helical nonenhanced CT, demonstrating anterior circulation artery occlusion on CTA, within six hours of symptom onset. Hyperattenuated artery sign was determined on 5 mm nonenhanced CT. The patients were classified into ICA (ICA terminus/ICA and others), M1, and M2-only occlusion groups. HUs and volumes of thrombi were measured on 1.25 mm nonenhanced CT and were compared between patients with and without HAS identified on 5 mm nonenhanced CT.
Results
Mean thrombus HUs were not significantly different between 53 (62.4%) patients with and 32 (37.6%) without HAS, stratified by occlusion location [ICA group (n = 25):

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

53.76±2.74 versus 52.54±3.11 (*P*>0.05); M1 group (n = 40): 51.86± .49 versus 50.56±2.11 (*P*>0.05); M2 group (n = 20): 49.52±2.78 versus 50.39±3.15 (*P*>0.05)]. Mean thrombus volume was significantly larger in patients with HAS compared to those without, except for the M2 group [ICA group: 218.40±151.58 mm^3 versus 71.49±47.41 mm^3 (*P* = 0.007); M1 group: 101.28±88.90 versus 61.90± 32.03 (*P* = 0.036); M2 group: 25.73±23.96 versus 25.21±25.84 (*P*>0.05)]. When further analyzed on 1.25 mm nonenhanced CT, no significant difference of thrombus HU between the patients with and without HAS on 5 mm nonenhanced CT was measured. However, in ICA and M1 occlusions, mean thrombus volume was significantly larger in patients with HAS than in those without.

	HAS-ICA (n = 25)			HAS-M1 (n = 40)			HAS-M2 (n = 20)		
	Present (SD)	Absent (SD)	*P*	Present (SD)	Absent (SD)	*P*	Present (SD)	Absent (SD)	*P*
	N = 20	N = 5		N = 23	N = 17		N = 10	N = 10	
HU	53.76 (2.74)	52.54 (3.11)	>0.05	51.86 (2.49)	50.56 (2.11)	>0.05	49.52 (2.78)	50.39 (3.15)	>0.05
Volume	218.40 (151.58)	71.49 (47.41)	0.007	101.28 (88.90)	61.90 (32.03)	0.036	25.73 (23.96)	25.21 (25.84)	>0.05

Conclusion
Therefore, HAS on 5 mm nonenhanced CT is dependent on thrombus volume, and thin-slice CT images are essential to determine thrombus HU.

Venous Attenuation CT Sign of Idiopathic Intracranial Hypertension

Ibrahim, Y.[1]·Mironov, O.[2]·Deif, A.[2]·Mangla, R.[2]
[1]Ain Shams University, Cairo, EGYPT, [2]University of Rochester, Rochester, NY.

Purpose
Idiopathic intracranial hypertension (IIH) is a clinical disorder of unknown etiology manifesting with increased intracranial pressure in the absence identifiable cause. Idiopathic intracranial hypertension may exhibit several nonspecific imaging findings including: an empty sella, posterior globe flattening, tortuosity of the optic nerve, and optic nerve sheath distention. Patients with intracranial hypertension (IH) demonstrate intracranial venous sinus attenuation with a characteristic change in contour and caliber of the distal transverse sinus seen on routine noncontrast sagittal reformatted CT images of the brain. We have termed this the venous attenuation sign (VAS). Our purpose is to introduce the venous attenuation sign as a new imaging marker for IIH.
Materials & Methods
The transverse sinuses on sagittal reformatted noncontrast CT 25 patients with IIH and 24 control patients were assessed independently in a blinded fashion by three readers for the presence of a VAS. A present or absent VAS was determined for each patient by each reader, and a consensus result for each patient was determined by unanimity or majority rule. Correlation of the VAS with CT or MR venographic studies was assessed. The presence of traditional cross-sectional findings in patients with IIH also was evaluated.
Results
Using the VAS, the readers correctly identified 96% (24 of 25) of the IIH patients and 83.3% (20 of 24) of the control patients. There was a high rate of agreement among the readers for the interpretation of the VAS. The overall sensitivity of the VAS for the diagnosis of intracranial hypotension was 96%. Specificity also was 83.3%.

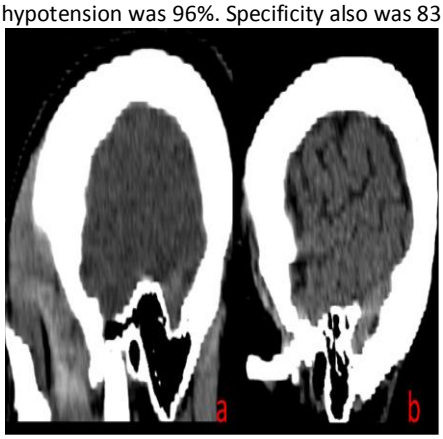

Figure: Noncontrast CT scan sagittal reformatted images at the level of distal transverse sinus. A positive VAS is demonstrated in A in a patient known to have IIH proved by lumbar puncture. Note the sinus is thin. B: shows normal sinus appearance in a control patient with normal CSF pressure on lumbar puncture.
Conclusion
Our study demonstrates the association of several classic imaging findings with IIH and supports the venous attenuation sign as an additional imaging marker which may be incorporated into the evaluation of patients suspected to have this condition.

MR Imaging Findings in Fungal Meningitis: A Comparative Categorization of 31 Cases

Joseph, O.[1]·Aulakh, M.[1]·Keyes, D.[2]·Sherry, R.[2]·Karolyi, D. R.[2]
[1]Virginia Tech Carilion School of Medicine, Roanoke, VA, [2]Carilion Clinic, Roanoke, VA.

Purpose

There is a current multistate outbreak of fungal meningitis related to contaminated preservative-free methylprednisolone acetate steroid injections into the spinal area. The purpose of this study was to (1) categorize the magnetic resonance imaging (MRI) findings related to these infections and (2) determine how many of these patients have positive imaging findings based on the subset of patients that are/were being treated at our institution.

Materials & Methods

This study was approved by the Virginia Tech Carilion institutional review board. Patients with fungal meningitis related to contaminated injections were identified by retrospective search of the electronic medical record through consultation with physicians in the infectious disease department. The PACS was searched for MRI examinations of these patients obtained after their contaminated steroid injections. These examinations were reviewed by two experienced board-certified neuroradiologists. The results were categorized based on anatomical site of imaging and findings.

Results

Thirty-three patients were identified with fungal meningitis, of which 31 received MRI exams. The average age of the patients was 61 years with 15 male and 18 female patients. A total of 125 MRI examinations were reviewed. At presentation, 16 patients received spinal MRI exams, 13 of which had positive findings. The three most common spinal MRI findings at presentation were leptomeningeal enhancement (4 focal/nodular, 6 diffuse), clumped nerve rootlets (5), and thecal sac debris (4). During followup, 23 additional spinal MRI exams were performed, 20 of which had positive findings. The three most common findings were leptomeningeal enhancement (8 focal/nodular, 6 diffuse), clumped nerve rootlets (9), and thecal sac debris (7). At presentation, 21 patients received brain MRI exams, nine of which had positive findings. The three most common findings were focal leptomeningeal enhancement (7), foci of restricted diffusion in the occipital horns of the lateral ventricles (6), and posterior circulation infarcts (4). During followup, 18 patients received brain MRI exams, 14 with positive findings. The three most common findings were focal leptomeningeal enhancement (9), posterior circulation infarcts (6), and foci of restricted diffusion in the occipital horns of the lateral ventricles (5). To date, four patients have had negative brain MRI, while three have had negative spinal MRI.

Summary of MRI Findings

SPINE		
		Number of patients
Leptomeningeal enhancement		15
	Diffuse	8
	Focal/nodular	7
Clumped nerve rootlets		10
Thecal sac debris		9
Loculated collection/Abscess		7
Paraspinal muscle enhancement		5
Foci of restricted diffusion in spine		5
Interspinous enhancement		3
Transverse myelitis		1
BRAIN		
Leptomeningeal enhancement		
		11
	Diffuse	0
Foci of restricted diffusion in ventricles	Focal/nodular	11
Posterior circulation infarcts		7
Hydrocephalus		5
		2

Conclusion

Of the 31 patients reviewed, 28 showed positive MR findings. The most common findings on spine MRI were focal and diffuse leptomeningeal enhancement, clumped nerve rootlets, and thecal sac debris. The most common brain MRI findings were focal leptomeningeal enhancement, foci of restricted diffusion in the occipital horns of the lateral ventricles, and posterior circulation infarcts. The categorization of the 31 patients studied resulted in a reproducible spectrum of MRI findings in the brain and spine that would be amenable to interval follow-up MR imaging to evaluate for progression or regression of disease.

Differentiation of Pyogenic and Fungal Brain Abscesses with Susceptibility-Weighted Imaging

Antulov, R.[1]·Dolić, K.[2]·Fruehwald-Pallamar, J.[3]·Miletić, D.[1]·Thurnher, M. M.[3]
[1]University Hospital Rijeka, Rijeka, CROATIA, [2]University Hospital Split, Split, CROATIA, [3]Medical University of Vienna, Vienna, AUSTRIA.

Purpose
Conventional magnetic resonance imaging (MRI) techniques are insufficient to determine the causative agent of brain abscesses. Recent studies have shown the value of susceptibility-weighted imaging (SWI) in providing additional information in the assessment of pyogenic abscesses. The goals of this study were: (1) to investigate the value of SWI in the differentiation of fungal and pyogenic brain abscesses; and (2) to analyze the effect of field strength (1.5T versus 3T) on SWI in detecting the specific imaging characteristics of brain abscesses.
Materials & Methods
We retrospectively reviewed the MR studies of 10 patients with pyogenic and five patients with fungal brain abscesses. Conventional MR sequences, DWI, and SWI were performed in all patients. Nine patients underwent MRI examinations on a 3T MR scanner, and six patients on a 1.5T MR scanner. We analyzed the size, number, and location of all abscesses. On T2-weighted images (WI), lesions were assessed for the presence of a hypointense rim. The enhancement on postcontrast T1-weighted imaging was defined as ring-like, nodular or absent. On diffusion-weighted imaging (DWI) lesions were categorized as homogeneously hyperintense or heterogeneous. Lesions on SWI images were described as having central low signal intensity or a low signal intensity rim. Lesions with a low signal intensity rim were characterized as: complete or incomplete; and smooth or irregular. On SWI, all lesions were assessed for the presence of a "dual rim sign".
Results
In 10 patients with pyogenic abscesses, 32 lesions were found, whereas in five patients with fungal abscesses, 28 lesions were detected. The mean size of pyogenic abscesses was 22.45 ± 1.87 mm and 12.61 ± 10.35 mm in fungal abscesses. Patients with pyogenic abscesses had a mean of 3.2 lesions per patient, while the group with fungal abscesses had a mean of 5.6 lesions per patient. On T2-weighted imaging, all pyogenic abscesses and 22/28 fungal abscesses showed a hypointense rim surrounding a central hyperintensity. Complete ring-enhancing lesions were present in all pyogenic abscesses and in 6/28 fungal abscesses, 1/28 fungal abscesses showed an incomplete enhancing rim, 2/28 nodular enhancement and 19/28 no enhancement. A homogeneously hyperintensity on DWI was present in 28/32 pyogenic abscesses, but only in 2/28 fungal abscesses. On SWI, 30/32 pyogenic abscesses had a complete low signal intensity rim. Five fungal abscesses showed a complete low signal rim on SWI. A "dual rim sign" was apparent in all pyogenic abscess scanned on a 3T scanner (6/6). Of the lesions scanned on a 1.5T scanner, none of the pyogenic abscesses (0/26) nor any of the fungal abscesses were positive for a "dual rim sign".
Conclusion
Pyogenic brain abscesses show T2-weighted imaging hyperintense center surrounded by hypointense rim along with the "dual rim sign" on SWI. The "dual rim sign" is a specific feature of pyogenic brain abscesses on a 3T scanner. In fungal abscesses "dual rim sign" will not be present; on SWI a prominent peripheral rim or marked central susceptibility effects will be seen.

Septic Thrombosis of Cavernous Sinus

Alazzaz, A. A. A.·Alsaadi, A.·Alattas, F.·Malhotra, R. M.·Hassan, A.
King Fahad Hospital
Madinah Monawara, SAUDI ARABIA.

Purpose
Septic cavernous sinus thrombosis is a rare disease and it was considered a fatal condition before the era of antibiotics with a mortality rate reaching 100%. With the use of antibiotics, the mortality rate was decreased dramatically down to 20-30%. The most important predisposing factors for acute septic cavernous sinus thrombosis are facial infections and complicated tooth extraction that are spreading by means of venous extension to the cavernous sinus along the normal drainage system. Our study reviewed four different patients of different ages (ranging from eight months to 64 years) who have been diagnosed having septic cavernous sinus thrombosis on the bases of clinical presentation, laboratory results and radiologic findings.
Materials & Methods
Imaging modalities are playing an important role in the early detection of cavernous sinus thrombosis. CT venogram is the modality of choice for the assessment of CVST especially with the use of the multiplanar reconstruction images.
Results
The most important findings are the visualization of the cavernous sinus filing defect associated with lateral wall expansion on the coronal images.
Conclusion
MR imaging is very useful in the detection and evaluation of septic cavernous sinus thrombosis and associated complications. MR imaging also is as an alternative choice for CT venogram in patients with renal impairment.

KEYWORDS: 1.5T, 1.5T

Whole Brain In Vivo Quantification of T1ρ of White Matter and Gray Matter in Multiple Sclerosis Patients Compared to Controls: Feasibility Study

Filippi, C. G.[1,2]·Gonyea, J. V.[3]·Hipko, S.[3]·Applebee, A.[3]·Karr, L.[2]·Andrews, T.[4]·Watts, R.[3]
[1]Columbia University, New York, NY, [2]University of Vermont School of Medicine, Burlington, VT, [3]University of Vermont School of Medicine-FAHC, Burlington, VT, [4]Philips Health Care, Cleveland, OH.

Purpose
T1 is an emerging MR imaging modality that is sensitive to anionic exchanges of large bulky molecules (i.e., proteins) determined by the use of spin lock sequence. In demyelinating disease leakage of proteins occurs and has been detected in the brains of MS patients. The purpose of this study is to compare quantitative in vivo measurements of white matter and gray matter at 3T in MS patients compared to age-matched control and to determine if there are any differences in white matter and gray matter and to correlate with disability scores.
Materials & Methods
This is an IRB-approved cross-sectional study of 17 age-matched controls (11 male, 6 female, age 44.5 +/- 10.3) to 14 MS patients (10 female, 4 male, age 44.5 +/- 11.1). Whole-brain T1-weighted images obtained with fluid-attenuated variable flip angle 3D turbo spin-echo technique (spatial resolution 1.8 x 1.8 x 1.8 mm^3). Images acquired with a spin lock frequency of 500HZ and spin lock durations of 0, 20, 40, 60, 80, and 100 ms. Each T1 map was calculated on a single exponential fit to the coregistered T1-weighted images. The T1 map was itself co-registered to T1-weighted 3D TFE anatomical scan. Using unified segmentation (SPM8) of the T1-weighted image, the T1 maps were segmented into white matter (WM) and gray matter (GM) and normalized to MNI space. Major white matter tracts were defined using the JHU atlas while cortical gray matter and juxtacortical white matter were defined by an intersection of the Harvard-Oxford cortical atlas with the subject-specific GM and WM masks respectively. 3D FLAIR (1.2 x 1.2 x 1.2 mm^3) and 3D DIR (1.2 x 1.2 x 1.3 mm^3) were obtained for lesion identification.
Results
T1 values of all the white matter fiber tracts sampled in this cross-section of MS patients as a group (superior and inferior longitudinal fasciculi, inferior frontal occipital fasiculi, anterior thalamic tracts bilaterally, superior longitudinal fasiculi, and forceps minor) were significantly elevated ($P < .002$), particularly the forceps minor and the inferior frontal fasiculus bilaterally. However there was little correlation with EDSS ($r < .042$). In cortical gray matter, group differences between MS patients and controls did not reach statistical significance, but individual areas including insula, paracingulate gyrus, occipital cortex, and Heschl's gyrus showed significantly different T1 values in MS patients ($p < .01$). However, many regions show significant negative correlations with disability scores ($r < -0.6$ to -0.7) in superior, middle, and inferior frontal gyri and precentral and postcentral gyri.
Conclusion
Whole brain quantification of T1 is a feasible, emerging MR modality that detects significant changes in white matter and cortical gyri of MS patients compared to age-matched controls in this initial cross-sectional study.

Decreased Frontal Lobe Gray Matter Perfusion in Cognitively Impaired Secondary Progressive Multiple Sclerosis Patients Detected by the Bookend Technique

Aviv, R.[1]·Francis, P.[1]·Tenenbein, R.[1]·O'Connor, P.[2]·Liying, Z.[1]·Eilaghi, A.[1]·Lee, L.[1]·Carroll, T.[3]·Mouannes-Srour, J.[3]·Feinstein, A.[1]
[1]Sunnybrook Health Sciences Centre, Toronto, ON, CANADA, [2]St. Michael's Hospital, Toronto, ON, CANADA, [3]Northwestern University, Chicago, IL.

Purpose
To quantify differences in MRI-based Bookend-derived cerebral perfusion between cognitively impaired and nonimpaired secondary progressive multiple sclerosis (SPMS) patients.
Materials & Methods
Patients were recruited prospectively and assessed using MRI and a standard cognitive battery, the Minimal Assessment of Cognitive Function In Multiple Sclerosis. Patients exhibiting impairment on ≥2 individual tests were classified as cognitively impaired. Healthy controls were recruited prospectively and assessed using MRI to validate Bookend assumptions. Structural and perfusion scans were coregistered and partitioned into anatomical brain regions and tissue compartments. Clinical and radiologic characteristics were compared between patients with and without impairment to identify potential confounders. A Bonferroni adjusted p-value threshold ($p<0.005$) was used for lobar and sublobar level analyses to correct for multiple comparisons.
Results
Thirty-seven SPMS patients (age: 56 ± 9 years, F/M: 23/14) and 10 age- and gender-matched healthy controls were recruited. Bookend assumptions were found to be valid in MS. Gray matter (GM) and white matter quantitative cerebral blood flow and volume (qCBV) all were reduced globally in impaired patients. After adjusting for potential confounders while examining sublobar level perfusion, only GM qCBV was significantly different between cognitive groups, and this hypoperfusion localized to the bilateral medial superior frontal regions and left inferior, middle, and superior frontal regions ($p<0.005$) of impaired patients compared to nonimpaired patients. GM qCBV accounted for 22.5% of the model variance compared to a

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

model including only confounders (p = 0.0007).

Robust Perfusion Deficits in Cognitively Impaired Secondary Progressive Multiple Sclerosis Patients

Francis, P.[1]·Jakubovic, R.[1]·O'Connor, P.[2]·Zhang, L.[1]·Eilaghi, A.[1]·Lee, L.[1]·Carroll, T.[3]·Mouannes-Srour, J.[3]·Feinstein, A.[1]·Aviv, R.[1]
[1]Sunnybrook Health Sciences Centre, Toronto, ON, CANADA, [2]St. Michael's Hospital, Toronto, ON, CANADA, [3]Northwestern University, Chicago, IL.

Purpose
We investigated the impact of cerebral perfusion and brain and lesion volumetry on cognitive performance in 45 secondary progressive multiple sclerosis (SPMS) patients using magnetic resonance imaging.
Materials & Methods
Cognition was assessed using a standard battery, the Minimal Assessment of Cognitive Function In Multiple Sclerosis. Focal (i.e., voxel-wise) analyses of gray matter (GM), white matter (WM), and WM lesion (WML) volume revealed no significant differences between patients with and without cognitive impairment, although global GM volume was significantly decreased and global WML volume was significantly increased in impaired patients. Cerebral perfusion was analyzed using Statistical Parametric Mapping (SPM) and Partial Least Squares (PLS).
Results
Both SPM and PLS demonstrated significantly reduced quantitative cerebral blood volume (qCBV) in the superior medial frontal cortex of impaired patients. Partial least squares also revealed significantly lower qCBV in the bilateral thalami and caudate nuclei of impaired patients and identified a pattern of significantly attenuated quantitative cerebral blood flow similar to that of qCBV. Performance on the Symbol Digit Modalities Test, which assesses information processing speed, correlated most strongly overall with cerebral perfusion.

Table 5: Correlations between predictive variables and brain scores based on either qCBF or qCBV (PLS Analysis)

Predictive Variable	Correlation Coefficient (qCBF)	Correlation Coefficient (qCBV)
Normalized WML volume	−0.71[a]	−0.72[a]
SDMT	−0.56[a]	−0.52[a]

CVLT-II Total Learning	−0.34[a]	−0.28[a]
CVLT-II Delayed Recall	−0.28[a]	−0.28

Note:—BVMT-R indicates Brief Visuospatial Memory Test-Revised; COWAT, Controlled Word Association Test; CVLT, California Verbal Learning Test; D-KEFS, Delis-Kaplan Executive Function System; JLO, judgment of line orientation; PASAT, Paced Auditory Serial Addition Test; SDMT, Symbol Digit Modalities Test.
[a] 95% confidence interval does not overlap zero.

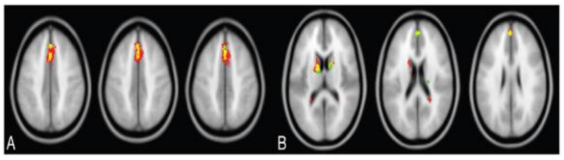

Fig 1. *A*, Decreased qCBV detected by SPM and PLS. Inferior-to-superior arrangement of axial sections with 3 different color overlays. The red overlay represents significantly reduced qCBV in cognitively impaired patients with SPMS identified by SPM alone. The green overlay represents significantly reduced qCBV in the same patients identified by PLS alone. The yellow overlay represents the overlap of the SPM and PLS results and thus significantly reduced qCBV found by both analytic techniques. *B*, Decreased qCBV and qCBF detected by PLS. Inferior-to-superior arrangement of axial sections with 3 different color overlays. The red overlay represents significantly reduced qCBV in cognitively impaired patients with SPMS identified by PLS. The green overlay represents significantly reduced qCBF in the same patients identified by PLS. The yellow overlay represents the overlap of the qCBV and qCBF hypoperfusion.

Conclusion
These results suggest that cognitively impaired SPMS patients exhibit robust perfusion deficits in cortical and subcortical GM and impaired processing speed.

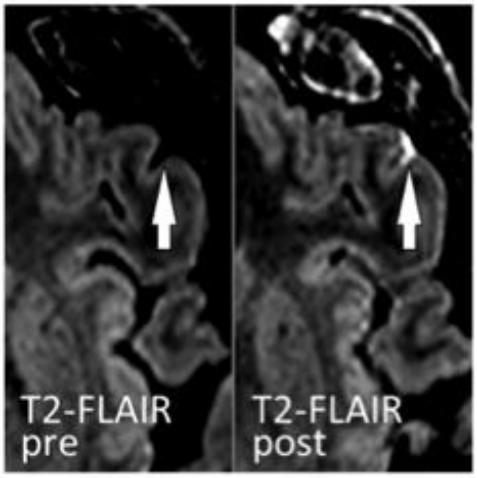
Leptomeningeal Contrast Enhancement in Multiple Sclerosis

Rao, A. T.[1]·Butman, J. A.[2]·Cortese, I. C. M.[2]·Reich, D. S.[2]
[1]George Washington University, Washington, DC, [2]National Institutes of Health, Bethesda, MD.

Purpose
To determine the incidence and characteristics of leptomeningeal inflammation in multiple sclerosis (MS)

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

using postcontrast T2-FLAIR imaging.
Materials & Methods
MR imaging scans from natural history protocols in the National Institute of Neurological Disorders and Stroke, obtained between November 2010 and December 2012, were reviewed retrospectively. 3D T2-weighted FLAIR scans were obtained on 3T systems, using phased-array head coils, 5-20 m following intravenous injection of single-dose gadolinium DTPA or gadobutrol. Noncontrast T2-FLAIR scans were available in a subset of patients. Two neuroradiologists (a fellow and an attending with eight years of experience in MS imaging), masked to the clinical diagnosis and findings, evaluated the T2-FLAIR data for presence of leptomeningeal enhancement. If present, enhancement was characterized by location, size, focal versus multifocal versus diffuse, and stability (if multiple datasets were available).
Results
The figure shows a typical example of focal leptomeningeal enhancement in primary progressive MS. Of the 271 participants, 231 (85%) had analyzable postcontrast 3D T2-FLAIR data and adequate clinical characterization. Assigned diagnoses and incidence of leptomeningeal enhancement were: MS (n = 27/167; 16%); other inflammatory neurologic disease (e.g., HTLV-associated myelopathy) (1/20; 4%); noninflammatory neurologic disease (1/26; 5%); no neurologic disease (n = 1/18; 6%). Leptomeningeal enhancement was more common in MS cases compared to all non-MS cases (p = 0.027, Fisher's exact test) and to cases of other neurologic diseases (p = 0.05). No difference was noted between relapsing (12/87; 14%) and progressive (13/75; 17%) forms of MS (p = 0.66). In virtually all cases, enhancement was focal or multifocal rather than diffuse. It was typically found adjacent to <5 cortical gyri and was not associated with nearby subcortical or juxtacortical white matter lesions. In 59% (12/29) of cases with repeated scans over the two-year period, the enhancement pattern was stable over time, whereas in the other 41% (11/57), the pattern fluctuated.



Conclusion
Although relatively infrequent, leptomeningeal enhancement, which may signify the presence of leptomeningeal inflammation, is a robust finding in MS. Leptomeningeal inflammation, which is sometimes organized into lymphoid follicle-like structures, is a pathologically described finding in all stages of MS that appears to be important for the development of cortical, especially subpial, demyelinating lesions. Further characterization of this imaging finding, with respect to clinical disability and other disease characteristics, will shed light on its significance for assessment of disease.

Detection of the Multiple Sclerosis Lesions with Quantitative Susceptibility Mapping: Preliminary Results

Kakeda, S.[1]·Ueda, I.[1]·Watanabe, K.[1]·Moriya, J.[1]·Murakami, Y.[1]·Ide, S.[1]·Ogasawara, A.[1]·Sato, T.[1]·Okada, K.[1]·Tsuji, S.[1]·Liu, T.[2]·Wang, Y.[2]·Korogi, Y.[1]
[1]University of Occupational and Environmental Health School of Medicine, Kitakyushu-shi, JAPAN, [2]Weill Cornell Medical College, Ithaca, NY.

Purpose
Quantitative susceptibility mapping (QSM) is a novel technique which allows determining the bulk magnetic susceptibility distribution of tissue in vivo from gradient-echo magnetic resonance phase images. Our purpose is to compare the detection of multiple sclerosis (MS) lesions with QSM, T2WI, and 2D FLAIR in patients with MS.
Materials & Methods
Conventional MR and QSM imaging examinations were performed in 18 patients (four male, 14 female) with MS. Quantitative susceptibility mapping was performed for various ranges of echo time by using both the magnitude and phase components in the morphology-enabled dipole inversion method. The MS lesions were categorized into five anatomical regions: intracortical, mixed white matter-gray matter, juxtacortical, periventricular white matter, and deep white matter. The numbers of lesions per category were compared between QSM images and conventional MRI (T2WI and FLAIR images).
Results
In 110 (75%) of 146 MS lesions, the area of abnormal signal intensity detected with QSM images was larger than the size of the corresponding lesion at qualitative visual evaluation on coregistered T2WI and FLAIR images. The total number of the detected lesions was 146 for QSM, 182 for T2WI and 178 for FLAIR. The mean numbers of the lesions per category is shown in the table. Quantitative susceptibility mapping was more sensitive than T2WI and FLAIR in detecting the cortical lesions (mean numbers of lesions per patients: 0.28 versus 0.06 and 0.00 for the intracortical lesion, and 0.61 versus 0.11 and 0.06 for the mixed white matter-gray matter lesion, respectively). However, QSM was less sensitive than T2WI and FLAIR

images for the detection of the white matter lesions.

Table Mean Numbers of Lesions per Patients with QSM, T2WI, and FLAIR

	QSM	T2WI	FLAIR
Intracortical	0.28	0.06	0
Mixed WM-GM	0.61	0.11	0.06
Juxtacortical	0.83	1.39	1.33
Periventricular WM	2.44	2.83	2.83
Deep WM	3.94	5.72	5.67
Total	8.1	10.11	9.89

Conclusion
Our preliminary results suggest that MR imaging with QSM may increase the sensitivity in cortical lesion detection, although its sensitivity to white matter lesion detection may be limited.

Diffusional Kurtosis Imaging of Normal-Appearing White Matter in Multiple Sclerosis

Spampinato, M.·Pravata, E.·Hatch, N.·Jensen, J.·Helpern, J.·Tabesh, A.
Medical University of South Carolina
Charleston, SC.

Purpose
Our aim was to assess the correlation between measures of brain tissue microstructure in the normal-appearing white matter (NAWM) derived from diffusional kurtosis imaging (DKI) and neurologic disability in multiple sclerosis (MS).
Materials & Methods
Eighteen patients with MS (16 relapsing remitting, two secondary progressive MS, median age + / - SD = 39 years + / - 12 years) underwent brain MRI on a 1.5T scanner. Approval for this retrospective study was obtained from the Institutional Review Board. The MRI protocol included axial FLAIR, 3D T1 MPRAGE, and diffusion-weighted imaging using a twice-refocused echo-planar sequence with three diffusion weightings (b = 0, 1000 and 2000 s/mm2) along 30 diffusion encoding directions (TR = 5500 ms, TE = 100 ms, FOV = 222 ×222 mm2, matrix size = 74 × 74, parallel imaging factor of 2, slice thickness = 3 mm, and 40 axial slices). Diffusional kurtosis imaging allows for estimation of the conventional DTI parametric maps of mean diffusivity (MD), axial diffusivity, radial diffusivity, and fractional anisotropy (FA), as well as the additional diffusional kurtosis metrics of mean kurtosis (MK), axial kurtosis, and radial kurtosis. These maps were obtained using in-house software. Fractional anistotropy (FA) maps were spatially normalized to the standard MNI space using the FMRIB Software Library (FSL) and the resulting transformation was applied to normalize the other maps. The white matter skeleton for each map then was obtained using FSL's Tract-Based Spatial Statistics. Finally, we obtained average values for all diffusion metrics in several regions of the skeleton. The regions consisted of the entire white matter skeleton, corpus callosum (genu, body, and splenium), bilateral corticospinal tracts (CST), and bilateral posterior thalamic radiations (including optic radiations). The white matter regions of interest were obtained from the Johns Hopkins University atlas after masking out T2 hyperintense areas for individual patients. Spearman's rank correlation coefficient was used for assessing the association between the diffusion metrics and expanded disability status scale (EDSS). Results were considered significant when $p < 0.05$.
Results
The median EDSS was 3.25 (range = 1 - 9). Statistically significant correlations were found between the EDSS and CST MD ($r = 0.535$, $p = 0.02$), FA ($r = - 0.488$, $p = 0.04$), radial diffusivity ($r = 0.519$, $p = 0.03$), MK ($r = - 0.555$, $p = 0.02$), and radial kurtosis ($r = - 0.577$, $p = 0.01$). The correlations between EDSS and diffusion metrics in the NAWM skeleton, corpus callosum, and posterior thalamic radiations were not statistically significant.
Conclusion
Diffusional kurtosis imaging can provide information about brain tissue microstructure complementary to that of DTI. Quantitative diffusion metrics are correlated with neurologic disability in MS and can be helpful in the assessment of disease severity, with the potential of guiding patient management.

Accumulation of Iron in Multiple Sclerosis in Normal-Appearing Brain Tissue and Lesions

Raz, E.[1]·Branson, B.[1]·Jensen, J.[2]·Fleyscher, L.[3]·Herbert, J.[1]·Grossman, R. I.[1]·Inglese, M.[3]
[1]New York University, New York, NY, [2]Medical University of South Carolina, Charleston, SC, [3]Mount Sinai Hospital, New York, NY.

Purpose
Accumulation of iron can lead to oxidative damage in the brain secondary to the formation of oxygen free radicals and its mesuration may provide insight into progression and severity of multiple sclerosis (MS). Significant differences in iron content between patients and controls using magnetic field correlation (MFC), were found. It has been posited that a portion of the signal may in fact originate from macroscopic interfaces in tissue density. The purpose of the present study is to remove such macroscopic irregularities, and draw a connection between the iron content of lesions and normal-appearing white matter.
Materials & Methods
Twenty-three patients (mean age = 39 years, range 21-61

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

years, M=7, F=16, mean disease duration = three years, range 0-13 years) with definite, clinically diagnosed relapsing and remitting MS, and 14 matched controls (mean age = 36 years, range 19-60 years, M/F=5/9), consented to inclusion in our study. Mean EDSS was 1.7 (range 0-4.5). The MFC and Micro estimation have been described previously. An echo-planar spin-echo imaging sequence was used to procure images which contained 48 axial, 1.7 mm thick contiguous sections. The parameters were: bandwidth = 1345 Hz, TR = 3420 ms, TE = 40 ms, matrix = 128*128, FOV = 220*220 mm2, voxel size = 1.719*1.719 mm2. The images were postprocessed for movement correction using Statistical Parametric Mapping (SPM), and macro and micro MFC maps were generated. Multiple ROI were analyzed in both the white and grqy matter including the centrum semiovale, splenium of the corpus callosum, thalamus, putamen, caudate, globus pallidus, red nucleus and hippocampus in all subjects. White matter ROIs were drawn in normal-appearing WM on T2. All white matter lesions greater than 6 mm were identified in the patients and corresponding MFC values were assessed.

Results

When patients to controls were compared in terms of macro MFC, correcting for age and gender, the centrum semiovale [122.89 (29.03) in controls; 141.8 (36.75) in patients; p = 0.05], globus pallidus [835.17 (167.31) in controls; 1009.38 (249.82)in patients; p = 0.006], putamen [338.42 (92.98) in controls 402.42 (102.86) in patients; p = 0.02] were significantly different. When patients to controls were compared in terms of micro MFC, correcting for age and gender, the centrum semiovale [111.66 (29.93) in controls; 130.92 (36.4) in patients; p = 0.05], globus pallidus [762.27 (167.21) in controls; 925.35 (230.23) in patients; p = 0.008] were significantly different. In patients the macro and micro MFC of lesions [respectively 121.44 (67.18) and 105.97 (65.65)] was significant lower than the values for GM.

Conclusion

Quantitative measurement of the macro and micro MFC, hence removing sources of macroscopic irregularities of the field, demonstrates increased MFC values in the white and gray matter in patients with MS, suggesting accumulation of iron.

Normal-Appearing White Matter Permeability Distinguishes Poor Cognitive Performance in Processing Speed and Working Memory

Eilaghi, A.[1]·Kassner, A.[2]·Sitartchouk, I.[2]·Francis, P. L.[1]·Jakubovic, R.[1]·Feinstein, A.[1]·O'Connor, P. W.[3]·Carroll, T. J.[4]·Mouannes-Srour, J.[4]·Aviv, R. I.[1]

[1]Sunnybrook Health Sciences Centre, Toronto, ON, CANADA, [2]University of Toronto, Toronto, ON, CANADA, [3]St. Michael's Hospital, Toronto, ON, CANADA, [4]Northwestern University, Evanston, IL.

Purpose

Localized blood-brain barrier (BBB) break-down in multiple sclerosis can be quantified using relative recirculation (rR). We hypothesize that severity of BBB breakdown in normal appearing white matter (NAWM) differs between cognitive impaired and unimpaired secondary progressive multiple sclerosis (SPMS) patients particularly in the functional areas of attention and processing speed.

Materials & Methods

The study was research ethics board approved. Cognitive performance was classified as impaired or unimpaired based on the Minimal Assessment of Cognitive Function In MS (MACFIMS) test components. Demographic data, brain parenchymal and white matter lesion fractions, WML and NAWM regions of interest (ROIs) and weighted mean NAWM rR ROIs were compared in cognitively dichotomized groups. Univariate comparison and multivariate logistic regression were used to investigate the association between cognitive test results and NAWM rR ROIs.

Results

The mean (SD) age of 36 SPMS patients studied was 55.9 ± 9.3 years; 13/36 (36%) patients were male. A highly significant difference between NAWM rR and WML rR was present for all patients ($p < 0.001$). Normal appearing white matter rR in impaired patients was significantly lower than unimpaired subjects for SDMT ($p = 0.007$), COWAT ($p = 0.008$), or PASAT ($p = 0.024$) shown in Table 1. EDSS score demonstrated an inverse correlation with NAWM rR (correlation coefficient = -0.319, $p = 0.075$). After adjusting for confounders, significant NAWM rR reduction persisted in impaired patients for SDMT ($p = 0.023$) and PASAT ($p = 0.047$) but not COWAT ($p=0.13$) as presented in Table 2.

Table 1: Univariate comparison of the nonimpaired (NI) and impaired (I) groups. Parameters showing $p<0.3$ in the univariate analysis were included in the multivariate logistic model.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Grey Matter Fraction	41.4 ±1.5	41 ±2.9	0.71	40.8 ±2.6	42.5 ±2.2	0.169	41.8 ±2.2	41 ±3.0	0.971

Table 2: Outcomes of multivariate logistic regression analyses for NAWM rR after controlling for potential confounders. NAWM rR continues to be significantly lower in the impaired group for both SDMT and PASAT tests.

Cognitive Test	Odds Ratio	p value
SDMT	0.177 (5-95%CI; 0.040-0.785)	**0.023**
COWAT	0.662 (5-95%CI;0.002-2.226)	0.130
PASAT1.6	0.053 (5-95%CI; 0.003- 0.961)	**0.047**

Conclusion

Significant NAWM rR reduction exists in cognitively impaired SPMS patients localizing to the domains of processing speed and working memory. Further validation and longitudinal studies are required to study the association between rR, cognition, disease progression and treatment response; however rR could be a useful surrogate for future pharmacologic and rehabilitative strategies targeting cognition.

Diffusion Tensor Imaging Tractography for Peripheral Nerve Lesions: Feasibility and Clinical Utility

Narvid, J.·Kliot, M.·Chin, C.
University of California San Francisco
San Francisco, CA.

Purpose

Imaging methods that can visualize nerve fascicles in peripheral nerves are needed. Such techniques would be extremely useful in helping to distinguish axonontmetic nerve injuries which can recover through axonal regeneration from neurotmetic injuries which cannot either due to physical discontinuity in the nerve or intraneural fibrosis which impedes nerve fibers from regenerating. It would also be useful to visualize the spatial relationship of nerve fibers vis-a-vis tumors arising from nerves (nerve sheath tumors) to help determine the surgical resectablility of such masses when clinically appropriate. Due to the geometric distortion that arises from the low phase-encoding bandwidth in single-shot echo-planar imaging (ssEPI), local susceptibility gradients due to tissue interfaces often degrades image quality. In particular, achieving good image quality and spatial resolution with ssEPI diffusion in the spine always has been technically challenging since with conventional 1D slice selective excitation, a large field-of-view (~32-36 cm) has to be prescribed to avoid aliasing artifacts. Encoding such a large FOV with high resolution requires a very long echo-train length, which exacerbates off-resonance artifacts. 2D partially selective RF can be used to limit FOV in the phase-encoding direction and avoid aliasing. We applied rFOV DTI to visualize nerve fibers in the clinical setting of traumatic nerve injuries and peripheral nerve tumors and correlated pre-operative findings with intra-operative electrophysiology.

Materials & Methods

Diffusion tensor imaging datasets were acquired on a 3T whole body MR750 scanner (GE Healthcare, Waukesha) utilizing the reduced field of view (rFOV) diffusion method which employs a 2D spatially selective RF excitation pulse in the ssEPI sequence with 10 direction-encoded images that uses a 2D echo-planar RF pulse to excite and read out a rectangular-shaped field of view. Fourteen patients were evaluated due to either traumatic nerve injury or suspected peripheral nerve sheath tumor. Slices were prescribed sagittally to cover the brachial-plexus. Imaging parameters common to all patients were: TR=3600 ms, TE=52 ms, acquisition matrix=128x64, FOV=24x12 cm, slice thickness=3 mm, 16 slices, b=500 s/mm2, 10 diffusion encoding directions, 10 averages, scan time=nine minutes 30 seconds. Tractography analysis was performed on the DTI images using Brainwave software.

Results

Reduced field of view DTI was used successfully to visualize the displacement and distortion of fascicles

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

adjacent to nerve sheath tumors. In four cases, these findings were correlated with intraoperative visual inspection and electrophysiologic testing. All such cases confirmed the location and relation of nerve fibers to tumor, confirming the utility of this technique in pre-operative planning. In eight cases, findings of fascicular discontinuity (the presence and absence of nerve fibers in damaged peripheral nerve) were correlated with EMG findings of nerve injury. All such confirmed the location of injury.
Conclusion
Peripheral nerve tractography using MR DTI can be used to visualize the relationship of nerve fascicles to masses such as nerve sheath tumors which can be helpful in the planning of surgical resection. It also provides useful information following traumatic nerve injuries to help determine the extent of axonal disruption.

Application of 3T Diffusion Tensor Imaging in Sciatic Neuropathy: Comparison to Normative Values

Thawait, G. K.[1]·Farahani, S. J.[1]·Andreisek, G.[2]·Thawait, S. K.[1]·Belzberg, A. J.[1]·Chhabra, A.[1]
[1]Johns Hopkins University School of Medicine, Baltimore, MD, [2]University of Zurich, Zurich, SWITZERLAND.

Purpose
To determine normative diffusion values of the sciatic nerve and compare these values with those in patients with sciatic neuropathy.
Materials & Methods
In this IRB approved study, 37 healthy volunteers with no sciatic neuropathy (19 men and 18 women) and 11 patients with EMG/surgery-proven unilateral sciatic neuropathy (five men and six women) were evaluated. In all the subjects, DTI was performed by utilizing 3T MR and single-shot echo-planar imaging sequence (TR/TE, 11300/ 77ms, b-values-0, 800 and 1000s/mm2; 12 encoding directions). Two readers independently determined fractional anisotropy (FA) and apparent diffusion coefficient (ADC) values of each patient's sciatic nerve with regions of interest (at least 3 mm^2 area) at two locations: at the level of greater sciatic notch, anterior to the piriformis muscle (point A); and outside the pelvis at the level of the ischial spine, behind posterior column of the acetabulum (point B). Paired and unpaired t-test was performed to determine any significant difference in FA and ADC between different sides and locations in the controls and also between the cases and controls. The level of agreement between the readers was determined utilizing inter-class correlation coefficient.
Results
There was 89% and 84% agreement for FA and ADC between two readers. The mean FA and ADC values at point A and point B for right sciatic nerve were, 0.46±0.11 and 1111.973 x $10^{-3}s/mm^2$, and 0.44±0.08 and 1172.17±207.9 x $10^{-3}s/mm^2$ for controls. While the mean FA and ADC for left sciatic nerve in the healthy volunteer were 0.43 ± 0.086 and 1147.33 ± 201.86 x $10^{-3}s/mm^2$ at point A and 0.43 ± 0.082 and 1202.41 ± 247.2 x $10^{-3}s/mm^2$ at point B. These values were 0.37 and 4763.763 x $10^{-3}s/mm^2$ for FA and ADC of the involved side of the cases and 0.31 and 1335.143 x $10^{-3}s/mm^2$ for noninvolved side, respectively. There was a significant difference between controls and patients with sciatic neuropathy (P <0 .005 for both FA and ADC for all observations). Fractional anisotropy and ADC values did not differ between men and women or between points A and B in the healthy group. According to the receiver operating characteristic (ROC) curve, the optimal cutoff value of mean FA value for predicting sciatic neuropathy was 0.34, with sensitivity and specificity of 100% and 69.3% (area under the ROC curve, 0.877; 95% CI, 0.728-1.000). The cutoff point for mean ADC value was 1254.675 x $10^{-3}s/mm^2$, with sensitivity of 91% and specificity of 88% (area under ROC curve, 0.9239; 95% CI, 0.85-0.99).
Conclusion
Decreased FA and increased ADC values have been reported to be important parameters for the diagnosis of carpal tunnel syndrome and cervical radiculopathy in previous studies. Similar trends in these quantitative parameters were observed in this study. Diffusion tensor imaging could be used in the diagnosis of sciatic neuropathies. Alterations in mean FA and ADC values can be used to identify cases with sciatic neuropathy and thus, DTI provides a good noninvasive diagnostic tool in sciatica.

Idiopathic Spinal Cord Herniation: An Imaging Diagnosis but with a Significant Delay

Carter, B.·Jain, R.·Griffith, B.·Newman, D.·Abdulhak, M.
Henry Ford Health System
Detroit, MI.

Purpose
Idiopathic spinal cord herniation (ISCH) is an under-recognized entity that often is missed on imaging studies and/or ignored by treating physicians leading to a delay in diagnosis. This leads to unnecessary imaging studies, nonimaging diagnostic studies such as EMGs, unnecessary surgeries, and continual office visits. The purpose of this study was to assess the length of delayed diagnosis of ISCH from a patient's original presentation and the associated costs of this entity going unrecognized.
Materials & Methods
A retrospective search was performed using Illuminate software from 6/20/2005 to 12/3/2012 yielding 37 patients that fit the clinical and imaging criteria typically seen in ISCH. Data including patient's age, sex, presenting

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

clinical symptoms, number and type of imaging studies performed as part of the workup, EMGs, pain procedures, surgeries, and most importantly, the period of time between the patient's original presentation and receiving the diagnosis of ISCH on imaging were collected.
Results
The most frequent complaints were neck/upper back pain in 70% (26/37), upper/lower extremity numbness/paresthesias/weakness in 49% (18/37), hyperreflexia in 22% (8/37), and burning chest pain in 22% (8/37). The average delay in diagnosis from presentation to imaging was 33 months (0-196 months). Three of these patients underwent dural repair which resulted in improvement of symptoms in each case. There was no change in symptoms in 73% (27/37), worsening of symptoms in 14% (5/37), and improvement in 14% (5/37) when comparing the patient's original presentation and most current office note. There were seven spine surgeries other than dural repair performed in six patients. The only patient to show improvement with surgery other than dural repair received a syrinx decompression and posterior thoracic laminectomy. There was an average of 14 outpatient office visits (1-67) and 1.5 (0-13) inpatient days per patient in which the chief complaint or admission was related to ISCH symptoms. There was also an average of 3.5 MRs (0-23), 1 (0-7) CT/CT myelography, and 1 EMG (0-7) per patient presenting with ISCH.
Conclusion
The symptoms of neck/upper back pain and numbness/paresthesias/pain in the extremities were the most common presentations seen with ISCH and MR was the most common imaging method by which it is diagnosed. There was still a delay of 33 months until this diagnosis was made, leading to repeat office visits and unnecessary surgeries. There was no change or worsening of symptoms in 86% of the patients, some of which had spine surgeries other than dural repair which did not improve the patient's condition. All of the patients that did have repair of the dural rent had improvement in their symptoms. An increase in awareness of ISCH on imaging and as a treatable disease with real symptoms would decrease both the delay in diagnosis/treatment and associated costs. Not only would this lead to improvement in patient care, but reduce national health care expenditures which have skyrocketed in the past decade.

Effect of Oscillatory Cerebospinal Fluid Flow on Fluid Movement in the Spinal Cord

Støverud, K. H.[1]·Langtangen, H.[1]·Haughton, V.[2]·Mardal, K.[1]
[1]Simula Research Laboratory, Lysaker, NORWAY,
[2]University of Wisconsin, Madison, WI.

Purpose
Cyclic CSF flow is driven by oscillations in the fluid pressure. The intracranial pressure is closely related to the cardiac cycle and generates pressure waves that travel through the spinal canal. The aim of this study was to investigate whether these pressure waves generate flow in open segments of the central canal assuming a poro-elastic spinal cord.
Materials & Methods
High-resolution diffusion tensor images (DTI) from a sheep cadaveric spinal cord were segmented to create a geometric model. In the segmentation procedure we distinguished between gray and white matter and the central canal. The geometric model was converted into a tetrahedral computational mesh consisting of interconnected nodes. We used continuous pressure measurements from the cranial and lumbal region in a Chiari patient to calculate the wave velocity of the CSF pressure wave. The pressure measurements at the two locations were sampled simultaneously at 200 Hz as described by P. K. Eide. Along the walls of the model we applied a prescribed normal stress and pore pressure calculated from the pressure measurements and representing one cardiac cycle. An open segment of the central canal was modeled by assigning a higher permeability to the central canal than to the surrounding tissue. With the FEniCS toolkit we calculated pressure, displacement and interstitial fluid velocity, assuming the spinal cord to behave as a linear poro-elastic medium.
Results
The antero-posterior and transverse diameter of the model was 0.9 cm and 1.3 cm respectively and the model was 1.7 cm in length. On its surface the central medial fissure was evident. The central canal was between 0.2 and 0.3 mm in diameter. The pressure wave applied along the walls had a velocity of 2 m/s and amplitude of 6 mmHg. Pressure gradients occurred since the pressure wave arrived at different times along the geometric model. In the first part of the cardiac cycle, the pressure increased in the rostral end of the model then caudally. In the second part, the pressure decreased in the rostral end and then caudally. The pressure wave spread inwards from the subarachnoid space towards the central canal. The elastic properties of the spinal cord caused displacements up to 70 µm. In regions of high pressure the tissue is compressed and in region of low pressure the tissue is expanded. Interstitial fluid moved in the direction of lower pressure with velocities ranging from 0.1 to 0.5 µm/s. In the central canal the fluid velocities were several orders of magnitude higher reaching 100 to 200 µm/s.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Conclusion
Pressure waves in the spinal subarachnoid space generate fluid flow in open segments of the central canal. The possible role of this fluid movement in the genesis of syrinx requires more study.

MR Myelography for Identification of Spinal Cerebrospinal Fluid Leak in Spontaneous Intracranial Hypotension

Chazen, J.·Dillon, W. P.
University of California San Francisco
San Francisco, CA.

Purpose
Spontaneous intracranial hypotension (SIH) is a debilitating disease characterized by low CSF pressure and symptoms of orthostatic headaches. Characteristic imaging findings have been described including diffuse pachymeningeal enhancement and sagging of the brainstem and cerebellar tonsils. Treatment requires precise localization of the site of CSF leak, commonly performed using CT, MR, or nuclear medicine myelography. This study aims to evaluate the benefits of MR myelography using intrathecal gadolinium in the localization of CSF leak.
Materials & Methods
A retrospective review of MR myelogram studies performed over the past five years at our institution. All patients had characteristic clinical and imaging findings for SIH including postural headaches and diffuse pachymeningeal enhancement. MR myelography was performed immediately following CT myelography in all patients using a mixture of 10 mL Omnipaque (iohexol 240 mg/mL) and 0.5 mL Magnevist (gadopentetate dimeglumine 469 mg/mL), instilled intrathecally by lumbar puncture. MR imaging was performed using axial, sagittal, and coronal T1-weighted sequences with fat saturation. Concurrent CT myelography also was performed.
Results
A total of 15 patients were identified from 2007-2012 that met inclusion criteria. All patients had SIH by clinical and imaging criteria and CT myelography performed with subsequent MR myelography. In nine of 15 patients (60%), no CSF leak was found on either CT or MR myelogram. In two of 15 patients (13%), a CSF leak was demonstrated on both CT and MR myelogram and in six of 15 patients (40%) a CSF leak was seen on MR myelogram.

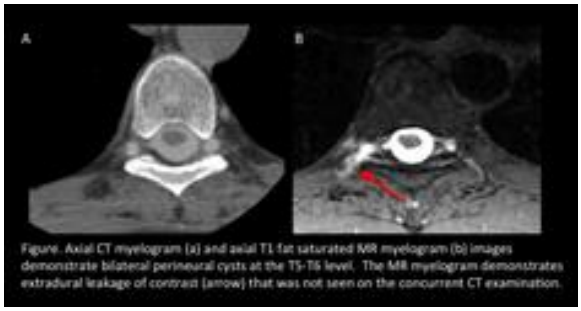

Figure. Axial CT myelogram (a) and axial T1 fat saturated MR myelogram (b) images demonstrate bilateral perineural cysts at the T5-T6 level. The MR myelogram demonstrates extradural leakage of contrast (arrow) that was not seen on the concurrent CT examination.

Conclusion
Our data suggests a significant benefit of MR myelography when investigating CSF leaks with four of 15 patients (27%) showing evidence of CSF leak only on the MR myelogram portion of the examination. These leaks often were subtle and benefitted from the high conspicuity and soft tissue contrast of fat-saturated T1 imaging. Though intrathecal administration remains an FDA off-label use of gadolinium, all patients in this cohort tolerated the medication well without complication. A possible confounding factor is the delayed nature of MR myelography in this cohort, which was performed following the CT portion of the examination, allowing additional time for contrast to diffuse into small leaks. Additionally, MR myelography is most useful in patients without obvious high flow leaks which may be better evaluated by dynamic CT or fluoroscopic myelography. Our data suggest MR myelography with intrathecal gadolinium is a well tolerated examination with significant benefit in the diagnosis of CSF leak.

MR Imaging Identification of Anatomical Landmarks to Determine the Correct Thoracic Vertebral Level

Connor, S.·Lung, P.
Kings College Hospital
London, UNITED KINGDOM.

Purpose
Accurate definition of the correct thoracic vertebral level is important for diagnosis and subsequent therapeutic management. MR imaging studies of the thoracic spine occasionally are presented without a cervicothoracic vertebral level "counting scan" in which case localization of vertebral segments may be problematic. This scenario is particularly frequent in the setting of low field or open MRI scanners. Our aim was to describe the anatomical locations of identifiable adjacent bony and soft tissue structures on focused sagittal thoracic spine sequences, and assess their accuracy in estimating the correct thoracic vertebral level.
Materials & Methods
One hundred focused thoracic sagittal T1-weighted and

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

T2-weighted MRI studies were analyzed retrospectively by two experienced radiologists. The bone and soft tissue landmarks (including the superior most rib, the aortic arch, the pulmonary trunk, the carina, the sternal notch and the morphology of the superior thoracic vertebrae and spinous processes) were extrapolated to the adjacent vertebral subsegment. The true thoracic vertebral level subsequently was determined and recorded by correlating with a sagittal cervicothoracic "counting scan". Interobserver reproducibility and accuracy of each anatomical landmark in determining a particular thoracic vertebral level was analyzed.

Results

The first rib was identified correctly as articulating with the T1 vertebral body in 98% and 97% of cases. The first long spinous process was identified as C7 in 62% and 80% of studies. The remaining anatomical landmarks produced results where the range was greater than four vertebral levels, localizing to a specific thoracic segment in only 26-71% of cases.

Conclusion

The superior most rib articulated with the T1 vertebral body and can be used as a reliable landmark on focused thoracic spine sagittal sequences for accurately localizing the thoracic vertebral levels in patients without a cervicothoracic "counting scan". Other anatomical landmarks produced inconsistent results and should not be used to define thoracic vertebral levels.

Longitudinally Extensive Spinal Cord Lesions in African American Patients with Neuromyelitis Optica and Neuromyelitis Optica Spectrum Disorder

Mitchell, C. H.·Levy, M.·Pekcevik, Y.·Izbudak, I.
Johns Hopkins Hospital
Baltimore, MD.

Purpose

Neuromyelitis Optica (NMO) is a neuroinflammatory disease causing optic neuritis and transverse myelitis. The autoantibody to aquaporin-4 (NMO-IgG) is 91% specific and 73% sensitive for NMO. Previous examinations on Caucasian and Asian populations found distinctive longitudinally extensive spinal cord lesions (LESCL) in NMO patients by MRI. In Asian populations, there was an association between NMO-IgG positivity and LESCL. In the African American population, this relationship has not been established. The aim of this study is to describe the relationship of NMO-IgG serostatus with LESCL in African Americans.

Materials & Methods

Clinical data and MRIs of 73 consecutive patients with NMO or NMO spectrum disorder diagnosis were reviewed retrospectively with our institutional review boards approval. Longitudinally extensive spinal cord lesions were defined according to the criteria of Misu to involve three or more vertebral body segments on sagittal images with T2 hyperintensity, involvement of the central gray matter on axial images, T1 iso to hypointensity, and lack of contrast enhancement. Lack of contrast enhancement and T1 hypointensity were used to include NMO cases both in the acute and chronic phase.

Results

Of the 73 patients, 81% (59/73) were NMO-IgG positive, 86% (63/73) were female, and 60% (44/73) African American. Of the African American patients, 89% (39/44) had positive NMO-IgG, and 80% (20/25) of NMO-IgG positive African American patients had LESCL. Extension inferiorly from the medulla was seen in 20% (5/25) of the antibody positive African American LESCL patients.

Conclusion

Our study showed an association of LESCL with NMO-IgG positivity as in previous investigations. In the African American population, 80% of antibody positive patients had LESCL. Although we have a selection bias due to our center's patient demographics, our investigation is the first to document a possible susceptibility of the African American population to LESCL in NMO.

KEYWORDS: Neuromyelitis optica, Spinal cord, African American

Diagnosis of Spinal Drop Metastases on Initial Presentation of Pediatric Brain Tumor Patients Using 3D Volumetric Postcontrast Axial Imaging

Kralik, S. F.[1]·Kamer, A. P.[1]·O'Neill, D. P.[1]·Rodriguez, E.[2]·Ho, C. Y.[1]
[1]Indiana University, Indianapolis, IN, [2]Indiana University School of Medicine, Indianapolis, IN.

Purpose
The purpose of this research was to evaluate MRI with 3D volumetric axial postcontrast imaging in pediatric patients for initial presentation diagnosis of drop metastases from brain tumors. We assessed the effect of replacing standard axial postcontrast T1-weighted spin-echo (SE) with postcontrast axial 3D volumetric T1-weighted sequence with regard to radiologist agreement for presence of drop metastases, image quality, and number of lesions detected.
Materials & Methods
From 1/18/2010 to 1/24/2012, a total of 35 consecutive pediatric patients with a new diagnosis of a brain tumor underwent total spine imaging at 1.5T for evaluation for the presence or absence of drop metastases in the spine prior to therapy. A total of 15 patients were labeled as group 1 whose imaging included postcontrast sagittal and axial T1-weighted SE imaging of the total spine. A total of 20 patients were labeled as group 2 whose imaging included postcontrast sagittal T1-weighted SE imaging and axial 3D T1-weighted postcontrast VIBE (volumetric interpolated breath-hold) sequence replacing postcontrast axial SE. A retrospective independent blinded review of the total spine imaging in groups 1 and 2 was performed by two fellowship trained neuroradiologists (AK, DO). Kappa (K) values were calculated to determine statistical concordance of the diagnosis of drop metastases. Independent reviewer diagnosis was compared to final diagnosis from a dedicated pediatric neuroradiologist, CSF cytology if present, and follow-up imaging.
Results
No false negative MRI was seen in either group. After reviewing the axial postcontrast images for group 1, K-value increased to 0.55 (SD 0.21), which was a statistically significant increase (Student *t*-test p value = 0.01). After reviewing the axial postcontrast images for group 2, K-value increased to 0.70 (SD 0.19), which was a statistically significant increase (Student *t*-test p value = 0.0001). The best possible K-values for group 1 versus group 2 also was statistically significantly different (Student *t*-test p value = 0.03) indicating improved concordance from the use of axial 3D VIBE compared to SE. Image quality (scale 0-5, 5 = best) of the sagittal images for group 1 versus group 2 was not significantly different for the reviewers (*t*-test p value = 0.77). However, image quality of the axial images was significantly better for group 2 versus group 1 (*t*-test p value = 0.002). The number of cases in which the axial images increased the number of lesions detected was two of 15 (13%) cases for group 1 compared to eight of 20 (40%) cases for group 2.
Conclusion
Axial 3D volumetric T1-weighted VIBE postcontrast imaging can be used for a diagnosis of drop metastases on initial presentation of pediatric patients with brain tumors. Compared to routine postcontrast SE axial images, axial 3D T1-weighted postcontrast VIBE further improves concordance between radiologist for diagnosis of drop metastases, consistently demonstrates improved image quality, and increases number of lesions detected. These characteristics are considered an advantage of 3D volumetric imaging compared to routine spin-echo imaging for the diagnosis of drop metastases.

Screening and Detection of Blunt Vertebral Artery Injury in C1/C2 Fractures: Role of Cervical CT/CT Angiography

Payabvash, S.·McKinney, A. M.·Palmer, C.·Truwit, C. T.
University of Minnesota
Minneapolis, MN.

Purpose
Upper cervical spine fractures are associated with increased risk of blunt vertebral artery injury (BVAI), particularly in those with transverse foramen (TF) fracture or subluxations. The purpose of our study was to evaluate the clinical utility of nonenhanced CT (NE CT) and CTA in screening and detection of BVAI in patients with C1 and/or C2 fractures.
Materials & Methods
The imaging and clinical records of all blunt trauma patients who underwent cervical spine NE CT, over a five-year period (8/2006-9/2011) were reviewed retrospectively. All patients with C1 and/or C2 fractures were included in our study. Nonenhanced CT and CTA studies were performed with the 64-multislice Brilliance CT scanner (Philips Medical Systems, Best, Netherlands). Cervical CTA was prompted by cervical fractures involving/adjacent to TF, or with significant subluxation. All CTA studies were reviewed and the BVAI was graded by two neuroradiologists, independently. We determined the inter-rater agreement and independent predictor(s) of BVAI among different patterns of cervical fracture (i.e., concomitant C3-C7 fracture, transverse foraminal fracture, subluxation, condylar fracture, vertebral artery hypoplasia, and comminuted fracture).
Results
There were 210 patients with upper cervical fractures (125 involving C2, 48 involving C1, and 37 involving both C1 and C2). In interpretation of CTAs, there was very good interobserver agreement in detection (kappa=0.93 , $p<0.001$), and grading the BVAI (kappa 0.90 ± 0.05, $p<0001$). From our cohort, 22 patients underwent both CTA and digital subtraction angiography, which showed

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

two false-positives for BVAI (one each of grade 1 and grade 2), and one false negative (grade 1). The presence of comminuted cervical fracture was the only independent predictor of BVAI (odds ratio = 3.0 (1.2 - 7.8), (p = 0.026). A clinical follow up of >seven days was available in 191/210 of all patients, and 114/124 who underwent CTA. Only three of 210 patients suffered a posterior circulation stroke. No patients suffered a symptomatic stroke who were negative for BVAI on CTA, or who were not evaluated for BVAI based on our radiologic screening criteria.

Conclusion
Multislice CTA reliably detects symptomatic BVAI in patients with upper cervical fractures or subluxations, although may occasionally miss low-grade, asymptomatic BVAI. Utilization of NE CT criteria (TF involvement or subluxation) may be adequate in deciding whether to perform CTA, as none of our patients who did not undergo CTA suffered a clinically symptomatic stroke.

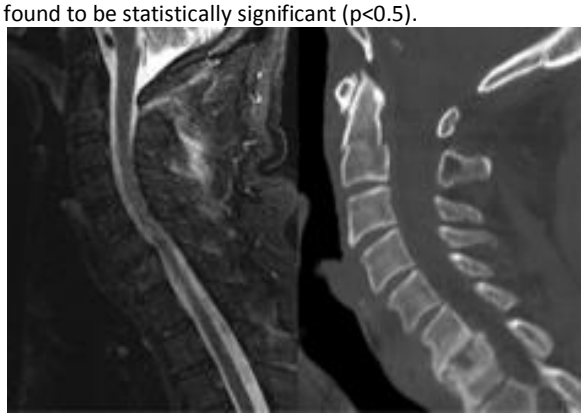
Marrow STIR Signal Underestimates Odontoid Fracture Acuity in Older Patients

Lensing, F. D.·Shah, L.·Wiggins, R.
University of Utah Health Sciences Center
Salt Lake City, UT.

Purpose
STIR hyperintensity is used routinely to assess for marrow edema to indicate an acute fracture. However, STIR may not accurately depict the acuity of a C2 fracture in older osteoporotic subjects. This may be explained by the intrinsic structural heterogeneity of the dens with reduced trabecular bone volume and decreased cortical thickness as well as histologic changes that occur with osteoporosis. The overall decreased bone mass reduction of the dens in osteoporotic patients with residual fat in the intertrabecular space may display diminished or absent edema on STIR images with acute injury. This is clinically relevant as there is high fracture nonunion, especially in older osteoporotic patients, when treated with external immobilization if there is delayed treatment. Furthermore, several series favor surgical fixation of C2 fractures in older patients, reporting better results when performed in the acute stage (< six months).
Materials & Methods
The RIS was queried for “C2 fracture,” “dens fracture” and “odontoid fracture” from 2007 to 2012. Those cases with both CT and MRI were included. Patient demographics were recorded. The odontoid fractures were categorized into the three types as initially described by Anderson and D’Alonzo. The images were evaluated for the presence of STIR hyperintensity in the bone marrow and fracture cleft. The angulation of the fracture fragments also was evaluated.
Results
In the study population meeting inclusion criteria, there were 24 females and 22 males with an average age 62.5 years. The odontoid fracture type distribution was 33 Type 2, 12 Type 3 and one Type 1. Though 50% of patients < 60 years old, demonstrated STIR hyperintense marrow signal, only 38% of patients < 60 years old had similar findings (Figure). A trend towards a negative correlation between age and STIR was seen in our group of patients. The average age of patients with a paucity of STIR signal (68.7 years +/- SD 21.6) was greater than that with STIR abnormality (54.4 years +/- 26.1). This age difference was found to be statistically significant (p<0.5).



Conclusion
It is critical to be aware of this STIR MR pitfall when assessing the acuity of dens fractures. Patients older than 60 years, particularly with osteoporosis, can have acute odontoid injuries WITHOUT correlative hyperintensity on STIR imaging. Further weight should be placed on multidetector CT findings and clinical history in this setting.

Reliability of Diffusion Tensor Imaging Values in Spinal Cord Injury: Analytical Variations and Effects from Injury Severity

Zoltani, Z.[1]·Kamali, A.[2]·Zohrabian, V.[1]·Dresner, M. A.[3]·Gorniak, R. J. T.[1]·Flanders, A. E.[1]
[1]Thomas Jefferson University Hospital, Philadelphia, PA, [2]Cooper Medical Center, Camden, NJ, [3]Philips Medical Systems, Philadelphia, PA.

Purpose
Diffusion tensor imaging (DTI) has potential to improve clinical accuracy in assessing initial neurologic deficit and forecast potential for recovery after spinal cord injury (SCI). Uniformity in the analysis of quantitative DTI data presents a unique challenge in that absolute values of DTI metrics vary considerably in the literature. This calls into question the reliability and reproducibility of spinal cord DTI metrics between studies. Prior studies often incorporate a single measure of DTI values. There are multiple methodologies for analyzing DTI datasets, some of which utilize proprietary algorithms. The purpose of this study was to assess reproducibility of quantitative DTI results when identical datasets are analyzed by two different DTI postprocessing methods and to assess whether the DTI values are potentially less reliable in areas of injury.
Materials & Methods
Twenty-three cervical SCI patients were evaluated on a 1.5T MR (Philips Achieva) within 24 hours of injury. Standard anatomical axial/sagittal SE T1, T2 and GE imaging was performed. Diffusion tensor imaging of the entire cervical spinal cord was performed using 4 mm axial single-shot SE EPI technique (TR/TE: 2500/75 msec; 6 directions; B-value: 800; FOV 20 cm; 8 NEX; scan time: 3:40). Two observers independently traced whole cord regions of interest (ROIs) around a total of 614 discrete axial DTI spinal cord images for each patient using a commercial analytical package (FiberTrak - Philips Medical) and a popular open source toolkit (DTI Studio - Johns Hopkins University). Fractional anisotropy (FA) and apparent diffusion coefficient (ADC) were recorded. Interobserver agreement between ADC and FA values for the two observers was calculated by using Pearson and intraclass correlation coefficients (ICC) while controlling for the patient's American Spinal Injury Association (ASIA) grade and presence/absence of anatomical injury on T2-weighted images.
Results
Distribution of injuries for the 23 patients included ASIA, A (9), B (4), C (4), D (2), unknown (2). Range in FA and ADC values reported were 0.3-0.91 and 0.05-2.2. Overall observer agreement for FA measures was low (0.35, <0.001) but substantially better for ADC measures (0.68, p<0.001). Agreement for values obtained within or outside region of visible injury was similar for FA at 0.34 (p<0.001) whereas agreement for ADC was better in normal-appearing spinal cord (0.77, p<0.001) compared to injured spinal cord (0.63, p<0.001). Agreement for FA measures stratified by ASIA grades were: A:(0.246), B:(0.203), C:(0.23), D:(0.49) and for ADC they were: A:(0.51), B:(0.74), C:(0.76), D:(0.54).
Conclusion
Defining absolute thresholds for DTI parameters in characterizing spinal cord injury may prove difficult because of inherent variations in acquisition, analytical methods and interobserver factors. Relative values may prove more effective to correct for some of these variations. In this regard, minimizing variability introduced through analysis is likely best achieved by central review using a single algorithm.

Altered Structural Connectivity in Mesial Temporal Lobe Epilepsy

DeSalvo, M.·Douw, L.·Tanaka, N.·Reinsberger, C.·Stufflebeam, S.
Athinoula A. Martinos Center for Biomedical Imaging Charlestown, MA.

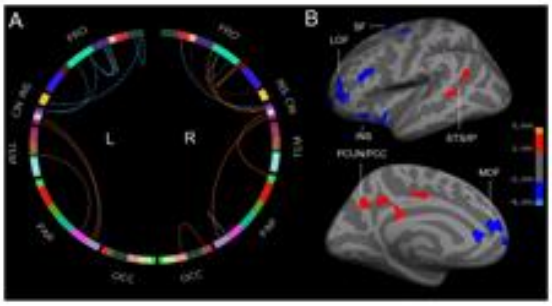
Purpose
Although mesial temporal lobe epilepsy (mTLE) has been theorized to relate to isolated injury of mesiotemporal structures, recent studies have revealed widespread cortical atrophy involving both temporal and extratemporal areas, leading to the concept of mTLE as a "network disease". The default mode network (DMN) consistently has been found to be affected by mTLE in studies of structural and functional connectivity. To our knowledge, this study is the first to use graph theory to compare whole-brain structural connectivity between patients with mTLE and healthy controls using diffusion tensor imaging (DTI) without selecting a priori seed regions or inspecting the results of independent component analysis (ICA).
Materials & Methods
Data were analyzed from 23 patients with left mTLE and 23 healthy controls. MR imaging volumes were segmented into 1000 regions of interest (ROIs) spanning the entire cortex. Whole-brain white matter tractography was performed after voxel-wise tensor calculation. Structural

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

connectivity matrices were generated using the pairwise density of connecting fibers between ROIs. Graph theoretical measures were calculated from these matrices and compared using two-sample t-tests.

Results

In patients with mTLE, increased connectivity was observed involving ipsilateral temporal and bilateral precuneus and posterior cingulate cortices, while decreased connectivity was observed among ipsilateral frontal areas (Figure 1). Although network modularity was not significantly different between groups, global efficiency was increased in the setting of mTLE ($p<0.001$). Local clustering and efficiency also were increased in ipsilateral temporoparietal and cingulate cortices($p<0.05$). Modularity analysis showed that the precuneus had a lower within-module z-score of degree ($p<0.05$) but higher participation coefficient ($p<0.05$) in the setting of mTLE.



Conclusion

We observed global and local alterations in structural networks of mTLE patients. Increased clustering and efficiency within the ipsilateral temporal lobe suggests increased interconnectedness likely related to aberrant self-reinforcing connectivity due to epileptic activity. In contrast to prior studies, our analysis showed increased structural connectivity between bilateral precuneus and posterior cingulate cortices, which are hub areas within the DMN. Our modularity analysis suggests that posterior DMN areas are connected less densely within the DMN while simultaneously more connected to other modules in mTLE. Similar to prior studies, we found decreased structural connectivity in ipsilateral frontal areas, which may relate to disrupted connectivity in posterior DMN areas. This altered pattern of long-range connectivity may underlie propagation of epileptiform activity that may reinforce an altered mTLE network. This also may lead to distant effects such as cortical thinning in the DMN.

7T MR Imaging of Nonlesional Mesial Temporal Lobe Epilepsy: Comparison to Volumetric Analysis and Clinical MR Imaging

Lin, D.·Trinh, H.·Ratnanather, T.·Bergey, G.·Barker, P.
Johns Hopkins University
Baltimore, MD.

Purpose

MR imaging at 7T offers higher spatial resolution and therefore more detailed depiction of the hippocampus compared to lower field strengths. The purposes of this study were (a) to prospectively evaluate the utility of 7T MRI in patients with mesial temporal lobe epilepsy (mTLE) compared to conventional, lower field MRI, and (b) to compare the results of visual interpretation with quantitative hippocampal volumetrics.

Materials & Methods

Ten surgical candidates with clinically diagnosed mTLE were scanned at 7T (Philips, Best, the Netherlands) using a 32-channel head coil, including high-resolution isotropic 3D MPRAGE whole-brain coverage obtained at 0.6 mm, and coronal T2-weighted images of the temporal lobes. On each scan the mesial temporal structures were evaluated specifically by an attending neuroradiologist for side of abnormality (classified as neither, left, right, or both), and the results were compared with semi-automated analysis of hippocampal volume, as well as findings from routine clinical MRI (1.5T or 3T) and the final clinical diagnosis (a combination of video EEG, intracranial EEG, clinical MRI, PET and histopathology). Kappa (κ) statistics were used to assess concordance between tests.

Results

7T offers superb high-resolution images of the hippocampi, with clear delineation of the CA fields particularly on the T2-weighted images (Figure). There is, however, limited evaluation of the anterior and lateral cortical regions of the temporal lobe related to image blurring and susceptibility artifacts. Neuroradiologic evaluation of combined T1 and T2 7T images showed a good concordance with T1 alone ($\kappa = 0.783$), volumetrics ($\kappa = 0.783$), clinical MRI ($\kappa = 0.600$) and clinical diagnosis ($\kappa = 0.677$). There was a very good concordance between volumetric data and T1 alone at 7T (8 of 10 cases; $\kappa = 0.8$), with hippocampal volume difference ranging from 1.3% to 53.5%. 7T MRI correctly lateralized 7 out of 10 cases based on T1 images, and 8 out of 10 when information from T2 was added; one of the 2 misdiagnosed cases had bilateral involvement based on clinical data. In contrast, clinical MRI had a lower accuracy rate in 6 of 10 cases. A very good concordance was also found between 7T volumetric results and lower field clinical MRI ($\kappa = 0.8$).

Conclusion

Temporal lobe imaging at 7T offers improved spatial resolution and anatomical delineation of hippocampal structures, potentially aiding the presurgical lateralization of epileptic focus with greater accuracy compared to

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

clinical MRI performed at 1.5T or 3T. Further study with a larger patient cohort is warranted.

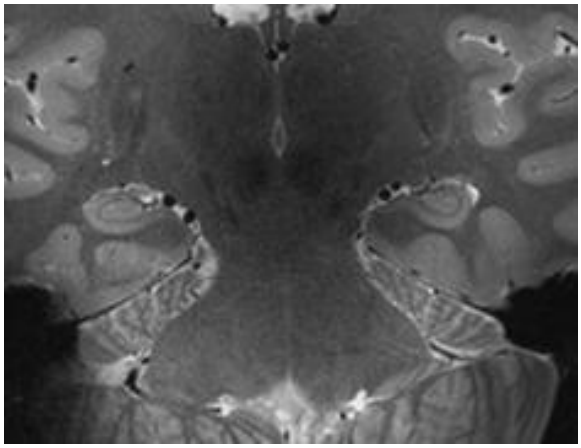
High-Resolution 7T MR Imaging in the Evaluation of Patients with Intractable Epilepsy

Barker, P. B.·Trinh, H.·Zhu, H.·Ratnanather, T.·Lin, D.·Bergey, G.
Johns Hopkins University
Baltimore, MD.

Purpose
To investigate the use of high-resolution 7T volumetric MRI for identifying lateralized hippocampal abnormalities in patients with drug-resistant partial seizures originating from mesial temporal structures.
Materials & Methods
Seventeen patients with medically intractable epilepsy (10 M, 32 ± 12 years) and nine normal control subjects (6 M, 36 ± 10 years) were recruited. All subjects underwent a 7T MR exam using a 32-channel head coil (Philips, Best, The Netherlands). The protocol included T1-weighted 3D MP-RAGE (0.6 mm isotropic resolution, 300 slices, TI 446 ms, SENSE factor 4) and a coronal multi-slice reduced flip angle FSE T2-weighted sequence (0.5 mm in-plane, 1 mm slice thickness, 40 slices, TR/TE 5000/56 ms, SENSE factor 2). Volumetric images were resliced in orthogonal views and hippocampal volumes determined by manual segmentation. Final diagnosis was based on surface and invasive EEG, clinical evaluation and (when available) pathology.
Results
Of the 17 patients, 11 had clinically defined mesial temporal lobe epilepsy (mTLE), while six had either neocortical or extratemporal epilepsy. Of the patients with mTLE, eight had abnormalities that could be detected in conventional 3T MRI scans. An example of a 7T coronal T2-weighted image in a control subject is shown in Figure 1. In the control group, mean hippocampal volume was 3.52 +/- 0.15 mL, and asymmetry ranged from +5.2% to -7.8%. Patient asymmetries ranged from +42.5% to -53.5%. 7T volumetric measurements correctly lateralized eight of 11 mTLE cases, including two cases with normal 3T MRI scans. Mean hippocampal volumes were significantly smaller than controls in the 3T abnormal MTLE patients (2.54 ± 0.78 ml, P<0.01, ANOVA/Dunnett multiple comparison correction), and showed a trend for reductions in the neocortical/extra-temporal cases (3.08 ± 0.24 ml, P>0.05).



Conclusion
Quantitative, high-resolution, volumetric 7T MRI shows promise in the presurgical evaluation of patients with intractable epilepsy, and may provide lateralizing information in some cases with normal clinical 3T MRI.

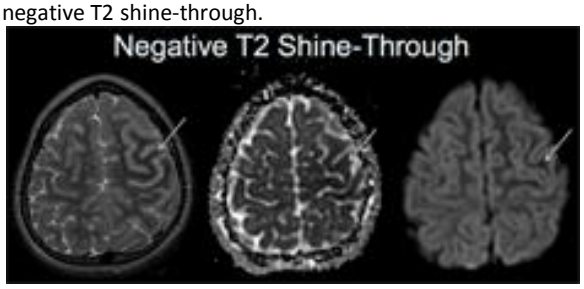
Dark Side of Seizures: Radiologic Clinical Correlation of Negative T2 Shine-Through in Seizure

Chu, E.·Hasso, A.·Handwerker, J.
University of California, Irvine Medical Center
Orange, CA.

Purpose
The magnetic resonance imaging (MRI) phenomenon of “negative T2 shine-through” or "T2 dark-through” refers to lesions that are hypointense on T2-weighted sequences and apparent diffusion coefficient (ADC) maps. It is a rare and often overlooked finding that has been described infrequently in cases of ischemia, hematoma, meningoencephalitis, malignancy, Sturge-Weber, and seizures. The goal of this study is to investigate the significance of this finding in the setting of seizure.
Materials & Methods
We retrospectively reviewed 11 patients whose MRI scans demonstrated “T2 dark-through” that was associated with seizure. Correlation was made with advanced MRI sequences including susceptibility-weighted imaging (SWI), arterial spin labeling (ASL), and perfusion imaging. Correlation was made with their clinical course, laboratory testing, and when available, ancillary testing such as positron emission tomography (PET) and electroencephalography (EEG).
Results
Eleven patients between the ages of three months and 82 years exhibited negative T2 shine-through in the setting of seizure. Three patients were significantly hyperglycemic at the time of their seizures with blood glucose levels ranging from 414 to 505 mg/dL. Three patients had an intracranial

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

infectious/inflammatory process. Two patients had an underlying congenital disorder, including Sturge-Weber. Two patients seized in the setting of subdural hematomas. The regions of negative T2 shine-through correlated to hypointensity on SWI, hyperperfusion on ASL imaging, hypermetabolic activity on PET scan, and epileptic activity on EEG. Follow-up imaging showed resolution of the negative T2 shine-through.



Conclusion
Negative T2 shine-through is a rare transient MRI finding in the setting of seizure that correlates to regions of hyperperfusion, hypermetabolic activity, and epileptic activity in the brain. It was observed in patients with superimposed intracranial processes, such as metabolic disturbances, meningoencephalitis, congenital disorders, and hematomas. This finding may relate to transient ischemia and increased oxygen consumption, especially as it was observed in areas of the brain that may be more metabolically active. Overall, negative T2 shine-through is an under-recognized yet promising finding with associated clinical correlations in the setting of seizure. Continued investigation and followup of this finding could help facilitate diagnosis and management of these patients.

Relationship of Brain MR Imaging Findings with Postsurgical Epilepsy Outcome in Children with Malformations of Cortical Development

Kadom, N.·Bansal, S.·Jubouri, S.·Prola Netto, J.·Tryggestad-Codispoti, K.·Gaillard, W. D.
Children's National Medical Center
Washington, DC.

Purpose
To determine if brain MRI variables predict epilepsy outcome after surgical removal of pediatric malformations of cortical development (MCD).
Materials & Methods
Retrospective study, IRB approved. Patients identified from internal epilepsy database. Inclusion criteria: pre-operative brain MRI, availability of surgical pathology. Observers: Five observers: A = pediatric neuroradiologist, B = neuroradiologist, C = radiologist, D = pediatric neurologist, E = neuropathologist. Image analysis performed on GE workstation, Functool. Regions of interest were placed manually by two observers independently. For quantitative analysis (FA, ADC) two ROI locations were placed per patient, one in the normal-appearing white matter closest to the MCD and one in symmetrical position in the contralateral hemisphere. For tractography two ROI locations were placed per patient, one directly over the MCD and one in symmetrical position in the contralateral hemisphere. Statistical analysis with Stata v12.1: Outcome variable was postsurgical state of epilepsy (based on Engel classification): Engel 1) seizure free, Engel 2) rare seizures, Engel 3) worthwhile improvement, and Engel 4) no worthwhile improvement. Predictor variables: quantitative DTI analysis (FA, ADC), conventional MRI signs (bright signal on T2/FLAIR/T1 magnetization transfer, cortical blurring, cortical thickening, radial line), MRI signal patterns (signal variable concatenations), qualitative analysis of fiber tracts (symmetry, color hues), clinical data, pathology data.
Results
We analyzed 29 patients, 16 boys and 13 girls. Mean age at onset of epilepsy, 2.5 years; mean age at surgery, 7.7 years. Postsurgically 12 patients were Engel 1; seven Engel 2; six Engel 3; four Engel 4. All Engel 4 patients had lesions in the left hemisphere, (temporal and extratemporal). All patients had architectural distortion: 17 patients had isolated architectural distortion; there were added dysmorphic cells in two; added dysmorphic cells and balloon cells in five, and added microgyria in five. There was better outcome for patients with T2 bright lesions (χ^2, $p = 0.05$). There was higher FA on the abnormal brain side when compared to the normal side (Wilcoxon signed-rank test, $p = 0.03$), especially in the subgroup with seizure free postsurgical outcome (Wilcoxon signed-rank test, $p = 0.002$). Apparent diffusion coefficient was statistically significantly lower on the abnormal side in the seizure free patient subgroup (Wilcoxon signed-rank test, $p = 0.03$).
Conclusion
Lesions with bright signal on T2 are associated with better postsurgical outcome. Left hemispheric lesions are associated with unfavorable postsurgical outcome, maybe due to less aggressive surgical approach to preserve eloquent cortex. Fractional anisotropy and ADC values from normal-appearing white matter in patients who are seizure-free after surgery showed significant differences between the abnormal and normal side of the brain. We did not find a relationship between MRI signal and pathology findings. MR imaging patterns were not related to postsurgical epilepsy outcomes (Engel). Combination of multiple MRI signal features into patterns did not improve statistical relationships compared to using only bright signal on T2 imaging.

MR Imaging Abnormalities in the Resection Region Correlate with Histopathologic Grade, Gliosis Extent, and Postoperative Outcome in Pediatric Cortical Dysplasia

Henkel, D.·Leach, J. L.·Miles, L.·Greiner, H.·Komlos-Kukreja, M.·Holland-Bouley, K.·Zhang, B.·Mangano, F.
Cincinnati Children's Hospital Medical Center
Cincinnati, OH.

Purpose
Cortical dysplasia (CD) is the most common pathology in children with intractable epilepsy. Recent classification schemes have demonstrated differences in clinical behavior, imaging, and outcomes amongst subtypes, mostly in adults. The pathologic basis for imaging findings and how imaging correlates with outcome has been evaluated incompletely in children.
Materials & Methods
Forty-three children with intractable neocortical epilepsy, high quality MR imaging, and CD formed the study cohort. Exclusions included: prior surgery, CD and destructive lesions/tumors, type IIIA CD (HS and adjacent CD), < 6m FU, or age >21 years. Dedicated seizure protocol MRI (3T-37, 1.5T-6) was performed. Image review was blinded to pathology but with knowledge of resection location determined by simultaneously reviewing: postoperative imaging, images of the operative field, grid locations, and operative notes. Each region was evaluated for: abnormal gyral pattern, WM signal, GM signal, cortical thickening, blurred cortical junction, "transmantle" signal, and volume loss. A "MRI score" was calculated for each region (0-7). The resection region was classified as “lesional” (a localized surgical target) or “nonlesional” based upon all imaging features. Neuropathology was reviewed according to 2011 ILAE classification. Cortical gliosis was classified as superficial (sG),or diffuse (dG, involving all layers). Outcome was based on the ILAE scale with 1-3 considered good outcome.
Results
There were 23 males, mean age: 10.2 years (6 months-19 years) and 89 resection regions. There were 50 type I CD, 29 type IIA CD, and 10 type IIB CD. Eleven of 43 (25.6%) had $\geq$2 types of CD. Eighty-four percent (32/38) type II CD versus 18% (8/44) with type I CD, exhibited dG ($p<0.0001$). Lesional findings were significantly more prevalent with type II (51%) versus type I (12%) CD. MR score $\geq$3 was significantly more prevalent in type II versus type I; types IIB versus type I, and type IIB versus type IIA CD. All MR features except localized volume loss, were more common in type II versus type I CD. Only GM signal was more common in type IIB (70%) versus type IIA (17.2%) CD ($p=0.004$). dG was more common in regions that were lesional, MR score $\geq$3, and with all MR features except volume loss. WM signal was most significantly associated with dG. Outcome correlated with CD subtype with 39% of type I CD and 72% of type II CD (100% IIB, 61% IIA), exhibiting good outcome ($p=0.03$). The presence of a lesional MRI abnormality or MR score >3 correlated with good outcome in 78% and 90% of patients respectively ($p<0.03$).
Conclusion
This study provides a detailed correlation between MRI, neuropathology, and outcomes in children with intractable epilepsy using a novel resection site specific evaluation in a large surgical group. Twenty-five percent of our patients had different CD types in different regions mandating a regional analysis approach for imaging pathology correlation in these patients. MR imaging abnormalities and Type II pathology correlated with better outcomes. Type II CD is more detectable by MR and is associated with dG. Improved imaging techniques for detecting CD in children are needed.

KEYWORDS: Cortical dysplasia, MR imaging

Abnormal White Matter Tracts Are Anatomically Related to Reduced Cortical Thickness in Children with Frontal Lobe Epilepsy

Widjaja, E.·Kis, A.·Go, C.·Snead, O.·Smith, M.
Hospital for Sick Children
Toronto, ON, CANADA.

Purpose
Previous research has demonstrated widespread reduction in cortical thickness in children with frontal lobe epilepsy (FLE), which may be related to spread of seizures through the white matter (WM) tracts. The aim of the current study was to assess WM integrity in children with FLE and to evaluate the relation between abnormal WM tracts and cortical thickness.
Materials & Methods
Forty-three children with FLE and normal MRI, and 44 healthy controls were recruited. Twenty-eight patients had left FLE and 15 had right FLE. High-resolution volumetric T1-weighted imaging and diffusion tensor imaging (DTI) were performed in all patients and controls. Whole brain DTI analysis was compared between right and left FLE with controls. Regions of abnormal fractional anisotropy (FA) were used as starting seed for probabilistic tractography. Whole brain cortical thickness was compared between FLE groups and controls. Fractional anisotropy of abnormal tracts was correlated with regions of cortical thickness.
Results
Patients with left FLE had significant FA reductions in left and right superior longitudinal fasciculi (SLF), genu/body and splenium of corpus callosum compared to controls. Patients with right FLE had significant FA reductions in left and right SLF, genu and body of corpus callosum compared to controls. In left FLE, tractography of left SLF overlapped with left precentral, insula, superior temporal, bank of superior temporal sulcus and postcentral reduced cortical thickness; tractography of right SLF overlapped with right supramarginal, superior temporal, middle frontal and

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

insula reduced cortical thickness; tractography of genu/body of corpus callosum overlapped with left and right superior frontal and right frontal pole reduced cortical thickness, and splenium of corpus callosum overlapped with left pericalcarine and right precuneus reduced cortical thickness. There was a trend for positive correlation between FA of right SLF with right supramarginal (r= 0.453, p = 0.015) and right insula (r = 0.416, p = 0.028) cortical thickness in left FLE patients. In right FLE, tractography of right SLF overlapped with right insula, postcentral, parstriangularis and superior parietal reduced cortical thickness; tractography of left SLF overlapped with left superior frontal, parsopercularis, superior parietal, precentral, postcentral, supramarginal, superior temporal and insula reduced cortical thickness; tractography of genu of corpus callosum overlapped with left superior frontal and left medial orbitofrontal reduced cortical thickness, and body of corpus callosum overlapped with left superior frontal and left paracentral reduced cortical thickness. There was no significant correlation between FA of WM tracts and regions of reduced cortical thickness in right FLE patients.
Conclusion
We have found abnormal WM both ipsilateral and contralateral to seizure focus in children with FLE. Tractography of abnormal WM demonstrated an anatomical connectivity with regions of reduced cortical thickness, suggesting that spread of seizures through the association tracts beyond the frontal lobes and via the corpus callosum to the contralateral hemisphere may have contributed to widespread reduced cortical thickness.

Features of Focal Cortical Dysplasias on 7T MR Imaging

Mehan, W. A.·Stemmer-Rachamimov, A.·Ratai, E.·Stufflebeam, S. M.·Caruso, P. A.
The Massachusetts General Hospital
Boston, MA.

Purpose
Malformations of cortical development (MCDs) including focal cortical dysplasias (FCDs) are estimated to cause 40% of cases of medically refractory epilepsy (Guerrini et al., Epileptic Disord 2003); however, MRI at 1.5 and 3T are only 76% sensitive and 53% specific for the characterization of the irritative zone in focal epilepsy (Brodbeck V. Brain 2011) and thus attention has turned to higher field MRI techniques to increase the diagnostic yield of the imaging evaluation. Our goal was to review our experience with pathology proven FCDs imaged preoperatively at 7T in order to determine if there are imaging features specific to 7T imaging that correlate with histopathologic findings.
Materials & Methods
A retrospective review was performed on a series of four patients with medically refractory epilepsy who underwent pre-operative 7T MR imaging between August 2008 to November 2010. Each of the four patients subsequently had surgical resection demonstrating pathology proven FCDs. The MR imaging was performed on a Seimens 7T research magnet; spoiled gradient recalled echo (SPGR), axial and coronal T2, and SWI sequences were performed in each case. Two board certified neuroradiologists and two board certified neuropathologists correlated the 7T MR images of the FCDs with the histopathologic findings together.
Results
The four patients included in the review had a mean age of 23.5 years (range 17 to 38 years). Each patient underwent epilepsy surgery demonstrating pathology-proven focal cortical dysplasia (FCD). Unique 7T imaging features of FCDs included: -linear signal isointense to gray matter that appeared to be arrayed from the cortex toward the subcortical white matter and that corresponded to lines of heterotopic neurons defined histopathologically, -a low signal arcade identified in normal cortex that appeared to be disrupted in dysplastic cortex and that correlated best with the cortical capillary network, and -prominent vessels seen best on SWI, oriented perpendicular to the dysplastic cortex.
Features of FCDs described at 1.5 and 3T such as abnormally thick cortex and blurring of the gray-white matter junction were redemonstrated.
Conclusion
We correlated the 7T MR imaging features of FCDs with histopathology in a series of four patients who underwent surgical resection of pathology proven FCDs, and demonstrated several imaging features of FCDs that we believe to be unique to 7T imaging.

Diffusion Tensor Imaging to Confirm Commissural Disconnection after Corpus Callosotomy

Choudhri, A. F.[1,2]·Whitehead, M. T.[1,2]·McGreggor, A.[1,2]·Einhaus, S.[1,2]·Boop, F. A.[1,2]·Wheless, J. W.[1,2]
[1]University of Tennessee Health Science Center, Memphis, TN, [2]Le Bonheur Children's Hospital, Memphis, TN.

Purpose
Corpus callosum transection can prevent propagation of epileptic discharges; however the procedure can be difficult to perform due to adjacent vasculature and the deep location of the corpus. If seizures persist after surgery, assessment of the efficacy of the transection requires knowledge that the commissural fibers have been disrupted. We evaluated whether diffusion tensor imaging (DTI) and diffusion tensor fiber tracking (DT FT) can assess the degree of callosal transection and determine which white matter pathways remain intact.
Materials & Methods

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Twenty-five patients (15 M, 10 F; age 12.3 ± 7.1 years, range 0.24 to 32.8 years) who underwent prior corpus callosotomy were evaluated with DT FT performed using deterministic and probabilistic techniques. Diffusion tensor imaging was obtained in the axial plane using 15 directions of encoding (n = 18) and 25 directions of encoding (n = 7), with additional coronal plane 25 direction DTI performed in 12 patients. Twelve patients had undergone complete callosal transection, nine patients had partial callosal transection with preservation of the splenium (n = 2) and the splenium and isthmus (n = 5), and four patients had functional hemispherectomies including complete callosal transection. DTI, DT FT, and conventional structural MR imaging were reviewed by two neuroradiologists.

Results

Of patients undergoing complete callosal transection, 17 patients had structural and DT FT evidence of complete transection, and one patient had a small quantity of intact forceps minor fibers within the rostrum on DT FT with transection of the remainder of the corpus callosum. In patients undergoing partial transection, the forceps major was intact in all patients. At least some perirolandic commissural fibers were intact in six of six partial transections where there was sparing of the callosal isthmus.

Conclusion

Diffusion tensor imaging and DT FT aid in the postoperative characterization in patients with callosal transection for seizure control. This can confirm whether the intended fibers have been disconnected, helping planning for possible further surgical intervention versus additional medical therapy.

Minimally Invasive MR Imaging-Guided Stereotactic Laser Thermal Ablation Technique in Neurosurgical Cases; Our Initial Experience

Medina, L.·Chamiraju, P.·Bhatia, S.·Ragheb, J.·Altman, N.·Miller, I.·Pacheco, E.
Miami Children's Hospital
Miami, FL.

Purpose

We present our preliminary experience on nine patients with brain lesions treated with stereotactic placement of laser probe and thermal ablation under MRI guidance.

Materials & Methods

Patient with focal brain lesion on MRI measuring less than 10 centimeters in long axis were selected for the study. Method is FDA approved. Stereotatic placement of the laser probe was done using 3D image guidance. Laser thermal coagulation was performed under continuous MRI guidance. Real time MR thermal images allowed live evaluation of target temperature (50-90^{o}C) and protect surrounding tissues (under 40^{o}C).

Results

Nine patients were enrolled with an age range of 4-20 years. Six patients had cortical dysplasia, one ganglioglioma, one tuberous sclerosis and one recurrent ependymoma. Mean followup was 8.3 months (range 2-16 months).The lesion after ablation showed low T2-weighted signal consistent with protein denaturalization from thermal ablation and halo of surrounding restricted diffusion due to ischemia/infarction. All patients developed perilesional edema after ablation which subsided over few weeks with steroids. Immediate postprocedure headache was seen in nine patients although less than expected in craniotomy patients. Expected unavoidable neurologic deficit was seen in one patient. No other neurologic deficits were seen. In short-term followup, six patients had an improvement in the clinical findings, one required a second ablation for residual lesion with subsequent improvement, two had stable seizures and one had worsening seizures even after ablation.

Conclusion

Minimally invasive laser thermal ablation under MRI guidance can be safely used in a specific group of lesional neurosurgical patients and may be an adequate alternative to open resection. A larger number of patients will need to be studied and long-term followup required before we gauge the adequacy of using laser thermal ablation.

Comparison of an Accelerated 3D Spiral Chemical Shifting Imaging and Single Voxel Spectroscopy at 3T in the Pediatric Age Group

Yazbek, S.·Prabhu, S. P.·Connaughton, P.·Grant, P. E.·Gagoski, B.
Boston Children's Hospital, Harvard Medical School
Boston, MA.

Purpose

With ~20 minutes acquisition times for 3D phase-encoded (PE) chemical shift imaging (CSI) clinically impractical, single voxel spectroscopy (SVS) remains the clinical “workhorse”. However, with no standardized single voxel location to enable comparison to normal data and with lack of spatial coverage limiting ability to assess for regional changes, the tremendous clinical potential of spectroscopy remains unrealized. To overcome lack of efficiency of 3D PE CSI and lack of spatial coverage of SVS, efficient encoding schemes using spiral k-space trajectories have been deployed successfully, enabling acquisition of volumetric CSI in < five minutes. Our aim is to assess feasibility of using 3D spiral CSI routinely in pediatric clinical settings by comparing its reconstructed spectra against SVS spectra.

Materials & Methods

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

All experiments were performed on 3T Siemens scanners, using a 32-channel coil. Volumetric spiral CSI obtained spectra from 2cc isotropic voxels. LASER-box excitation was placed entirely within the brain to avoid lipid contamination from the skull. No outer volume suppression bands were used. Acquisition covered bilateral basal ganglia and parieto-occipital white matter. Chemical shift selected pulses were used for water suppression. Acquisition time was *3 minutes* (TR=1.8s, TE=30ms, 3 averages). Single voxel spectroscopy acquisition encoded a 3.4cc (1.5mm isotropic) voxel using conventional PRESS-box excitation, with voxel placement in the left basal ganglia. Acquisition time was *3 minutes* (TR=1.8s, TE=3 ms, averages=100). Higher order shimming was done automatically for all acquisitions. Data was gathered prospectively from 10 random patients presenting for brain MRI. Spectra from left basal ganglia obtained using both techniques were processed with Siemens postprocessing software. Following metabolite ratios were calculated: NAA/Cr, Cho/Cr, Lac/Cr.

Results

The study included seven boys and three girls aged between four days and 10 years. In 9/10 cases, spectral quality of both methods was acceptable. In one case, the SVS spectrum had artifacts due to suboptimal shimming. Considering nine of 10 cases, the *mean ± standard deviation* of the normalized metabolite ratio differences were: NAA/Cr-13.1%±10%, Cho/Cr-17.5%±3.2% and NAA/Cho-17.3%±9.4%. In one subject where lactate peak was detected, Lac/Cr ratios were identical.

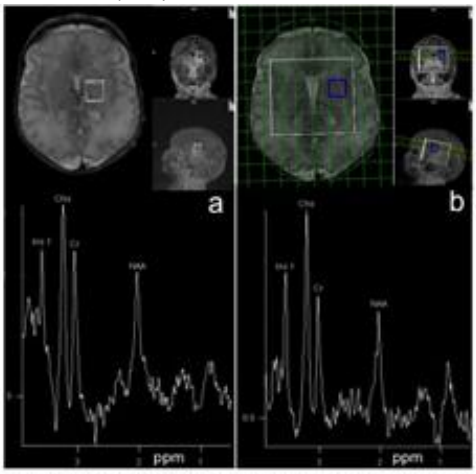

Figure 1. (a) SVS in the left basal ganglia; (b) Spiral CSI spectrum in the left basal ganglia; Also seen is the 3D coverage of spiral CSI

Conclusion

Accelerated 3D CSI is feasible in pediatric patients and can potentially substitute for SVS. 3D CSI can be registered to volumetric acquisitions and offers potential to gather regional and normative group data for reference. Observed differences may be driven primarily by differences in voxel location and size. Future studies will match voxel size and include a larger patient population.

Deciding Which Unruptured Aneurysm Should Be Treated or Not Treated

Murayama, Y.
Division of Endovascular Neurosurgery, Department of Neurosurgery, Jikei University School of Medicine
Tokyo, JAPAN.

Presentation Summary

Whether or not to treat unruptured intracranial aneurysms (UIAs) depends on various factors, including the risks associated with the natural history of UIAs and those associated with preventive treatment. To date, there are no data from prospective, randomized trials comparing conservative management of UIAs with preventive treatment. The ISUIA and UCAS Japan found a low overall rupture rate and appreciable treatment risks, which could be interpreted to mean that preventive treatment is rarely justified. Larger UIAs, associated with a higher risk of rupture, usually benefit from preventive treatment. However, it is unclear above which aneurysm size there is therapeutic benefit over natural history. Furthermore risk of aneurysmal growth and rupture also is unclear. In this lecture, we discuss the clinical outcome of patients with UIAs that were either managed conservatively or treated preventively.

Which Recurrent Aneurysms to Treat?

Moran, C. J.
Washington University School Of Medicine
St. Louis, MO.

Presentation Summary
The decision to retreat an aneurysm that has been either surgically clipped or treated endovascularly is strongly dependent upon the reason for the initial treatment. The patient whose aneurysm has previously ruptured will most likely require treatment until the offending aneurysm is obliterated. While there are circumstances that would change this approach, many of these same circumstances apply to the patient with a nonruptured aneurysm being evaluated for recurrence and possible retreatment. There are multiple factors that must be considered in these retreatment decisions. Most are related to the patient and their specific circumstances. Age and life expectancy, vibrancy, and the medical condition of the patient are foremost in these decisions. The location of the aneurysm, the size of the recurrence, and its configuration are significant in the reasoning behind these decisions. The psychosocial aspects of the incompletely treated aneurysm should be remembered as the patient is informed of the results of the recent imaging and subsequent treatment plans. In the follow-up evaluation of patients treated for intracranial aneurysms, the type of evaluation that the patient receives is also important. Magnetic resonance angiography (MRA) with contrast material may provide evidence of flow within treated large aneurysms that may not be detected by CTA or even angiography. The operator must be familiar with the limitations of the imaging modality as well its accuracy. After evaluating the patient who has been found to have a residual or recurrent aneurysm, there are numerous important questions about the aneurysm and the patient that should be answered. Has the aneurysm grown? Over what time period? Is the recurrence due to coil compaction? What is the access? Are adjuncts such as balloons, stents, liquid agents, or flow diversion necessary? If retreatment is undertaken, will the administration of antiplatelet agents be necessary? If so, for how long? Are these agents prudent in this particular patient? Finally the results of the operator with endovascular techniques, particularly with the use of adjunctive devices, must be known so that the complication rate with the proposed retreatment can be compared to the natural history of the aneurysm. In summary, multiple factors must be considered when retreatment of an intracranial aneurysm is being considered. The patient and their particular circumstances, the aneurysm and its particular circumstances, and finally the operator's experiences all combined to make the best decision for the patient. **QUESTIONS:** 1. The most important factor in deciding to retreat an aneurysm is: a. The initial reason for retreatment, b. The age of the patient, c. The configuration of the aneurysm, d. Operator experience. ANSWER: A. 2. Factors important in consideration of retreatment of the recurrent aneurysm include: a. Aneurysm size, b. Aneurysm growth, c. Aneurysm access, d. Operator experience, e. All of the above. ANSWER: E.

(15) Advanced Imaging Seminar: MR PET

O-153 **5:00 PM - 5:30 PM**

Aspects of PET/MRI Instrumentation

Judenhofer, M. S.
University of California Davis
Davis, CA.

Presentation Summary
In the field of molecular imaging, positron emission tomography (PET) has had great success as a functional imaging modality in major fields like cardiology, oncology and neurology, both in the clinical and the research domain. However, spatial localization of very specifically targeting tracers can be challenging due to the lack of morphologic clues. As a result, PET was combined with x-ray computed tomography (CT) which alleviated the problem of accurate spatial mapping of tracer accumulations. The success of PET/CT has shown that the combination of functional and morphologic information can be superior in difficult or ambiguous situations. A caveat of CT is its limited soft tissue contrast and the significant radiation dose from the x-rays. This is in sharp contrast to magnetic resonance imaging (MRI) where a great variety of tissue contrasts can be obtained and no ionizing radiation is involved. While early attempts to combine PET and MRI were pursued as early as the 1990s, considerable advances in the realm of combined PET/MRI devices have been made possible with the advent of silicon-based and MR compatible light detectors. Even though these light detectors do not always yield the same performance as a PMT and require very sensitive readout electronics, their very compact size allows for directly coupling to scintillators to build PET inserts and facilitates larger axial fields of views which were always hindered by the bulk of optical fibers used in early systems. The good quantification of PET data relies in part on the use of attenuation correction which compensates for the effect of signal underestimation due to absorbed gamma photons in the object being measured. Since this effect is more dominant for larger sized objects, the availability of

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

clinical PET/MRI systems calls for methods to obtain this information. Current methods seek to harness the MRI data to derive attenuation correction factors. Since the MR data provide mainly information about 1H-proton distribution which is not directly correlated with tissue density this proves to be a nontrivial task. Current approaches therefore often are based on segmentation and pattern recognition to provide the necessary information. This presentation will provide an overview of past and current developments and challenges of combined PET/MRI systems in both the clinical and preclinical areas with a focus on instrumentation and discussion of methods used for MRI-based PET attenuation correction.

O-154 **5:30 PM - 6:00 PM**

Clinical and Research Applications of PET MR in Brain Imaging

Benzinger, T. L. S.
Mallinckrodt Institute of Radiology
St. Louis, MO.

Presentation Summary
Dual PET MR scanners are now available for human clinical use and offer potential breakthroughs for neurologic imaging. In this presentation, current and future clinical and research applications of PET MR for brain and head and neck imaging will be discussed. PET MR offers several potential advantages over PET CT, including reduced radiation dose, particularly in pediatric patients or patients with an anticipation of multiple PET exams over a lifetime, such as for patients with lymphoma. It combines the physiologic sensitivity of PET tracers, such as FDG, with the resolution and contrast of MR, which may be particularly helpful in cases with small lesions anatomically, such as perineural spread of head and neck tumors. Or, in the case of treated gliomas, the possibility of simultaneous metabolic imaging with FDG combined with dynamic contrast enhancement (DCE) or dynamic susceptibility contrast (DSC) MRI. Although image fusion software for combining separately acquired PET and MRI is available for brain imaging, it is limited in the setting of head and neck cancers, where it is difficult to achieve identical positioning on separate exams. Two commercial designs are now available - one which allows simultaneous and one which provides for sequential PET MR acquisition. Major advantages of simultaneous acquisition are shorter exam times and better coregistration, resulting in less patient burden, particularly in the setting of dementia and advanced oncologic patients, better patient throughput, and potentially offering improved radiosurgical planning. Advantages of the sequential design include fewer artifacts related to the two technologies which might arise from performing PET in an MR environment and vice versa. Issues of attenuation correction, required for quantitative longitudinal studies, are challenging for both designs. PET CT has revolutionized the field of oncologic imaging, particularly for whole body exams. Challenges of PET MR for clinical workflows include development of MR protocols to fit within the PET timing (four-six minutes per station), interpretation of large complex datasets, including data transfers, PACS integration, and specialty readouts, and billing and compensation. Despite these challenges, the potential benefit for clinical patients and research participants are tremendous and are likely to permanently alter the future of neuroradiology.

O-155 **6:00 PM - 6:30 PM**

Hybrid PET/MR Imaging in Neuropsychiatry and Neurooncology

Förster, S.
Technical University Munich
Munich, GERMANY.

Dr. Stefan Forster currently works as an Associate Professor and Head of Neuroimaging at the Department of Nuclear Medicine, Technical University (TU) Munich and is additionally affiliated (PI) to the TUM Neuroimaging Center (TUM-NIC; http://www.tumnic.mri.tum.de/tumnic). He received clinical training in Nuclear Medicine, Radiology and Neuroradiology in two of the most honorable institutions in Germany (LMU and TU Munich). Up to now he has published more than 40 peer-reviewed original articles and more than 40 abstracts. In his recent scientific projects, which were well recognized by the international neuroimaging community ("Young Investigator Award" from SNM Brain Imaging Council 2011 as well as "Georg-von-Hevesy-Preis" from the German Society of Nuclear Medicine 2012), Dr. Forster applied longitudinal FDG- and Amyloid (PiB)-PET as well as MRI in patients with early Alzheimer Disease (AD) and investigated the spread of AD neuropathology in vivo. Currently he receive neurooncologic funding for "Characterization of hypoxic brain tumor regions in high-grade glioma using simultaneous PET/MRI".

Presentation Summary
The research focus is multimodal imaging of the brain using PET and MRI, applying these technologies to neurodegenerative diseases and neurooncology, currently using the worlds first integrated whole-body PET/MRI system.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Intra-Arterial Chemotherapy

Horton, J. A.
Our Lady of Lourdes Hospital
Lafayette, LA.

Presentation Summary
Intra-arterial cis-platinum infusion for treating squamous cell carcinoma (SCC) has been used for some years, but never reached general acceptance. We will be presenting an overview of the technique, its rationale, and a few exemplary cases of this treatment for SCC, inter alia.

O-158 **6:00 PM - 6:30 PM**

Retinoblastoma Therapy

Abruzzo, T.
University of Cincinnati, Neuroscience Institute & Mayfield Clinic
Cincinnati, OH.

Presentation Summary
Selective ophthalmic artery infusion chemotherapy has emerged as an important treatment option for children with retinoblastoma. Interventional neuroradiologists have assumed a primary role in contemporary patient evaluation and management. The clinical features, biology, epidemiology, neuroradiology and oncologic classification of retinoblastoma will be reviewed. Current treatment options will be discussed, emphasizing indications, remission rates, complications, advantages and disadvantages. The evolution of interventional approaches to the management of retinoblastoma will be presented. Variations in technique and adjunctive treatments will be highlighted. The fundamentals of ocular vascular anatomy, which form the guiding principles of selective ophthalmic artery infusion chemotherapy will be illustrated. Technical challenges encountered by neurointerventionalists during selective ophthalmic artery infusion chemotherapy, and related practical solutions will be reviewed. Various strategies for the management of retrograde ophthalmic artery flow will be discussed. Technical advances, which have improved the safety and efficacy of the SOAIC procedure, particularly in patients with challenging anatomy and hemodynamics, will be underscored.

Basics of Tablets

Shah, G. V.
Univ. Michigan Health System
Ann Arbor, MI.

Presentation Summary
The "new online" (Web 2.0) world is here and is expanding rapidly. The digital information, educational resources, communication tools, and networking resources helpful to radiologists have exploded over the past two decades. The rapid adoption rate and integration of mobile technology, especially tablet computing devices by physicians is reshaping the current clinical and radiologic landscape. These devices have sparked a revolution in a variety of arenas, including educational media dissemination, remote patient data access and point of care learning applications and clinical tools. This course gives an overview of tablet computing and communication devices and informs of different platform, products, their capability and suitability to the needs of radiology resident, educator and clinician.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Long-Term MR Imaging Signal Change in the Spinal Trigeminal Nucleus and Tract after Ramsay Hunt Syndrome and Trigeminal Herpes Zoster

Clerk-Lamalice, O.·Savage, J.·Fisch, C.
University of Sherbrooke
Sherbrooke, QC, CANADA.

Purpose
Ramsay Hunt syndrome (RHS), an illness caused by varicella zoster virus, refers to the association of a unilateral facial nerve palsy with herpes zoster oticus. Cranial nerve(CN) VIII often is involved and rarely CN V, VI, IX, X, XI and XII. Only four other cases of both RHS and trigeminal herpes zoster have been reported in the literature. We present a case of RHS, multiple CN palsies and trigeminal herpes zoster that developed postherpetic neuralgia(PHN). Longitudinal MRI-signal-intensity abnormalities were followed in the spinal trigeminal nucleus and tract(STNT).
Case Report
A 69-year-old man, on immunosuppressants for a heart transplant, slowly developed dysphagia, sore throat and right otalgia two weeks after a right hemicolectomy. Over the next few days he developed severe right tooth, pinna, and hemifacial pain as well as a lower motor neurone facial paralysis, House-Brackman grade 5/6. Plasma immunosuppressant levels were abnormally high. The patient was treated for RHS with Prednisone and Acyclovir. Vesicular skin lesions appeared gradually over the following days on the right tympanic membrane, and external auditory canal with right audition decrease and vertigo. Nasolaryngoscopy confirmed presence of vesicles on the right hemipharynx, indicating CN IX involvement. The patient also developed vesicular skin lesions and allodynia in the right trigeminal nerve territory. At six months, he had PHN and persistent multiple cranial deficits.
Imaging Findings
MR imaging was performed six weeks and six months after the beginning of symptoms. The initial MRI demonstrated enhancement of the right intratemporal portion of CN VII and swelling of the cisternal portion of CN VII and CN VIII. Right STNT showed initial diffusion restriction and corresponding increase in T2-weighted signal intensity persisting six months after the beginning of symptoms.

Summary
We present a patient with RHS and trigeminal herpes zoster. Transaxonal spread of VZV in the brainstem, between the facial nerve nucleus and STNT, has been hypothesized to explain the rare incidence of both pathologies. This case is interesting because of long-term T2-hyperintensity in the brainstem and the development of PHN. In a study of patients with trigeminal herpes zoster, brainstem signal abnormalities were associated more frequently with PHN. In our case, we believe that the initial severity and intensity of STNT diffusion restriction and T2-weighted hyperintensity relates to the deleterious outcome. Future MR prospective studies should investigate the prognostic value of initial diffusion and T2-weighted signal intensity abnormalities of STNT in patients with RHS and/or trigeminal herpes zoster.

KEYWORDS: Brainstem, Infections, Ramsay Hunt syndrome

O-161 **5:05 PM - 5:10 PM**

West Nile Virus Meningoencephalitis Initially Presenting as Intraparenchymal Hemorrhage in a Hypertensive Patient

Endale, B.·Morales, R.·Steven, A.
University of Maryland Medical Center
Baltimore, MD.

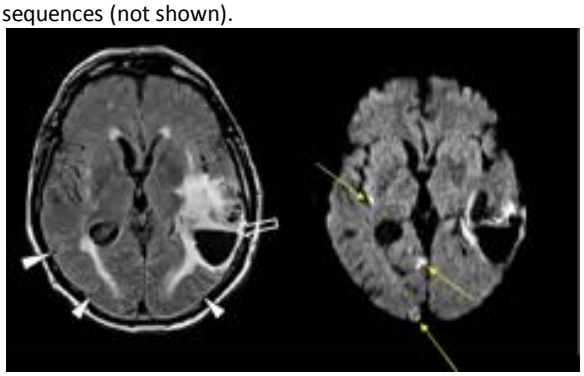
Purpose
To report a case of West Nile virus (WNV) meningoencephalitis initially presenting as intraparenchymal hemorrhage.
Case Report
A 79-year-old male with a past medical history of hypertension and vascular dementia presented with several days of high fevers to 103, shaking chills, and rigidity. Initial examination demonstrated paratonia, meningeal signs including neck stiffness, and a GCS of 11. Blood pressure early in the patient's hospital course was noted to be as high as 170/80 mmHg. Cerebrospinal fluid analysis revealed elevated WBC (265 per mm^3) and protein (134 mg/dL). CT scan revealed a large left temporal lobe intraparenchymal hematoma. MR imaging revealed several predominantly cortical foci of diffusion signal in the right cerebral hemisphere and FLAIR sulcal hyperintensity bilaterally. CT angiography and catheter

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

angiogram were negative for underlying vascular anomaly or vasculitis. Cerebrospinal fluid analysis by PCR later revealed WNV infection, and the diagnosis of WNV meningoencephalitis was made. The patient showed improvement in alertness and mental status following treatment with a five-day course of IVIG and blood pressure control.

Imaging Findings

Axial FLAIR MRI reveals a 4.9 x 4.1 cm parenchymal hemorrhage centered in the left temporal lobe. In addition there is extensive sulcal hyperintensity throughout both cerebral hemispheres (Figure 1). Diffusion-weighted images demonstrate multifocal areas of restricted diffusion involving the right insular cortex and medial right occipital lobe (Figure 2). No abnormal parenchymal or leptomeningeal enhancement was shown on postcontrast sequences (not shown).



Summary

West Nile virus is a widespread mosquito-borne infectious agent with cases of meningoencephalitis reported throughout the United States. Roughly 1/150 of infected patients will develop CNS syndromes of meningitis, encephalitis, and acute flaccid paralysis/poliomyelitis. Imaging findings are typically absent; however, T2/FLAIR abnormalities in the deep gray matter and brain stem as well as diffusion abnormalities in the white matter including the corona radiata and internal capsule have been described. This patient had several atypical features including predominantly cortical diffusion restriction and leptomeningeal FLAIR signal in addition to intraparenchymal hemorrhage. Our patient also had a history of hypertension which may have made him more prone to develop intraparenchymal hemorrhage. It is still unclear whether the patient suffered from an unusual sudden onset of WNV meningoencephalitis manifested as multifocal infarction/hemorrhage or whether those same areas made the patient more susceptible to developing WNV meningoencephalitis.

KEYWORDS: Meningoencephalitis, Hemorrhage, West Nile virus

Teratoma-Associated Anti-NMDA Receptor Encephalitis

Hong, Y.·Opatowsky, M. J.·O'Connor, J. C.·Layton, K. F.
Baylor University Medical Center
Dallas, TX.

Purpose

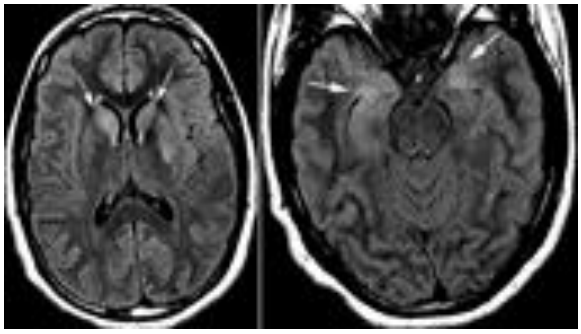
To present the clinical course and MRI findings associated with a case of anti-NMDA (N-methyl-D-aspartate) receptor encephalitis.

Case Report

A 20-year-old woman presented with status epilepticus and subsequently was found to have serum anti-NMDA receptor antibodies associated with a pathology-proven benign cystic teratoma of the ovary. Initial MRI findings in this clinical setting were compatible with paraneoplastic limbic encephalitis. Surgical resection of the ovarian teratoma, plasmapheresis, and adjuvant chemotherapy were performed with near complete resolution of MRI findings although status epilepticus persisted and continued clinical decline resulted in eventual withdrawal of advanced supportive care.

Imaging Findings

Initial MRI demonstrated extensive FLAIR signal elevation in the bilateral deep gray nuclei and mesial temporal lobes including the hippocampi, compatible with paraneoplastic limbic encephalitis in the setting of a benign cystic teratoma of the ovary and serum anti-NMDA receptor antibodies. Two weeks after surgical resection of the ovarian teratoma, a repeat MRI demonstrated near complete interval resolution of the initial imaging abnormalities.



Summary

Although paraneoplastic limbic encephalitis is a well-known entity, the association with anti-NMDA receptor antibodies has been described only recently and appears to be primarily associated with teratomas. The best treatment at this time is thought to be surgical resection of the teratoma with supportive care.

KEYWORDS: Paraneoplastic, Limbic encephalitis, NMDA

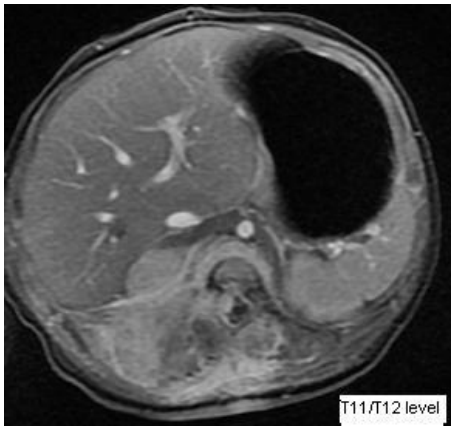
Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

O-163 **5:15 PM - 5:20 PM**

Thirty-Five-Day Old with an Expanding Bruise on the Infants Back

Trinh, V.·Ngo, M.
Kaiser Permanente Los Angeles Medical Center
Los Angeles, CA.

Purpose
To present a case of paraspinal Kaposiform hemangioendothelioma and illustrate the association of this lesion with Kasabach-Merritt phenomenon.
Case Report
A 35-day-old infant without history of trauma found to have an expanding bruise on the back and associated marked thrombocytopenia.
Imaging Findings
X-ray of the spine demonstrates loss of visualization of the right T11/T12 pedicles suggesting erosion. Follow-up postcontrast fat suppressed MRI demonstrates a heterogeneously enhancing right paraspinal mass that has eroded the adjacent pedicle with evidence of retroperitoneal and epidural extension into the spinal canal.



Summary
There is a wide spectrum of pediatric soft-tissue tumors ranging from benign to malignant and/or vascular and nonvascular lesions. The majority of pedatric soft-tissue lesions will be vascular or lymphatic in origin. Kaposiform hemangioendothelioma is a vascular lesion that can be differentiated from a common hemangioma of infancy due to its aggressive nature on imaging and also its association with Kasabach-Meritt pheonomenon (>50% of cases), a profound thrombocytopenia thought related to platelet trapping as the lesion grows in size.

KEYWORDS: Pedicle, Pediatric spine, soft tissue

Imaging Manifestations of Pseudomonas Aeruginosa Chondritis of the Thyroid Cartilage

Howard, E. A.·Gomez, C.·Weprin, L. S.·Opatowski, M. J.
Baylor University Medical Center
Dallas, TX.

Purpose
To describe imaging findings of purulent chondritis of the thyroid cartilage secondary to pseudomonas aeruginosa.
Case Report
A 52-year-old male with end-stage liver disease developed increasing hoarseness over one month. Initial CT of the neck demonstrated mild laryngeal edema. Laryngoscopy showed edematous vocal cords. One month after the first CT, the patient developed acute respiratory distress and CT of the neck showed interval destruction of the thyroid cartilage and replacement by low density collections. Differential considerations included granulomatous, infectious and less likely neoplastic processes. Laryngoscopy and tracheotomy were emergently performed. Biopsies revealed purulent chondritis of the thyroid cartilage, with cultures positive for pseudomonas aeruginosa. Imaging after tracheotomy and intravenous antibiotics showed resolution of abscesses centered at the site of the thyroid cartilage and dissipation of laryngeal edema.
Imaging Findings
CT of the neck performed one month prior to admission

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

showed laryngeal edema without cartilaginous destruction. CT of the neck with contrast at the time of admission (Image 1) shows interval worsening of edema of the false cords, aryepiglottic folds and epiglottis. The ventral cords and glottis also demonstrate edema and an ill-defined enhancing 1 cm soft tissue mass at the anterior midline of the glottis. The thyroid cartilage demonstrates interval subtotal replacement by low-density fluid collections with faint rim enhancement. No surrounding inflammatory change or enlarged cervical lymph nodes are seen. Intraoperative images provide correlation for CT findings. Two follow-up CTs of the neck reveal postoperative changes of laryngotomy with evacuation of fluid collections centered at the area of the thyroid cartilage. The enhancing soft tissue component at the glottis had largely resolved.

Summary

Purulent chondritis of the laryngeal cartilages is a rare entity that has been described in case reports as having a subacute clinical course. Etiologies include history of relapsing polychondritis or previous prolonged intubation. Infectious agents previously reported include staphylococcus aureus, aspergillus fumigatus, and a single case report of pseudomonas aeruginosa. Imaging findings in this case are most notable for destruction of the majority of the thyroid cartilage and replacement by low-density collections with mild peripheral enhancement and little surrounding inflammatory change. Due to the subactue time course of PCLC, differential considerations including neoplastic and granulomatous lesions should be considered. This case emphasizes that infectious processes may occur in the laryngeal cartilages, and must be kept in mind and considered a viable differential diagnosis when such imaging findings are encountered.

Eagle Has Landed: Internal Carotid Pseudoaneurysm and Subsequent Stent Erosion Secondary to an Elongated Styloid Process

Burns, P. A.[1]·Almekhlafi, M. A.[1,2]·Yavin, D.[1]·Morrish, W.[1]·Eesa, M.[1]·Goyal, M.[1]·Mitha, A. P.[1]
[1]University of Calgary, Calgary, AB, CANADA, [2]King Abdulaziz University, Jeddah, SAUDI ARABIA.

Purpose

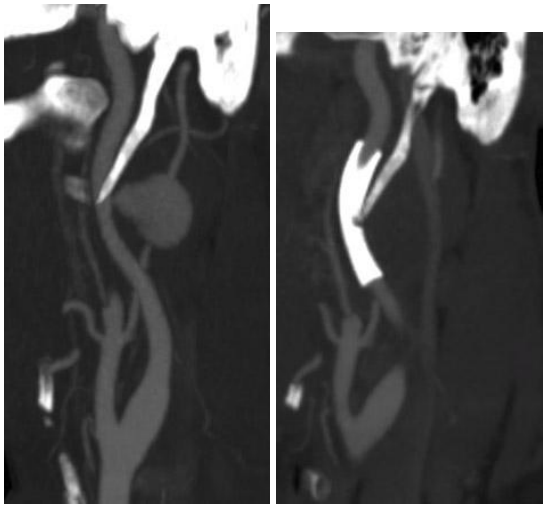
To report an unusual case of post-traumatic internal carotid pseudoaneurysm secondary to Eagle syndrome and subsequent stent erosion by the offending elongated styloid process.

Case Report

A 45-year-old man presented with a two-week history of left-sided neck pain and voice hoarseness after he fell while snowboarding. Examination showed partial left ptosis, tongue deviation to the left and weak left palate elevation. CT angiogram demonstrated a left internal carotid pseudoaneurysm arising from the lateral wall adjacent to the tip of an elongated styloid process(Figure 1). This measured approximately 18 x 15 mm (transverse x craniocaudal) with a 2 mm neck. These findings also were confirmed with catheter angiography. Double antiplatelet therapy was commenced and two days later the pseudoaneurysm was treated using a 7 x 30 mm carotid WALLSTENT (Boston Scientific Corp., Natick, Massachusetts) deployed over the aneurysm neck. An ultrasound performed 24 hours poststenting showed that the majority of the aneurysm was thrombosed, with only a small amount of residual flow. The patient re-presented two weeks later following an episode of transient global amnesia. CT angiography confirmed stent patency; however a focal defect in the stent wall approximate to the styloid process was identified (Figure 2). The pseudoaneurysm was completely thrombosed. A stent fragment embolus was noted within the left parietal lobe, although no focal infarct was seen. This was confirmed with MRI performed on the same day. The styloid process was ultimately resected six weeks later.

Imaging Findings

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Summary
Vascular complications secondary to Eagle syndrome are unusual and typically involve carotid dissection. Transient ischemic attacks also can occur secondary to stylo-carotid compression. This case illustrates not only the potential for traumatic pseudoaneurysm, but also demonstrates the traumatic effect the elongated styloid process can have on an endovascular stent within a relatively short time frame.

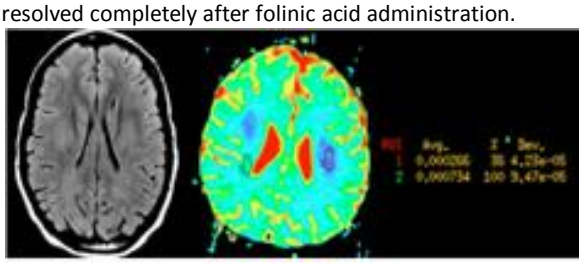
KEYWORDS: Aneurysm formation, Aneurysm treatment, Eagle syndrome

O-166 **5:30 PM - 5:35 PM**

Acute Pyrimethamine Toxicity: MR Imaging Findings

Trunet, S.[1]·Galanaud, D.[1]·Gerber, S.[1]·Jarquin, S.[1]·Henry, C.[2]·Dormont, D.[1]·Leclercq, D.[1]
[1]Hôpital de la Pitié Salpétrière, Paris, FRANCE, [2]Hôpital de Saint Denis, Saint Denis, FRANCE.

Purpose
To present the first reported case of pyrimethamine neurotoxicity. Pyrimethamine commonly is used in the treatment of toxoplasma gondii infections in immunocompromised patients, such as HIV-positive individual. Pyrimethamine is an antifolate drug, like methotrexate. Both molecules interfere with tetrahydrofolic acid synthesis from folic acid by inhibiting the dihydrofolate reductase. Methotrexate can induce acute white matter neurotoxicity with a typical imaging pattern. The pathophysiology of this neurotoxicity is poorly understood, but folate implication is suspected. The purpose of this presentation is: 1. to present the clinical and MRI aspects of pyrimethamine toxicity. 2. Discuss the physiopathology of pyrimethamine and methotrexate toxicity.
Case Report
A 20-year-old immunocompetent woman was addressed to our institution with sudden right hemiparesis associated with confusion and mutism.
Image Findings
An MRI performed the same day showed symmetrical areas of restriction diffusion with discrete high-signal T2 intensity in the centrum semiovale as is commonly observed in acute methotrexate-related leukoencephalopathy: Anamnesis revealed that the patient had been taking pyrimethamine without supplementary folinic acid for the past threee weeks to treat a suspicion of toxoplasmic retinitis. Symptoms resolved completely after folinic acid administration.



Summary
We present the first reported case of pyrimethamine toxicity in a young adult treated for toxoplasmic retinitis. Clinical presentation and MRI findings were similar to acute methotrexate toxicity: stroke-like episode and symmetrical centrum semiovale restricted diffusion areas. Since both pyrimethamine and methotrexate are antifolate drug, this case report suggests that acute methotrexate neurotoxicity is indeed folate-related.

KEYWORDS: pyrimethamine, intoxication, folinic acid

O-167 **5:35 PM - 5:40 PM**

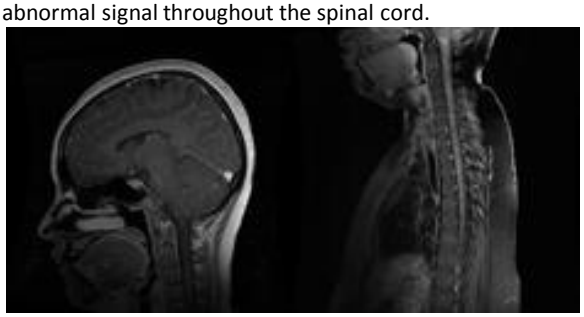
Chronic Lymphocytic Inflammation with Pontine Perivascular Enhancement Responsive to Steroids

Wang, B.·Fuller, G.·Ketonen, L.
M. D. Anderson Cancer Center
Houston, TX.

Purpose
To illustrate the imaging findings of CLIPPERS, which to our knowledge has not been reported in radiology literature. Our purpose is to raise awareness of the neuroradiology community concerning this unique recently described disease.
Case Report
A 35-year-old right-handed woman with a one-year history of fatigue, generalized aches and low-grade fever was found to have Hodgkin lymphoma. She underwent spine and brain MRI which showed diffuse nodular enhancement. CSF cytology was obtained twice with no evidence of malignancy. The patient underwent biopsy of the meninges and brain parenchyma, which showed reactive perivascular lymphocytic infiltrates consisting primarily of CD3-positive T cells. There was no morphologic or immunophenotypic evidence of Hodgkin lymphoma or of Hodgkin-associated giant cell arteritis.
Imaging Findings

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

On the brain MRI, diffuse nodular enhancement is seen extending along the perivascular spaces throughout the brain including along the pituitary stalk. Extensive parenchymal enhancement also is seen throughout brain stem, all compatible with advanced perivascular disease with parenchymal involvement. The CSF spaces on the T2 FLAIR images are well defined, contrary to expected findings in LMD. On the spine MRI, there is diffuse nodular enhancement along the entire spine along with foci of abnormal signal throughout the spinal cord.



Summary
Chronic lymphocytic inflammation with pontine perivascular enhancement responsive to steroids (CLIPPERS) is a central nervous system (CNS) inflammatory disease that was defined initially in 2010 in a case series of eight patients with common clinical, radiologic, and pathologic features of brainstem involvement that was responsive to and dependent on corticosteroid therapy. The diagnostic criteria for CLIPPERS include the following: (1) episodic brainstem symptoms, (2) characteristic punctuate and curvilinear gadolinium-enhancing lesions peppering the brainstem, especially in the pons, and (3) T-lymphocytic infiltrate with perivascular predominance in brain biopsy specimens. CLIPPERS is a treatable relapsing-remitting disorder without progressive forms. It has been suggested that a diagnosis of CLIPPERS can be made without brain biopsy if the characteristic clinical and MR imaging features are present and if alternative diagnoses are excluded. This particular case has extensive perivascular enhancement involving bilateral cerebral hemispheres and the entire spinal cord, in addition to the characteristic pattern of punctate and curvilinear enhancement peppering the pons. To our knowledge, this recently recognized disease has yet to receive attention in the neuroradiology literature. Although relatively rare, neuroradiologists should be aware of this entity and consider it in the differential diagnosis when the characteristic features are encountered.

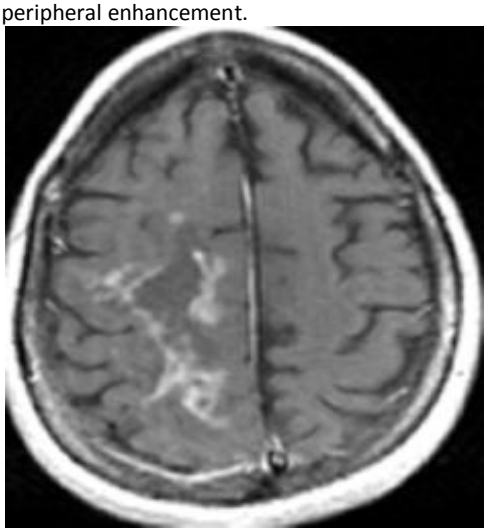
KEYWORDS: Brain disease, Spinal cord, CLIPPERS

O-168 **5:40 PM - 5:45 PM**

Inflammatory Progressive Multifocal Leukoencephalopathy following Natalizumab Withdrawal

Hanley-Knutson, K.·Kinder, K.
Santa Barbara Cottage Hospital
Santa Barbara, CA.

Purpose
Natalizumab (Tysabri) is an immunosuppressive drug indicated for treatment of multiple sclerosis and Crohn's disease that has been linked to a number of cases of progressive multifocal leukoencephalopathy (PML). In rare instances, this can progress to inflammatory progressive multifocal leukoencephalopathy (iPML) following discontinuation of the medication.
Case Report
A 38-year-old woman with refractory multiple sclerosis on natalizumab presented to the emergency room with worsening neurologic symptoms. She had an MRI of her brain that was compatible with PML and, as a result, was taken off of natalizumab. She continued to have worsening neurologic symptoms and a follow-up MRI of her brain was concerning for iPML.
Imaging Findings
In addition to baseline MS findings, the initial MRI in the ER revealed new confluent areas of T2/FLAIR hyperintensity in the subcortical white matter in the high right frontal lobe that were volume neutral and did not enhance with contrast. On the MRI performed after stopping natalizumab, the same region of T2/FLAIR hyperintensity had enlarged, demonstrated mass effect on surrounding cortex, and was associated with avid peripheral enhancement.



Summary
Progressive multifocal leukoencephalopathy is a demylinating process that results from activation of the JC virus in immunocompromised patients and has been linked to the use of natalizumab and similar immunologic agents. Cessation of immunosuppressive therapy is indicated in the setting of PML, but can result in immune

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

reconstitution inflammatory syndrome (IRIS), the CNS manifestation of which is iPML. Progressive multifocal leukoencephalopathy and iPML both preferentially involve the subcortical U-fibers, but can be differentiated on MRI. Specifically, iPML, unlike PML, typically is associated with mass effect and peripheral enhancement, as was seen in this case.

KEYWORDS: Leukoencephalopathy, Multiple sclerosis

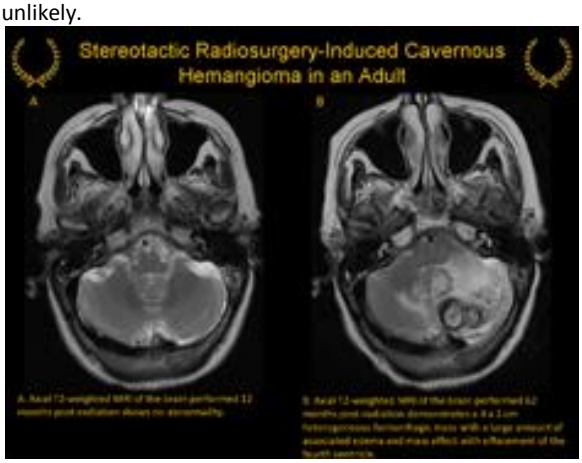
Stereotactic Radiosurgery-Induced Cavernoma in Adults: A Rare but Important Entity

Thurlow, P. C.·Goldberg, M. F.
West Penn Allegheny Health System
Pittsburgh, PA.

Purpose
Cavernomas, or cavernous hemangiomas, are CNS vascular lesions comprised of thin-walled, dilated venous channels without intervening brain tissue. A growing and well established literature supports the correlation between childhood radiation to the brain and cavernomas. However, cavernoma formation in adults that have received radiation to the brain is a very rare entity and can represent a diagnostic dilemma. We report a unique and rare case of stereotactic radiosurgery (SRS)-induced cavernoma in an adult. The purpose of this report is to increase the awareness of SRS-induced cavernomas in adults and highlight an unusual presentation of this rare entity.
Case Report
A 77-year-old woman presented 62 months following SRS for a tentorial Borden type-1 dural arteriovenous fistula (AVF) with progressive ataxia and short-term memory loss. MR imaging revealed a left cerebellar mass that was felt to be radiation necrosis with a hemorrhagic component rather than a neoplasm. The patient subsequently underwent third ventriculostomy with symptomatic improvement. Follow-up MRI performed two months later revealed a heterogeneously enhancing mass in the left cerebellum with a large amount of surrounding edema; mass effect resulted in effacement of the fourth ventricle with associated obstructive hydrocephalus. Over the course of the next six months, the mass demonstrated progressively increasing size and mass effect. Owing to the increasing size of the lesion and mass effect with hydrocephalus and cerebellar tonsillar herniation, the decision was made to proceed to primary resection of the mass via suboccipital craniotomy. Surgical pathology of the vascular mass confirmed a diagnosis of cavernous hemangioma.
Imaging Findings
The patient's initial post-radiation MRI demonstrated no abnormality at the site of SRS. Sixty-two months later, when the patient presented with ataxia, there was a 4 x 2 cm heterogeneous enhancing hemorrhagic mass with a large amount of associated edema. Over the next six months, there was progression in size and mass effect, ultimately measuring 6 x 4 cm. The mass demonstrated a heterogeneous "popcorn" appearance with a hypointense rim on T2-weighted images and susceptibility artifact on gradient-echo images. However, given the highly aggressive behavior of this mass, as well as age of the patient at the time of SRS, cavernoma was considered unlikely.



Summary
We present an atypical, highly-aggressive SRS-induced cavernoma. Given increasing role of SRS in clinical practice, the radiologist should be aware of the association between cavernous malformation and radiation therapy when encountering an atypical intracranial mass.

KEYWORDS: Cavernoma, Radiation

O-172 **6:00 PM - 6:05 PM**

Atypical Growth of Persistent Restricted-Diffusion Associated with Atypical Necrosis in Bevacizumab and Radiotherapy-Treated Anaplastic Oligodendroglioma

Chen, J. Y.[1,2]·Lee, R.[1,2]
[1]University of California San Diego Health System, La Jolla, CA, [2]San Diego Veterans Administration Medical Center, La Jolla, CA.

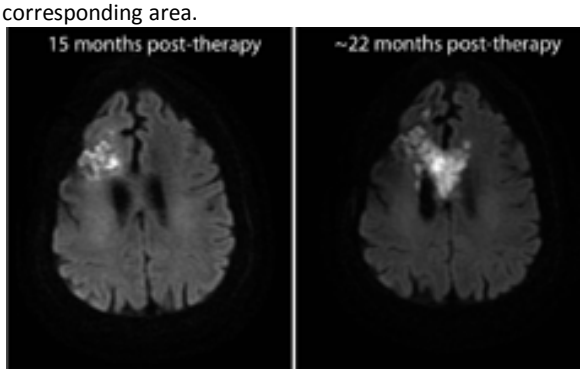
Purpose
Atypical or gelatinous necrosis, manifested by marked restricted diffusion and stippled peripheral enhancement mimicking cellular tumor progression, has been described in high-grade primary neoplasms after treatment with radiation and bevacizumab. A previous case series demonstrated that this atypical necrosis remains stable in volume over a six-month follow-up period, but may increase in volume a median of 23%. The purpose of this submission is to describe a case of atypical growth of atypical necrosis, which increased in volume by approximately 225% during a seven-month follow-up period.
Case Report

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

A 43-year-old right-handed male with a right frontal anaplastic oligodendroglioma with a 1p/19q deletion underwent a gross-total surgical resection and was treated with radiotherapy and chemotherapy using temozolomide and subsequently bevacizumab. After 15 months, the patient developed a rim of presumed atypical necrosis around the resection cavity, which subsequently increased in volume over seven and a half months to approximately 225% times the initial volume without developing new clinical symptoms.

Imaging Findings

Fifteen months after beginning therapy, a rim of marked restricted-diffusion with stippled peripheral enhancement developed around the periphery of the resection cavity. The area had low relative blood volume on susceptibility-weighted perfusion and photopenia on FDG-PET, and was thought to represent atypical necrosis. The area of restricted-diffusion and enhancement continued to enlarge on subsequent follow-up MRIs and by 22 1/2 months after beginning therapy, had increased in volume by approximately 225%. There was no significant change in ADC values and perfusion-weighted images again demonstrated low relative blood volume. Subsequent FDG-PET again demonstrated photopenia in the corresponding area.



Summary

Atypical necrosis associated with primary neoplasms treated with radiotherapy and bevacizumab may mimic progressive cellular neoplasm due to its marked restricted diffusion. Reports have described stability or mild median enlargement of the necrotic area, this case demonstrates more than doubling of lesion size which did not result in new symptoms or a change in therapy.

KEYWORDS: Necrosis, Tumor-like conditions, bevacizumab

O-173 **6:05 PM - 6:10 PM**

Supplemental Motor Area Syndrome after Colloid Cyst Resection

Hernandez, R. J.·Minja, F. J.
Yale University
New Haven, CT.

Purpose

Revisit the clinical features and radiographic findings of the supplemental motor area (SMA) syndrome. Highlight the anatomical location of the SMA with fMRI correlates and stress the importance of the knowledge of functional anatomy in diagnostic imaging.

Case Report

A 31-year-old gentleman presented to the emergency department with altered awareness. Initial CT demonstrated a hyperdense mass in the third ventricle with obstructive hydrocephalus. MR imaging revealed a corresponding T1 hyperintense cystic mass, with hydrocephalus, and transependymal cerebral spinal fluid flow. A presumptive diagnosis was made of a colloid cyst. The patient underwent shunting and transcallosal resection of the cyst. Postoperatively the patient had a significant left-sided motor deficit. Repeat MRI showed expected postoperative changes and a small area of restricted diffusion in the right paracentral lobule corresponding to the SMA. The restricted diffusion was thought to represent cytotoxic edema secondary to operative retraction. In light of the clinical findings, SMA syndrome was suggested as a diagnosis. By postoperative day four, the patient had improved strength and one month later had completely recovered.

Image Findings

Initial CT without contrast demonstrated a 1.1 cm hyperdense mass in the third ventricle with obstructive hydrocephalus. MR imaging with contrast revealed a corresponding T1 hyperintense cystic mass with hydrocephalus and transependymal cerebral spinal fluid flow. Postoperative MRI with contrast showed a left frontal ventricular shunt catheter, postoperative changes related to transcallosal resection of the cyst, improved hydrocephalus, moderate hemorrhage in the lateral ventricles, and a small area of restricted diffusion in the right medial aspect of the superior frontal gyrus (paracentral lobule) which corresponds to the SMA.

Summary

The SMA syndrome refers to pathology of the SMA producing a contralateral motor deficit which can mimic a pyramidal or motor cortex injury. The syndrome presents with difficulty in initiating movement or apraxia and is most commonly described postoperatively in resected tumors of the SMA. However, in contrast with pyramidal damage most patients have significant recovery with minimal residual deficit. The importance of the SMA is sometimes forgotten and its anatomical location is sometimes misplaced. However, as fMRI becomes more pervasive, the SMA has become increasingly visible as it is

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

ubiquitously activated when localizing the motor cortex. It is located in the paracentral lobule or medial aspect of the superior frontal gyrus in what corresponds to the medial aspect of Brodmann area 6. It is thought to have a somatotopic organization and is responsible for the coordination of movement. This case reinforces the benefits of accurate functional anatomical knowledge. When pathology is localized to the SMA, one should report this fact, suggest the potential clinical presentation, and even propose a positive prognosis.

Carotidynia: A Trauma, Infectious or Fluoxetine-Induced Inflammatory Process on Imaging

Feltus, W. Y.[1,2]·Rojas, R.[1,3]·Moonis, G.[1,3]
[1]Beth Israel Deaconess, Boston, MA, [2]Wake Forest School of Medicine, Winston Salem, NC, [3]Harvard Medical School, Boston, MA.

Purpose
Carotidynia is a transient inflammatory condition characterized by unilateral neck pain and enhancing soft tissue thickening surrounding the carotid artery. The cause of the condition remains unknown. Prior to its removal from the classification system of headaches, few reports were published about the radiographic characteristics of carotidynia, which have since provided enough evidence to classify it as a separate and distinct entity.
Case Report
A 21-year-old male presented to the emergency department with sharp pain at the angle of his left jaw which began three weeks prior to being struck in the temple by an elbow. His medical history was significant for use of Symbyax which was discontinued around the time of his presentation. The patient's exam and laboratory workup was also unremarkable except for pain with palpation of the neck on the left. He was discharged three days later with near resolution of his symptoms on oral antibiotics.
Imaging Findings
A CTA of the head and neck was obtained and showed a soft tissue infiltration around the left common and internal carotid artery extending into the parapharyngeal region, compression of the left internal jugular vein with impaired venous drainage, and a small effusion in the retropharyngeal space. An MRI of the head and neck also revealed mild enhancing T2 signaling of the soft tissue density surrounding the left carotid artery, and small reactive cervical lymph nodes with no evidence of an abscess.

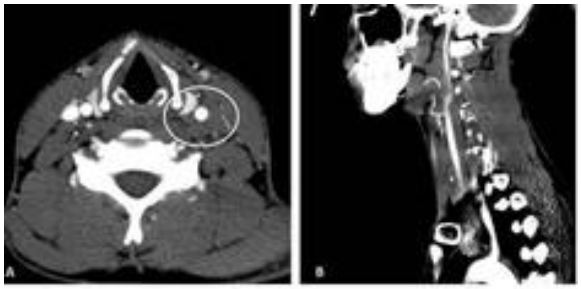

Figure 1. Circumferential soft tissue thickening along the length of the cervical portion of the left carotid artery on contrasted axial (A) and sagittal (B) CTA of the head and neck.

Summary
One case reported fluoxetine-induced carotidynia that resolved with discontinuation of the drug. The exact mechanism is unknown but there have been reports of fluoxetine-induced serum sickness and other hypersensitivity reactions to the medication. Our patient was afebrile with a normal CBC throughout his hospital course. Whether this case is a postinfectious or post-traumatic reaction is unknown. No particular bacteria or pathogen has been isolated in carotidynia, and laboratory values that would indicate an infection are typically normal. The imaging characteristics found in carotidynia separate it from other pathologies of the carotid artery including atherosclerosis, dissections, aneurysms and vasculitis. It is critical to recognize these conditions early on, further warranting a separation of carotidynia from the class of potentially fatal conditions. Although many causes have been linked to the carotidynia, the distinction between this inflammatory condition and other causes of pain in the neck has been provided by its imaging characteristics.

KEYWORDS: Carotid artery, Inflammatory

What Is That Fat Doing in the Thyroid?: Case Discussion and Brief Review of Fat-Containing Lesions of the Thyroid

Fredriksen, J. R.·Morris, J. M.
Mayo Clinic
Rochester, MN.

Purpose
To describe the imaging characteristics of an amyloid goiter and review the rare fat-containing lesions in the thyroid.
Case Report
A 58-year-old male with a past medical history of a renal transplant secondary to chronic glomerulosclerosis and amyloid deposition presented to our institution with an enlarging neck mass in the region of the thyroid. On physical exam he had firm diffuse enlargement of the thyroid gland without nodularity. Clinically and by laboratory testing he was euthyroid. A CT scan was obtained demonstrating diffuse fatty infiltration of an

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

enlarged thyroid (see imaging findings). Ultrasound-guided fine needle aspiration yielded amyloid deposits staining with Congo red. Liquid chromatography and mass spectroscopy then was performed on peptides extracted from the tissue staining with Congo red detecting a peptide profile consistent with serum amyloid A type amyloid. The patient was treated conservatively as he was euthyroid at the time.

Imaging Findings

Axial noncontrast CT of the neck with coronal reformats demonstrates diffuse fatty infiltration of a markedly enlarged thyroid. Internal soft tissue nodules and soft tissue stranding was seen within the gland. The lesion extended superiorly bilaterally wrapping posteriorly around the thyroid cartilage into the retropharyngeal space with mass effect on the hypopharynx.

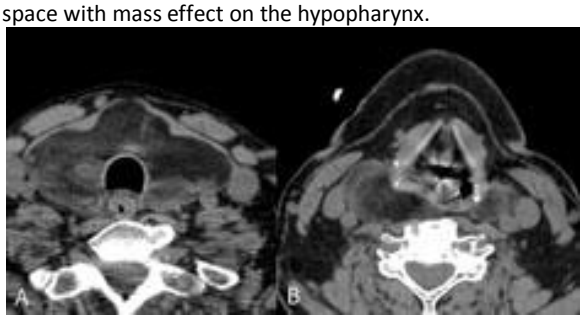

Figure 1.

Summary

Thyroid lesions containing macroscopic fat either radiographically or histopathologically are extremely rare and include amyloid goiter, thryrolipomatosis, liposarcoma, lymphocytic thyroiditis, thyrolipoma/adenolipoma of the thyroid, hamartomatous adiposity of the thyroid, and papillary carcinoma with macroscopic fat. Similarly diffuse enlargement of the thyroid by amyloid infiltration is a rare complication of systemic amyloid and in a minority of these patients can be the presenting sign of systemic disease. These rare lesions have been addressed from a histopathologic standpoint in the medical literature mainly in the form of case reports or small case series. However, little has been written regarding the radiographic evaluation of fat-containing lesions of the thyroid. We present this case to review the findings of amyloid goiter as well as the findings in other fat-containing lesions of the thyroid. Neuroradiologists should be aware that in a patient with known systemic amyloidosis who is euthyroid and has an enlarging thyroid gland that amyloid goiter is high on the differential diagnosis and can present with macroscopic fatty infiltration. FNA may be needed to make the diagnosis and surgery may be necessary due to compressive symptoms.

Reversible Diffusion Restriction of the Middle Cerebellar Peduncles and Dentate Nucleus in Acute Respiratory Syncytial Virus Cerebellitis

Tang, Y.[1]·Suddarth, B.[1]·Du, X.[2]·Matsumoto, J. A.[3]
[1]Virginia Commonwealth University, Richmond, VA, [2]Hunter Homles Mcguire VA Medical Center, Richmond, VA, [3]University of Virginia, Charlottesville, VA.

Purpose

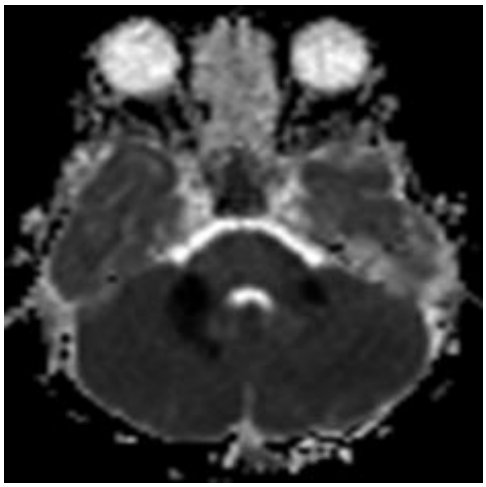
To report a rare case of acute RSV cerebellitis.

Case Report

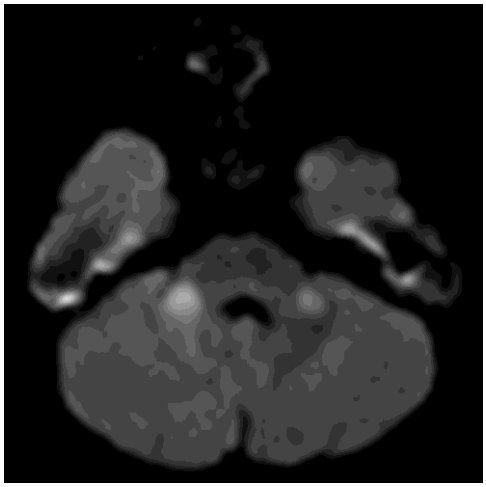
A previously healthy three-year-old girl presented with altered mental status and fever after one week of cough and congestion. Nonenhanced head CT was negative except for bilateral mastoid effusions. The lumbar puncture revealed mild CSF pleocytosis, normal protein, glucose, lactate and negative cultures. The nasal aspirate tested positive for RSV. Two days after admission, the patient developed progressive hypotonia and cerebellar mutism. A contrast-enhanced head MRI was suggestive of acute cerebellitis. The patient significantly improved after a five-day course of intravenous methylprednisolone. At the six-month follow-up, she had returned to her baseline.

Imaging Findings

Initial head MRI demonstrated symmetric restricted diffusion of both middle cerebellar peduncles and the right dentate nucleus (Figure). There was corresponding mild FLAIR hyperintensity and no abnormal contrast enhancement. There were no other lesions. Repeat head MRI five days after the initiation of steroid treatment showed resolution of the diffusion and FLAIR abnormalities.



Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Summary
Acute cerebellitis is a rare postinfectious or postvaccinal inflammatory disorder that can present with fever, headache, altered mental status and cerebellar symptoms. The classic imaging appearance is transient edema involving the gray and white matter of the cerebellar hemispheres. The involvement of dentate nuclei is associated with cerebellar mutism. It is important to recognize that diffusion restriction of the middle cerebellar peduncles or dentate nucleus can be an imaging manifestation of acute cerebellitis, as has been reported previously in cases of rotavirus gastroenteritis. Our case expands these DWI abnormalities to include RSV as an associated pathogen. The transiently reduced diffusion may be due to intramyelinic edema, interstitial edema in tightly packed fibers, or a transient inflammatory infiltrate. Differential diagnoses include acute demyelinating encephalomyelitis (ADEM), infarction of the anterior inferior cerebellar artery (AICA) territories and toxic/metabolic encephalopathies.

Utility of Susceptibility-Weighted and Constructive Interference in Steady-State Sequences in the Evaluation of Hydrocephalus in the Newborn

Williams, S. C.·Saigal, G.
University of Miami
Miami, FL.

Purpose
Susceptibility-weighted imaging (SWI) is a magnetic resonance imaging (MRI) technique that is highly sensitive for blood, iron, and calcium deposition in the brain. In certain neonatal neurologic disorders such as traumatic brain injury, coagulation disorders, vascular malformations, cerebral infarction, neoplasms, and neurodegenerative disorders, Susceptibility-weighted imaging has an established role. In the evaluation of hydrocephalus in the newborn, SWI traditionally is not performed. However, in unexplained neonatal hydrocephalus, SWI can play an important role by demonstrating blood products in the ventricles and subarachnoid spaces. Constructive interference in steady state (CISS) is a gradient-echo MRI sequence with increased sensitivity for differentiating cerebrospinal fluid (CSF) intensity from pathologic structures. Constructive interference in steady state provides superior topographic information that helps to delineate the exact location of various cranial pathologies, and is useful in evaluating aqueductal stenosis. The purpose of this exhibit is to demonstrate the utility of SWI and CISS sequences in the evaluation of hydrocephalus in newborns by helping to differentiate congenital aqueductal stenosis from acquired aqueductal stenosis.
Case Report
Five patients underwent conventional MR imaging which demonstrated enlargement of the lateral and third ventricles without enlargement of the fourth ventricle, indicating obstructive hydrocephalus.
Imaging Findings
Etiology of the obstructive hydrocephalus was not determined on standard imaging. Addition of SWI and CISS sequences helped to differentiate acquired aqueductal stenosis from congenital aqueductal stenosis. In three cases, SWI demonstrated hemorrhage along the ventricles and cerebral aqueduct suggesting an acquired cause for the obstructive hydrocephalus. In the remaining two cases, CISS sequence demonstrated a clear narrowing of the cerebral aqueduct to indicate congenital aqueductal stenosis.
Summary
Susceptibility-weighted imaging and CISS are useful sequences in the evaluation of neonatal hydrocephalus at the level of the cerebral aqueduct. Susceptibility-weighted imaging increased the diagnostic sensitivity and specificity of MRI for evaluation of hemorrhage that was not evident on standard sequences. Constructive interference in steady state imaging increased the diagnostic sensitivity for determining congenital aqueductal stenosis in cases where SWI was negative. Therefore, inclusion of SWI and CISS sequences in the standard neonatal brain MRI protocol when evaluating for hydrocephalus should be considered.

KEYWORDS: Hydrocephalus, Aqueductal stenosis, SWI and CISS

(19) Maintenance of Certification Review Session – Pediatrics (AR)

O-178 **7:30 AM - 8:00 AM**

Pediatric Brain

Moore, K. R.
Primary Children's Medical Center
Salt Lake City, UT.

Presentation Summary
A series of pediatric brain imaging cases will be presented with correlative differential diagnosis and comprehensive discussion. The cases will be selected to be reasonably representative of patients who may be encountered routinely in a pediatric neuroradiology practice as well as periodically in an adult-oriented neuroradiology practice where pediatric patients are imaged as well. The goal of the presentation is to review common and uncommon presentations of important pediatric neurologic disorders, with differential diagnosis discussion, in order to prepare practicing neuroradiologists for the ABR Neuroradiology recertification exam.

O-179 **8:00 AM - 8:30 AM**

Pediatric Head and Neck

Koch, B. L.
Cincinnati Children's Hospital
Cincinnati, OH.

Presentation Summary
This presentation will focus on the differential diagnosis of neck masses in the pediatric population. A variety of congenital and acquired masses will be reviewed, with emphasis on the variable imaging characteristics and location of lesions, to enable the attendee to more appropriately narrow the differential diagnosis when faced with a neck mass in a child. Congenital lesions such as vascular malformations and branchial apparatus cysts will be reviewed. The International Society for the Study of Vascular Anomalies (ISSVA) classification of vascular lesions will be discussed. In addition, the presentation will review a variety of the more common, and a few uncommon, acquired neck masses that occur in children, such as infantile hemangioma, fibromatosis colli, rhabdomyosarcoma, neuroblastoma and neurofibromas. Finally, the various head and neck manifestations of Neurofibromatosis type 1 will be presented.

O-180 **8:45 AM - 9:15 AM**

Current Tools and Concepts for Accelerating Imaging: Parallel Imaging, CS

Roberts, T. P. L.
Children's Hospital of Philadelphia
Philadelphia, PA.

Presentation Summary
This presentation will review the conceptual approaches to faster MRI. As such it will cover the concept of “filling k-space faster”, through shortening TR (transitioning from spin-echo to gradient recalled echo), acquiring multiple lines (FSE/TSE) to single shot approaches (EPI). Approaches capitalizing on certain symmetries of k-space (partial Fourier) will be discussed as well as hybrid approaches (GRASE, HASTE). All sequence approaches will be unified in this theoretical framework. Just when it seems the limits of fast acquisitions have been reached (and only marginal “engineering” improvements are possible), the concept of parallel imaging with multiple receive coils will be introduced (SENSE, GRAPPA), again in the framework of “filling k-space faster”. Finally, a brief introduction to compressed sensing will be presented, again in the unified framework.

O-181 **9:15 AM - 9:45 AM**

What is Compressed Sensing and How Can We Use It?

Nayak, K. S.
University of Southern California
Los Angeles, CA.

Krishna Nayak is an Associate Professor of Electrical Engineering at the University of Southern California (USC), with joint appointments in Biomedical Engineering, Medicine, and Radiology, and is Director of the Magnetic Resonance Engineering Laboratory (http://mrel.usc.edu/). Dr. Nayak received his PhD in Electrical Engineering from Stanford University in 2001, his MS in Electrical Engineering from Stanford in 1996, and BS degrees in Electrical Engineering, Computer Science, and Applied Mathematics from Florida State University in 1995. Dr. Nayak has published 80+ journal papers, 200+ conference papers, and 10+ US patents.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Presentation Summary
Compressed Sensing is a new method for accelerating the acquisition of medical images that is based on compressibility of resulting images. This talk will review the basic principles of CS (how it works, when it works, what happens when it fails), and will explain in detail several emerging applications in Neuro MRI.

O-182 **9:45 AM - 10:15 AM**

Applications of Compressed Sensing and Dynamic Imaging

Law, M.
Keck Medical Center of the University of Southern California
Los Angeles, CA.

Presentation Summary
The objectives for this lecture are to review some of the applications of compressed sensing (CS) in neuroradiology and dynamic imaging. Below are some techniques which can be utilized for accelerating MRI. Compressed sensing is a method of constrained reconstruction to compress imaging data so that faster imaging times can be obtained. This can be applied to conventional neuroimaging and advanced imaging techniques below. Furthermore, imaging which inherently has spatial and temporal sparsity are ideally suited for CS. These include time-resolved 4D MRA, dynamic contrast-enhanced MRI (DCE MRI) and dynamic susceptibility contrast MRI (DSC MRI). Finally multicontrast and synthetic imaging will be reviewed which is another means of reducing the neuroimaging protocol. **• Fast and Ultrafast MRI Techniques. • Parallel Imaging, View Sharing, Compressed Sensing. • Dynamic Imaging, Airway and Speech Imaging. • Advanced Imaging: Perfusion, DWI, DTI, MR Spectroscopy. • DCE MRI, DSC MRI, Time Resolved MRA. • Multicontrast Imaging, Synthetic Imaging.**

The presentation will discuss preclinical and clinical data which provide insight into the mechanism of action of flow diverters to treat brain aneurysms.

O-184 **9:15 AM - 9:45 AM**

Flow Diverters: Application and Issues

Moran, C. J.
Washington University School Of Medicine
St. Louis, MO.

Presentation Summary
Imaging of the patient treated with flow diversion devices [Pipeline embolization device (PED), eV3 Neurovascular/Covidien, Inc., Minneapolis, MN] has three phases. Preprocedural, intraprocedural, and postprocedure. Each of the imaging modalities [computerized tomography (CT), magnetic resonance imaging (MR), digital subtraction angiography (DSA)] have strengths and weaknesses in evaluating the candidate for flow diversion, undergoing flow diversion, or being followed to determine the adequacy of treatment. In the preprocedure evaluation, CT, CTA, MR, and MRA identify many of the aneurysms suitable for flow diversion. In addition, they depict the relationships of parent arteries to the treatment aneurysm as well as characterizing the lumen and wall. They do not seem to be completely accurate in generating measurements for device sizing. They are very useful in characterizing the brain and other intracranial contents. 2. Most important to intraprocedural imaging is the quality of the digital subtraction image and its accuracy with calibration. Fluoroscopy must be of high quality so that the device can be positioned correctly and deployed. Most equipment has a lower radiation exposure for the fluoroscopic mode and has an available radiographic exposure - which increases the visibility of the device during its deployment. Standard biplane angiographic exposures with a calibration device in place (usually a guiding catheter) allow accurate calibration for device sizing. Rotational angiography (3D) depicts the relationship of the aneurysm, its neck and the parent artery. DynaCT provides the exact relationship of the deployed device to the parent vessel wall. 3. In the postprocedural period, CT is very useful in evaluating the possibility of intracranial hemorrhage without significant artifacts from the deployed PED. Widely windowed CTA can evaluate the patency of the device as well as other vessels. MR is extremely useful to evaluate the brain parenchyma looking for ischemic or thromboembolic

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

injuries. MRA is only useful for evaluating flow signal in vessels distant from the PED due to the artifact arising from the PED. In the later postprocedural period, operators have utilized angiography to evaluate the patency of the device, flow into the aneurysm either through the device or with endoleaks, and finally the degree of occlusion of the aneurysm. These evaluations are performed at intervals ranging from 3-6 months and up to a complete aneurysm occlusion. In summary, the imaging modality chosen is based on the phase of the treatment sequence.

O-185 **9:45 AM - 10:15 AM**

Imaging Techniques to Optimize Visualization: What INR Is Looking For

Nesbit, G. M.
Oregon Health & Science University
Portland, OR.

Presentation Summary
The introduction of flow diversion for the treatment of intracranial aneurysms over the past five years has changed the approach to large and wide-necked aneurysms. Flow diversion disrupts intra-aneurysmal flow and encourages aneurysmal thrombosis and progressive angiographic obliteration. Imaging of these devices is designed to determine aneuyrsmal obliteration and evaluation of potential complications. The currently available devices are cobalt chromium and platinum and are conditionally MRI compatible at 1.5 and 3T. Thromboembolic complications and occlusion of perforator vessels are always of concern with endovascular implants, but appear to be very rare, as patients are on dual antiplatelet medication for a variable period and anticoagulation during the procedure. The ideal dosage and duration of antiplatelet therapy in patients undergoing flow diversion and the need for routine antiplatelet sensitivity testing remains controversial. An uncommon but most-feared complication of this technology is delayed aneurysm rupture which usually occurs in the first few weeks, but can be delayed for months. The exact incidence of this is unknown, very low, unpredicatable, but usually confined to very large and giant symptomatic aneurysms. Contrast enhancement within the lumen (indicating lack of complete thrombosis) or of the wall (indicating an inflammatory component) may be of benefit, but needs further study to determine its predictive value. Another complication is distal intraparenchymal hemorrhages. These seem to occur within the first few days after treatment. The etiology of distal intraparenchymal hemorrhage is poorly understood but in part may be due to distal guidewire manipulation in the sometimes difficult delivery of these systems. Imaging followup in patients treated with flow diversion is extremely important is assessing efficacy and risk. Further study of imaging's role in the prediction of potential complications such as delayed rupture and intraparenchymal hemorrhage is recommended.

(22) ASSR Programming: Next Generation of Imaging the CSF: Myelography, Has the Magic Returned?

O-186 **8:45 AM - 9:15 AM**

Evolution of the Myelograms

Nguyen, D. T. D.
Penn State Hershey University Medical Center
Hershey, PA.

Presentation Summary
The Myelogram study was developed to critique positional status of the thecal sac, spinal cord, and spinal nerve roots decades ago. Its technique has gone through several enhancements through the years, ranging from contrast agents to postprocedure imaging techniques. The study is a minimally invasive procedure that has some limitations and intrinsic risks. Knowledge and recognition of some of these can assist neuroradiologists in minimizing such shortcomings. With such, development of alternate methods to visualize the spinal sac and its contents were developed. Despite the use of these techniques to replace or augment some of its capabilities, the myelogram study still remains a robust study in modern day neuroradiology practice. In this presentation, we will visit: • Myelogram history and techniques. • Myelogram pitfalls. • Advance technique applications.

O-187 **9:15 AM - 9:45 AM**

State of the Art Imaging CT Myelography - Best Indications and MRI Greatest Benefits

Miller, T. S.
Albert Einstein College of Medicine Montefiore
Bronx, NY.

Presentation Summary
Attendees will gain a thorough understanding of myelography. A review the history of myelography will be shared. Indications, contraindications and best practices will be discussed. The current state of the art CT myelography will be presented. Finally, future trends in MRI myelography will be introduced, and MRI will be compared to CT. Myelography originally grew out of

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

pneumoencephalography in 1919 when Dandy realized that spinal cord imaging would eventually be accomplished with similar techniques used to image the brain. In 1921 Jacobeus reported successful cord tumor localization, and Dandy reported his experience in 1925. Sicard and Forestier introduced epidurography in 1926 as an x-ray diagnostic method using Lipiodol. Dandy published a series on gas myelography in 1922. Several authors published series on canal access methods. There were issues with gas, and then removal of Lipidol. Both lumbar and cervical access were introduced. Myelography is used to visualize the outline of the spinal cord and subdural space. Multiple agents including gas, lipid soluble: Lipidol, Thorotrast, Pantopaque, and water soluble: Abrodil, Conray, Omnipaque have been used. While originally developed during the pre-MRI plain x-ray era, myelography continues to be used as a problem-solving tool utilizing postinjection CT. Narrowing of the canal and nerve root exit zones is clearly demonstrated on postinjection imaging. Myelography has been shown as superior to MRI in detection of cervical nerve root avulsions. Dynamic or delayed imaging can be used to evaluate cysts in the canal or within the cord. Patients with low-pressure headache syndromes also may be imaged in a delayed or dynamic fashion to delineate CSF leaks. It is in this often young patient group where, due to radiation concerns, off-label use of gadolinium-based agents has gained popularity in MRI myelography.

Gadolinium: A Special Preview of the 21st Century

Tali, E.
Gazi University School of Medicine
Besevler, Ankara, TURKEY.

Presentation Summary
Animal and human studies showed that the intrathecal administration of Gd in the low dose range is a relatively safe procedure without significant side effects at diagnostic dosages. Intrathecally administered GD in animal studies showed no significant change in any of the physiologic or histological parameters examined. A mixture of 0.5 cc (500 mmol/L) Gd and 5 cc of the patient's CSF generally was administrated intrathecally for MR cisternography/myelography (MRCM). No serious side effects or complications were observed related to this technique. Mild transient headache may be the only symptom observed in the first 24 hours following the procedure. This side effect was assumed to be caused by the lumbar puncture instead of intrathecally administered Gd and responds well to oral analgesics. CT cisternography and radioisotope cisternography have been used in the past to evaluate different subarachnoid space pathologies. Conventional myelography is an out-of-date method due to the lack of cross-sectional features and being invasive. Radionuclide cisternography is obsolescent because of its limitation in localization of leak and its difficulties in application. High-resolution CT combined with contrast injection also has been used in detecting different CSF pathologies and especially CSF leakage but turned out to be inadequate in showing the leaks in cases with multiple defects or fractures of the skull base. The most important difficulty that must be overcome in CT cisternography is the restricted distribution of iodinated contrast media in the CSF, the artifacts of the surrounding bones and increasing radiation doses with repeat scans. As MRI provides multiplanar imaging, high contrast-to-noise ratio, thin-section image acquisition, with no bony artifacts and risk of ionizing radiation, it is used more frequently in the setting of CSF leakage. The main advantage of MRI contrast medium compared to CT contrast agents, is their free distribution in the subarachnoid space. These features enable MRCM to readily depict faint or slow flowing CSF fistula, compared to CT cisternography. Meanwhile, MRCM also can be used in any pathology regarding the CSF space such as loculations, adhesions, etc. Although management of arachnoid cysts is still controversial, the detection and characterization of CSF pathway communication or noncommunication with arachnoid cysts by means of MRCM can be useful for surgical planning in symptomatic patients.

proceedings, 19; Honors, awards and special recognitions, 9; and funded studies, 8. Dr. Toh's research interests ore: Physiologic-based MR techniques (e.g., DTI, SWf and PWI}, CNS tumor imaging, CNS infections, White matter disease and imaging-pathologic correlations. His Website is: https:/ /sites. google. com/site/chtohvc/.

Presentation Summary
Conventional MRI remains the primary imaging modality for noninvasive evaluation of brain lesions. One major limitation of conventional MRI, however, is that it cannot provide physiologic and metabolic information of the lesions. More advanced MR imaging techniques such as diffusion tensor imaging (DTI), dynamic susceptibility contrast-enhanced perfusion-weighted imaging (DSC PWI) and susceptibility-weighted imaging (SWI), hold much promise to fill that role by potentially providing novel physiology-based information. Diffusion tensor imaging provides information on histologic architecture such as cellularity and cellular organization by measuring the directional variation of water diffusivity. Dynamic susceptibility contrast-enhanced PWI assesses the degree of angiogenesis and has been shown to correlate with microvascular proliferation. Susceptibility-weighted imaging is a high-resolution 3D gradient-echo sequence that combines phase and magnitude information to detect magnetic susceptibility differences between adjacent tissues. Its high sensitivity in the detection of paramagnetic and diamagnetic substances such as iron deposits, blood degradation products, and calcifications provides clinically useful information in the evaluation of various disorders. The true strength of physiologic MRI is the ability to provide quantitative surrogate MR markers and depict changes in the internal architecture in the setting of no overall change in the conventional MRI. In this talk, the physics of these physiologic MR techniques will be discussed briefly. The roles of physiologic MRI, particularly in the presurgical workup of common intracranial mass lesions such as gliomas, abscesses, lymphomas, etc. will be presented. The correlations between physiologic MR imaging findings and histopathology will be demonstrated. Finally, the limitations of these MR techniques also will be addressed.

O-190 **9:05 AM - 9:23 AM**

Peritherapeutic Neuroimaging on Brain Tumors

Hirai, T.
Graduate School of Medical Sciences
Kumamoto University
Kumamoto, JAPAN.

Presentation Summary
Peritherapeutic neuroimaging in patients with gliomas has an important role to evaluate structural, hemodynamic, metabolic, cellular, and cytoarchitectural alterations. Although histopathologic assessment remains the reference standard for determining the glioma grade, sampling error, large range of WHO classification and grading systems, inter and intrapathologist variability, and difference in biology within WHO grades of gliomas may result in inadequate evaluation of the entire tumor. Thus, for a final brain tumor diagnosis, neuroimaging studies may provide information in addition to the pathologic assessment. Advanced MR techniques such as diffusion-weighted and perfusion imaging are useful to diagnose and grade gliomas and to assess treatment response and patient prognosis. For diffusion-weighted imaging, it has been suggested that the regions with minimum apparent diffusion coefficients reflect the sites of highest cellularity within heterogeneous tumors, and, therefore, these sites may be of diagnostic value in identifying high-grade tumor components. Perfusion imaging provides information about tumor angiogenesis and is performed with dynamic contrast-enhanced methods or arterial spin labeling techniques. We present and discuss peritherapeutic applications of these neuroimaging techniques especially for tumor grading and prognostic value in patients with gliomas.

Advanced MR Imaging in the Post Therapy Brain Tumor Microenvironment

Kim, H. S.
Asan Medical Center
Seoul, KOREA, REPUBLIC OF.

Dr. Ho Sung Kim (MD, PhD} is assistant professor, Department of Radiology, Division of Neuroradiology, As an Medical Center, Seoul, Korea. Dr. Kim's education is as follows: Han yang University School of Medicine {1993.3 - 1996.2) and Postgraduate: University of Ulsan College of Medicine {2004.3-2006.2). His research interests include advanced CT and MR technologies and imaging processing, especially perfusion MR imaging in brain tumor. Dr. Kim's publication list contains about 40 SCL Papers some of which appeared in Radiology and AJNR.

Presentation Summary
Brain tumor microenvironment has been investigated by a desire to understand, and mitigate, the hypoxic fraction of tumors that are resistant to radiation therapy. The microenvironment within brain tumors is significantly different from that in normal tissues. A major difference is tumor vasculature which results in unbalanced blood supply and significant perfusion heterogeneities, causing tumor hypoxia. It is commonly believed that the hypoxic tumor microenvironment is usually associated with poor perfusion and elevated metabolic rates, respectively. The tumor hypoxia also have important consequences for antitumor therapy and can contribute to the progression of tumors by induction of upregulation of tumor vascularity. Tumor hypoxia can lead to a more aggressive phenotype of tumor cells, with a number of altered behaviors, such as increased metastasis. Hence, tumor

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

hypoxia may be essential intermediates in the malignant transformation of low-grade tumor. The most well studied effects of the tumor microenvironment are the inhibition of chemo and radiotherapies. Such physiologic resistance can be caused by direct action of pH and O2 on the therapy or more generally by poor perfusion, which limits the delivery of drugs to the target cells. Resistance to radiotherapy at low pO2 is a direct consequence of the ability of oxygen to propagate radical damage to macromolecules and membranes through the generation of reactive oxygen species. Consequently, hypoxic tumor cells are three to five times more resistant to ionizing radiation compared to well oxygenated cells. Although the mechanisms are unknown, tumor hypoxia incontrovertibly stimulates metastatic behavior by a direct mechanism. This phenomenon is related to expression of vascular endothelial growth factor (VEGF). Many MR imaging techniques including diffusion, perfusion, susceptibility, and BOLD have emerged and allow the interrogation of the brain tumor microenvironment. Studies employing these physiologic imaging methods have provided new insights into the causes and consequences of the hostile tumor microenvironment. Elucidation of pathologic background and imaging correlation will yield further insights into the tumor microenvironment. In this presentation, we attempt to identify various MR imaging techniques, postprocessing and their application to post-treatment brain tumor microenvironment.

Peritherapeutic Functional MR Imaging of Normal Pressure Hydrocephalus: Moving from Research to Clinical Practice

Chen, S.
Tri-Service General Hospital
Taipei, TAIWAN.

Dr. Cheng-Yu Chen was born in 1960. He received his medical degree in the School of Medicine, National Defense Medical Center, Taipei, Taiwan in 1985. Dr. Chen's Professional appointments are: the Executive Dean, National Defense Center, Professor, School of Medicine, National Defense Medical Cent4er, Taipei, 2000. He has served as an editorial board member of the American Journal of Neurology {AJNR) from 2001-2011. He was appointed the section editor, Classic Image, special consultant, AJNR in 2011. Dr. Chen was a member of the scientific program committee, RSNA from 2007-2012 and Editor-in-chief of the Journal of Radiological Science since 2011. He has published several articles in Radiology.

Presentation Summary
Idiopathic normal pressure hydrocephalus (iNPH) has long been recognized as a treatable disease by early shunting with clinically notable improvements, most often on the gait disturbance, followed by the incontinence, and less noticeably the demented symptoms. In the past, efforts have been made on the prediction of shunt responsiveness in iNPH patients, for example, CSF tapping, which, though still being the current standard, is considered invasive. Early studies using noninvasive methods on this regard include MRI measurements of CSF stroke volume by hand drawing regions of interest within the small aqueduct of Sylvius. However, the cut-off value set for the prediction of responsiveness (greater than 42 microL) by Bradley, et al. has not gained wide consensus, partly because the differences in the measurement techniques, imaging parameters, and even the scanners used. More recently, new MR technologies have added to the research realm for iNPH, those including perfusion imaging, diffusion tensor imaging and MR spectroscopy, in addition to the improved phase contrast techniques and objective ROI methods. Independent imaging predictors, such as cerebral blood flow (CBF), loss of vasomotor response in the periventricular WM, mean CSF stroke volume, and distension of the corpus callosum can be measured quantitatively using cutting-edge technology. In this lecture, a short review of the possible etiologic factors for iNPH and the perspectives of using advanced MR imaging to establish the independent predictors potentially useful for clinical applications will be addressed. 1. Noninvasive imaging biomarkers that could be used to differentiate lumbar-drain responded iNPH patients from those unresponded. 2. Early gait disturbance in iNPH, mechanism approach. 3. Incontinence in iNPH as a result of hydrocephalus or ischemia, imaging approach.

MR Voxel-Based Histogram Analysis of Atherosclerotic Basilar Artery in Patients with Isolated Pontine Infarct

Lee, H.
Kyungpook National University Hospital
Daegu, KOREA, REPUBLIC OF.

Dr. Lee was born July 13, 1971. He received his education at Kyungpook National University, School of Medicine from 1992-1997 and at Kyungpook National University, Graduate School from 1998-1999. He received his Doctor of Medicine degree from Kyungpook National University in 2004. Dr. Lee is Associate Professor Deportment of Radiology at Kyungpook National University Hospital (KNUH}, Daegu, South Korea. He is also the Instructor-Assistant Professor (Radiology) at KNUH from 2006.5 to the present. Dr. Lee's interests are Clinical Neuroradiology, Manganese-enhanced MRI (experimental), Thyroid USG. He has published more than 56 articles and has received multiple honors.

Presentation Summary
Each voxel magnetic resonance imaging (MRI) of atherosclerotic vessels represents various tissue components of atherosclerotic plaque according to the physical property of the corresponding tissue. We hypothesized the pattern of voxel-based magnetic

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

resonance histogram (MRH) represent the status of atherosclerotic status quantitatively. The aim of this study is to evaluate the usefulness of MRH for atherosclerotic basilar artery in patients with isolated pontine infarction. A total of 42 patients diagnosed with acute isolated pontine infarction (PI) were included and 10 normal healthy volunteers were included as normal controls. Using home-made program (CI image, version 1.0), we analyzed voxel data and calculated the numbers of voxels according to signal intensities from the T1- and T2-weighted MRI of basilar arterial wall. From the histogram, the number of pixels from wall, lumen CSF and brain were defined as Σwall, Σlumen, ΣCSF, and Σbrain. We compared the patterns of histogram between groups of PI with plaque and without plaque. The spectra from the normal healthy control group showed two phasic peaks on spectrum T1-weighted images and multiphasic peaks from T2-weighted images. The spectra from PI with plaque group showed decreased height of the peak from area of the lumen and increased peak from the atherosclerotic plaques. The ratio of area under curve of Σwall/Σlumen were higher in PI with plaque group than PI without plaque on spectrum form T1WI (2.47 versus 1.06, p<0.001) and T2WI (1.22 versus 0.71, p<0.001). We observed a significant difference among the patient with or without pontine infarction and normal control group comparing each histogram. From the MRH of control group, we could get the histograms of wall and lumen and we found that they had their own peak and range in histogram. On base of this histogram, we could compare the histogram of the control group and that of basilar artery with pontine infarction. Also there was no difference in the wall component between patients with plaque and without plaque, whereas the luminal component is much more and has a prominent peak in patients without plaque. Peak in lumen component was not evident in control group and patients with plaque.Therefore, we can identify the wall thickening by atherosclerotic plaques before their impact on the luminogram or even in HRMRI. These findings also suggest that there is ongoing adaptation mechanism of atherosclerotic change, namely “positive remodeling”. Therefore, MRH has several advantages for the evaluation of atherosclerotic plaque. First, it can measure atherosclerotic itself, which makes it possible to evaluate degree of atherosclerotic plaque as well as degree of stenosis. Second, this method is quantitative analysis, which could be useful in follow-up study. Third, it could be a promising method for analysis of the histology of atherosclerotic plaque. Because, the signal intensities of MR depend on the chemical property of voxel, proper acquisition for atherosclerotic plaque could predict vulnerable plaque. In conclusion, this study demonstrated that histogram of basilar arteries in patients with isolated pontine infarction. We thought this method could give the quantitative information for vascular status in atherosclerotic disease.

O-194 **10:07 AM - 10:15 AM**

Utility of Skewness and Kurtosis Derived from MR Perfusion Histogram to Predict Pseudoprogression in Patients with Glioblastoma

Baek, H.
Inje University College of Medicine, Haeundae Paik Hospital
Busan, KOREA, REPUBLIC OF.

Dr. Hye lin Baek received his education at Inje University College of Medicine (2000.3-2006.2) and his Postgraduate from Inje University College of Medicine (2010.3-2012.2). He interned at Busan Paik Hospital (2006.3 -2007.2). He was a resident, Department of Radiology, Busan Paik Hospital {2007.3-2011.2). Dr. Lee then became a Clinical instructor (Fellow): Department of Radiology at Asan Medical Center (2001.3-2012). Currently he is Assistant Professor, Division of Neuroradiology, Department of Radiology, Inje University College of Medicine, Haeundae Paik Hospital. Dr. Baek has published many papers in the Journal of the Korean Society of Radiology, RadioGraphies, Neurointervention, and Radiology.

Presentation Summary
The purpose of this presentation is to test the predictive value of skewness and kurtosis changes of normalized cerebral blood volume (nCBV) during early treatment period for differentiating early tumor progression from pseudoprogression in patients with newly diagnosed glioblastomas. The institutional review board approved this retrospective study. We assessed 135 patients with newly diagnosed glioblastomas who underwent concurrent chemoradiotherapy (CCRT) after surgical resection. Patients who developed new or enlarged contrast-enhancing lesions after CCRT were assessed by conventional and perfusion MR imaging. The percent change of skewness and kurtosis of nCBV histogram between the first and second post-CCRT followup were classified into four categories. Independent predictors of early tumor progression were determined by logistic regression analysis. Of 135 patients, 79 patients had new or enlarged contrast-enhancing lesions after CCRT, and subsequently classified as early tumor progression (n =42, 53.2%) and pseudoprogression (n = 37, 46.8%). Pseudoprogression was observed in 23 of 24 (95.8%) patients in category 1, 10 of 15 (66.7%) in category 2, four of 20 (20.0%) in category 3, and 0 of 20 (0%) in category 4 (Chi-square test, P < 0.0001). The histographic pattern of nCBV was the best independent predictor (odds ratio, 3.51; P = 0.0032) for early tumor progression, representing the largest area under the receiver operating characteristic curve (A_z) (A_z = 0.934; 95% CI: 0.855, 0.977), with a sensitivity of 85.7% and a specificity of 89.2% rather than each percent change of skweness or kurtosis. The change of skewness and kurtosis of nCBV may be a potential imaging biomarker for early treatment response in patients with newly diagnosed glioblastomas.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

(24) Young Professionals Programming: Choosing Your Career

O-195 **8:45 AM - 9:00 AM**

Benefits of Academic Medicine

Russell, E. J.
Northwestern University
Chicago, IL.

Presentation Summary

Concerning economics, the inducements for residents to opt for private practice include excellent compensation and time off. While academic radiology departments cannot compete directly, since a percentage of earned income must be reinvested in support for research and teaching time, competitive compensation is more prevalent now in academic departments. Furthermore, the involvement of academic radiologists in management roles within the institutions/hospitals/medical schools in which they practice, and connections that develop with other departments through joint educational, research and clinical activities, can provide a more secure practice environment, in this era of "commoditization". Having said that, it is important that the true advantages of an academic career are fully considered when making a career choice. It affords one the opportunity to develop a career where the joys of developing new knowledge through research is supplemented by the time off the clinical schedule given to travel and present your work at national and international meetings, and develop connections with other academic radiologists that can last a lifetime. Furthermore, academic radiologists can focus on a single area of practice. While some may enjoy a more general practice required more often in private groups, market forces and teleradiology companies willing to deliver subspecialty interpretations at all hours are making it less desirable for new radiologists to be a "Jack of all trades but a master of none". Apart from these considerations, there are key factors influencing those who choose an academic career as summarized by Gunderman: 1. *Patient care*: An academic environment best supports state-of-the-art clinical practice, often based on industrial collaborations and translational research. The availability of cutting edge techniques allow faculty to develop the deepest level of expertise. 2. *Intellectual stimulation*: As eloquently stated by Gunderman, "the inquisitive attitude that characterizes good academic radiologists leads them to attend professional meetings, to get involved in organized radiology, and to read research journals regularly, and these are precisely the venues in which new ideas are disseminated." An academic center also facilitates interaction with academicians in other fields and departments, and provides teaching opportunities that further stimulate the teacher ("those who teach a subject understand it better than those who do not"). 3. *Service opportunities*: Academic radiologists, particularly those with an interest in management, can have a significant impact on the future role of radiology in health care delivery and patient care, never more important than it is today to secure the specialty. 4. *The joy of teaching*: Those who have spent time in an academic setting generally say that the most enjoyable and rewarding aspect of their careers is teaching. There is an opportunity to disseminate your knowledge and help patients indirectly by permanently imprinting your "scientific children" with your perspectives and knowledge, a lasting legacy indeed. 5. *Research:* Physicians working in academic centers enjoy a special opportunity to engage in in-depth study of things that puzzle them, and it is deeply satisfying to see the practice of radiology change because your research leads to new information. A career in academic radiology makes the most sense for those who are curious and take pleasure in pursuing knowledge, who enjoy teaching and think they might be good at it, who feel at home in an academic environment where people tend to think critically and creatively about what they do, and who wish to make distinctive leadership contributions in their field.

Benefits of Private Practice

Pramanik, B. K.
Medical Center Radiology Group
Orlando, FL.

Presentation Summary

Private practice radiology offers a number of considerable advantages over academic radiology. One key advantage is personal freedom. There is much more autonomy to make decisions as there is less bureaucracy. The workload is predominantly clinical and there is no research or very little teaching responsibilities. Private practice enables radiologists to capitalize on a broader range of their training. Most private practice radiologists practice general radiology and see a broad range of patients encompassing every radiologic subspecialty and modality. By seeing a breadth of cases, there is more flexibility to adapt. Finally, the major advantage is compensation. Private practice salaries are higher than academic radiology. Moreover, the benefits packages including vacation are frequently more generous.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Negotiating a Position in Academic Medicine: What You Need to Know

Mukherji, S. K.
University of Michigan Health System
Ann Arbor, MI.

Presentation Summary
The intent of this presentation will be to review important aspects about negotiating an academic radiology position. The attendees will be familiar with important information that will permit them to properly assess different academic opportunities.

O-198 **9:30 AM - 9:45 AM**

Negotiating a Contract in Private Practice: What You Need to Know

Barr, R. M.
Mecklenburg Radiology Associates, P.A.
Charlotte, NC.

Presentation Summary
This will be a practical, "how to" session for attendees preparing to enter the private practice radiology workforce. The basics of the employment contract will be discussed from the perspective of the group practice. The speaker hopes to make up for a lack of legal expertise with a plethora of common-sense advice. The typical steps from recruitment to contracting will be reviewed. The talk will highlight the most important elements of the contract, including the elements that tend to raise the most questions, such as noncompete clauses and tail coverage responsibility. We'll discuss what's typically missing from the contract, and the most common mistakes job seekers make when contracting.

O-199 **9:45 AM - 10:00 AM**

Why I Did What I Did and Did I Make the Right Decision

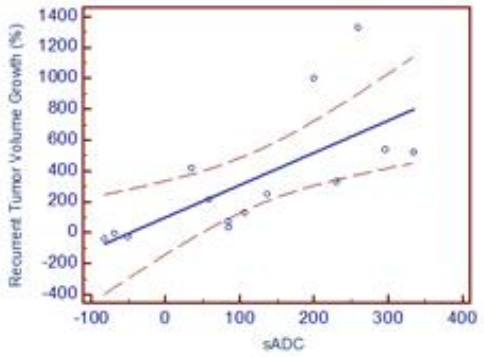
Glioblastoma Multiforme: Peritumoral Apparent Diffusion Coefficient Analysis in Prediction of Tumor Volume Recurrence

Chow, D. S.·Lignelli, A.·Qi, J.·Guo, X.·Miloushev, V.·Pisapia, D.·Yun, J.·Canoll, P.·Lassman, A.·Zhao, B.·Filippi, C.
Columbia University
New York, NY.

Purpose
Glioblastoma multiforme (GBM) is an invasive and aggressive tumor. While therapy typically includes maximal surgical resection followed by radiation therapy (XRT) with adjuvant temozolomide (TMZ), rates of recurrence are highly variable. Apparent diffusion coefficient (ADC) maps represent an imaging tool that may be related to prognosis in GBM patients. Low ADC values demonstrate restricted water movement which is suggestive of increased cellular density. Thus, decreased ADC values may correlate to tumor infiltration. We hypothesize that GBM patients with decreased ADC in the peritumoral edema will exhibit a higher amount of tumor regrowth following resection.
Materials & Methods
This retrospective study included patients with native glioblastomas with pre-operative, 24-48 hour postoperative, and 2-3 month follow-up MRIs. All patients received XRT with concurrent TMZ following maximal resection. Two consecutive regions of interests were drawn on pre-operative ADC maps in the (1) immediately adjacent and (2) distant peritumoral FLAIR abnormality. The adjacent ADC value was subtracted from distant ADC value to obtain a subtracted ADC (sADC) value. Therefore, when the immediate peritumoral ADC value was lower than the distant peritumoral ADC values, higher sADC values were obtained. Postoperative tumor volumes were assessed using postcontrast T1-weighted images at 24-48 hours and at 2-3 month followup. Volumes were obtained using a semi-automated algorithm that combines region-based active contours and level set approach. Student's *t*-test was used to compare sADC values between patients with a recurrent tumor volume growth of less than 50% and greater than or equal to 50%. Linear regression analysis also was performed to assess the relationship between peritumoral sADC values and tumor growth by volume. A p-value of < 0.05 was considered statistically

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

significant.
Results
A total of 14 patients met inclusion criteria, of which 10 displayed greater than 50% growth on 2-3 month follow-up MRI. The mean sADC in individuals with recurrent tumor volume growth less than 50% and greater than or equal to 50% was -19.8% and 208.3% respectively ($p < 0.01$). Linear regression analyses revealed a significant correlation between sADC values and tumor growth ($p < 0.01$).



Conclusion
Evaluation of the pre-operative peritumoral ADC potentially can predict the volume of postoperative recurrence within the first 2-3 months of treatment. Additionally, these measurements may represent a potential biomarker for tumor infiltration in the immediate nonenhancing peritumoral region.

KEYWORDS: Glioblastoma, Apparent diffusion coefficient

O-202 **10:53 AM - 11:01 AM**

May the Diffusion Tensor Imaging Metrics Be Used to Predict Survival in Patients with Newly Diagnosed Glioblastoma?: A Preliminary Diffusion Tensor Imaging Histogram Analysis in Glioblastoma

Tian, W.·Liu, X.·Zhong, J.·Ekholm, S.
University of Rochester Medical Center
Rochester, NY.

Purpose
Glioblastoma is the most common malignant primary brain tumor in adults, with median survival of approximately 12-15 months after initial diagnosis. However, occasional long-term survivors have been reported and a subset of patients may show a significant response to therapy. Diffusion tensor imaging (DTI) is a novel noninvasive advanced imaging technique to provide multiple quantitative metrics revealing molecular motion and microstructure information. Although DTI has been shown to be helpful in pre-operative grading of gliomas, its value for predicting survival is still unknown. The purpose of this study is to evaluate the value of DTI derived parameters, and histogram analysis in predicting the survival time in patients with glioblastoma.

Materials & Methods
The study included pre-operative DTI examinations in 34 patients with histologically confirmed glioblastoma (WHO grade IV). Diffusion tensor imaging data were coregistrated to postcontrast T1WI using nordicICE. Region-of-interest (ROIs) was manually delineated to include enhancing tumors. Histogram analysis of FA and MD, age, sex, and Karnofsky performance scale (KPS) were evaluated in overall survival (OS) analysis by the Kaplan-Meier method and Cox proportional hazards regression model. Receiver operating characteristics (ROC) curve analysis was performed for mean FA, maximal FA mean MD and minimal MD in predicting OS of 12 months.
Results
The median survival time in this group is 9.26 ± 1.5 months. Univariate analysis with the Cox proportional hazards model show age, KPS, mean FA, mean MD and minimal MD were associate with survival hazard, the multivariate analysis demonstrated that mean FA and minimal MD were the best predictors after adjusting for age and KPS. Receiver operating characteristics curve analysis showed that mean FA and minimal MD have better area under the curve (0.687 and 0.722 respectively). Discussion: Our preliminary result showed that mean FA, maximal FA mean MD and minimal MD of enhancing glioblastoma could correlate with OS. The mean FA > 0.145 and minimal MD > 0.485 may indicate poorer prognosis.
Conclusion
Our results show mean FA and minimal MD were the best predictors for survival after adjusting for age and KPS. Our study suggested that quantitative histogram analysis of DTI-derived metrics may have potential early predictive value for overall survival (OS) in patients with glioblastomas, warrants further investigation in a large multicenter prospective study.

KEYWORDS: Diffusion tensor image, GBM, survival analysis

Dynamic Contrast-Enhanced Perfusion Imaging for Biopsy-Targeting in Patients with Newly Diagnosed Glioblastoma

Radbruch, A.[1,2]·Decker, C.[1]·Abello, M.[1]·Lutz, K.[1]·Wiestler, B.[1]·Wick, W.[1]·Bendszus, M.[1]·Heiland, S.[1]
[1]University of Heidelberg, Heidelberg, GERMANY, [2]German Cancer Research Center (DKFZ), Heidelberg, GERMANY.

Purpose
Contrast-enhancing areas on T1-weighted images are at present the preferred target for glioma biopsy or resection as they are thought to express the most anaplastic tumor portions. However, the information of this enhancement is limited as it only reflects contrast agent uptake at a single point of time and does not represent kinetic parameters. In brain tumor imaging T1-weighted dynamic contrast-enhanced (DCE) imaging is used mainly to describe the

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

status of the blood-brain barrier. We used the pharmacokinetic model introduced by Tofts et al to calculate the transfer constant K^{trans} that is equal to the blood plasma flow per unit volume of tissue. We hypothesized that this approach can separate different tumor compartments even though these compartments may present with comparable signal enhancement on T1-weighted images and thus provide additional information for possible biopsy targets.

Materials & Methods

Images were acquired in the clinical routine workup from 20 patients with newly diagnosed and histologically proven glioblastoma before surgery using a 3T MR system (Magnetom Tim Trio, Siemens Healthcare, Erlangen, Germany). DCE MRI was performed using the following parameters: TR/TE, 5.44/2.47 milliseconds; 40 slices, slice thickness, 3 mm; time resolution, 17.5 seconds; matrix, 256 x 256; FOV, 23 cm x 18 cm,18 measurements, contrast media (0.1 mmol/kg body weight of DOTAREM) infusion rate 3.5 ml/s, starting with the second measurement. We calculated K^{trans} Maps and Maximum Enhancement Maps with in-house developed software. Two experienced neuroradiologists independently evaluated areas presenting either high or low K^{trans} values that presented comparable values on the Maximum Enhancement Map within the enhancing lesion. Two ROIs of the same size were placed in each area and the corresponding values of K^{trans} and the Maximum Enhancement Map were calculated for each voxel within the ROI.

Results

In 17 of 20 patients areas of high and low K^{trans} values that presented comparable enhancement and thus comparable values on the Maximum Enhancement Map could be detected visually. Analysis of these regions revealed significantly different ($p<0.001$) K^{trans} values [(43.25 +/- 25.13 (low K^{trans}) versus 201 +/-67.45 (high K^{trans})] while the corresponding ROIs on the Maximum Enhancement Map did not show any difference [306.6 +/- 110.61 (corresponding ROI for low K^{trans}) versus 315.63 +/- 121.43 (corresponding ROI for high K^{trans})].

Conclusion

K^{trans} Map provides additional information regarding the state of the blood-brain barrier that cannot be visualized on static T1-weighted images. As there is a theoretical basis for a relationship between endothelian permeability and malignancy, it could be beneficial to target voxels that show either only elevated K^{trans} or both - intense enhancement and elevated K^{trans} values. Further studies, especially correlations with biopsies are needed to determine the exact correlation between K^{trans} and malignancy.

KEYWORDS: Glioblastoma, Dynamic contrast-enhanced MR

O-205 **11:17 AM - 11:25 AM**

Cerebral Blood Flow Changes in Glioblastoma Multiforme Patients Undergoing Bevacizumab Treatment Are Seen in Both Tumor and Normal Brain

Andre, J. B.[1]·Nagpal, S.[2]·Hippe, D. S.[1]·Schmiedeskamp, H.[2]·Bammer, R.[2]·Thomas, R.[2]·Straka, M.[2]·Recht, L.[2]·Zaharchuk, G.[2]

[1]University of Washington School of Medicine, Seattle, WA, [2]Stanford University School of Medicine, Stanford, CA.

Purpose

Bevacizumab (Bev), a vascular endothelial growth factor receptor-A antagonist, has been used increasingly for the treatment of recurrent glioblastoma multiforme (GBM). We examine the effects that Bev administration exerts on cerebral blood flow (CBF) contralateral to the tumor in patients with recurrent GBM.

Materials & Methods

Eighteen post-chemoradiation patients with histologically confirmed GBM were treated with Bev and underwent routine tumor imaging at 1.5T and 3T, following informed consent. Pseudocontinuous arterial spin labeling (pCASL) imaging without vessel suppression was serially performed using a 3D background-suppressed fast-spin-echo stack-of-spirals readout module with eight in-plane spiral interleaves. Cerebral blood flow quantification (in mL/100g/min) was performed as described previously using an automated script1. Regions of interest were drawn on pCASL images over tumor regions, symmetrically in the contralateral normal-appearing white matter/tissue, and the contralateral middle cerebral artery (MCA) territory gray matter on an imaging slice 40 mm below the vertex. Changes in CBF from each side within the period before and after Bev administration, and differences between sides for these periods, were evaluated using paired t-tests in eight patients who underwent pCASL imaging during both periods. A linear-mixed model statistical approach with CBF (GBM or contralateral MCA) as the dependent variable and an indicator for Bev treatment period as the independent variable, also was employed in order to utilize all patients, including those with pCASL imaging performed in only one period. To account for any correlation between repeated CBF measurements on the same patient, a random intercept was included and the residual covariance was modeled as a first-order moving average process. The nonparametric bootstrap was applied to assess the difference in change in CBF between the GBM and contralateral sides.

Results

Sixty-three pCASL studies were serially acquired. Pseudocontinuous arterial spin labeling was performed only before and during Bev treatment in eight patients, only during Bev treatment in six patients, only during and after Bev treatment in three patients, and only before Bev treatment in one patient. Initial chemoradiation was performed in all patients, and most patients underwent chemotherapy(most frequently TMZ and/or CCNU, but

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

also including others) prior to, or concurrent with Bev treatment. In some, radiation therapy was performed in conjunction with TMZ. Using paired t-tests in eight patients only, significantly lower mean CBF was identified in GBM tumor regions during, compared with before, Bev treatment(p=0.04), while there was a nonsignificant tendency for CBF to be lower in the contralateral MCA territory during the same period (p=0.23). Using a linear mixed model incorporating all patient data to achieve higher statistical power, the trend for lower CBF in the contralateral MCA territory further approached statistical significance (p=0.14) (Figure 1), while the drop in average CBF was found to be significantly greater in GBM compared with contralateral MCA regions(p<0.05).
Conclusion
Bevacizumab appears to preferentially and directly target the tumor vasculature thereby decreasing tumor perfusion, although some mild decrease in global CBF also may occur. A small sample size, prior and concurrent chemo- and radiotherapies, and non-Bev CBF modifiers (such as caffeine) may confound the results.

Differentiation between Gliomas and Brain Metastases Using MR Imaging, Resonance Spectroscopy, Perfusion and Diffusion-Weighted Imaging

Guzmán-De-Villoria, J. A.[1]·Mateos-Pérez, J. M.[1]·Fernández-García, P.[1]·Borrego-Ruiz, P.[1]·Desco, M.[2]
[1]Hospital General Universitario Gregorio Marañón, Madrid, SPAIN, [2]Universidad Carlos III. Instituto de Investigación Sanitaria Gregorio Marañón, Madrid, SPAIN.

Purpose
High-grade gliomas and metastases sometimes appear similar on MR imaging (MRI) but require different treatment strategy. Few attempts have been made to combine different MRI techniques to differentiate between these types of tumors. Our aim was to evaluate the role of MRI, perfusion-weighted imaging (PWI), diffusion-weighted imaging (DWI) and proton spectroscopy (1H-MRS) in the differentiation of brain metastases and gliomas.
Materials & Methods
One hundred ninety-one consecutive patients with an untreated intraaxial brain tumor underwent prospectively conventional MRI, T2*-weighted PWI, DWI (*b* = 2500 s/mm^2) and single voxel 1H-MRS at short (23 ms) and long (144 ms) TE with 1.5 T MR equipment. The gliomas (2 low grade astrocytoma; 7 anaplastic astrocytomas and 72 glioblastomas) and metastases (n = 46) which showed necrosis and enhancement were included in the analysis. The presence of edema, neoformative vessels (neovascularization), and hemorrhage were evaluated with conventional MRI. The relative cerebral blood volume (rCBV) and relative apparent diffusion coefficient (rADC) were calculated by using different regions-of-interest within the enhancing tumoral part and immediate zone of the edema normalized by the contralateral normal-appearing area. Metabolite ratios Cho/Cr; NAA/Cr; Cho/H_2O and NAA/H_2O and the presence of lipids or lactate within the tumor area also were determined. Univariate and multivariate logistic regression analyses were employed to determine the best model for classification.
Results
Significant differences were obtained for the presence of neovascularization (p<0,001), hemorrhage (p = 0.004), lipids (p = 0.046), lactate (p = 0.021) and lower values of NAA/Cr (p<0.04) at long TE in gliomas. The best results were obtained combining the presence of neovascularization, lactate and lipids and low values of NAA/Cr at long TE with an accuracy of 79.3%.
Conclusion
The assessment of some MRI features (neovascularization and hemorrhage) and spectroscopic variables (values of NAA/Cr at long TE, presence of lipids and lactate) could differentiate between gliomas and metastases with similar MRI appearance. However, a conventional analysis of PWI and DWI data do not differentiate between both histologic types due to the overlapping values. This result could explain the controversial published results and may justify the use of high-field MR equipment (≥ 3T) or more sophisticated postprocessing methods.

MR Imaging of Progressive or Recurrent Glioblastoma Multiforme Treated with Laser-Induced Thermal Therapy

Derkatch, S.[1]·McClarty, B.[1]·Tyc, R.[2]·Barnett, G. H.[3]·Sloan, A. E.[4]
[1]University of Manitoba, Winnipeg, MB, CANADA, [2]Monteris Medical Inc., Winnipeg, MB, CANADA, [3]Cleveland Clinic, Cleveland, OH, [4]Case Western Reserve University School of Medicine, Cleveland, OH.

Purpose
Thermal therapy is a cytoreductive modality that can be employed in the treatment of both primary and metastatic intracranial malignancies. The present effort was undertaken with the goal of characterizing immediate and long-term changes to the MRI appearances of glioblastoma multiforme lesions following treatment with MRI-guided, focused laser-induced thermal therapy.
Materials & Methods
A retrospective review was performed of MRI data from 10 patients with progressive or recurrent glioblastoma multiforme enrolled in the phase I trial of an MRI-guided, gas cooled, focused laser interstitial thermal therapy device. Pre and postintervention multisequence MRI images were obtained and analyzed at defined intervals.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Imaging followup ranged from one to six months.
Results
Distinctive patterns of signal change and evolution were noted on all sequences. A consistent zonal architecture was observed on T1- and T2-weighted images within the confines of the treatment area and this diminished in a generally predictable manner. The margins of the target area were demarcated by a thin rim of enhancement that was evident from the first postoperative days. Many patients ultimately experienced tumor progression related to additional untreated malignant foci but, in all cases, at least a portion of this enhancing rim demonstrated comparative stability. In other patients, this margin persisted to the latest follow-up examination. A transient increase in the volume of the surrounding region of T2 hyperintensity frequently was observed but this rapidly returned to the pretreatment baseline and, in several cases, further improvement was evident. A rim of T1 hyperintensity invariably developed at the periphery of the treated lesion in a delayed fashion and this frequently resolved over a period of two-three months when followup was of suitable duration. Roughly coinciding with the presence of this finding, a thin margin of low signal on gradient-recalled echo images was transiently apparent. Signal abnormalities correlating with restriction of diffusion developed immediately and persisted for one to three months or the most recent examination date.
Conclusion
Progressive or recurrent glioblastoma multiforme lesions treated with focused, laser-induced thermal therapy have characteristic MRI appearances that differ significantly from those of conventional treatment modalities. The variable cooccurrence of complications such as tumor progression and hemorrhage into the necrotic defect provided informative comparisons that may aid in the development of hypotheses regarding the underlying histopathology of laser-induced coagulative necrosis in normal brain parenchyma and tumor. In particular, it is possible that the immediate development and frequent long-term persistence of peripheral enhancement in treated lesions often does not represent residual tumor but rather breakdown of the blood-brain barrier at an immunologically active transition zone between viable and nonviable tissues. These observations are presented with the aim of familiarizing radiologists with expected MRI findings in the ongoing intracranial application of thermal tissue ablation as well as with a view to further research regarding the observed radiopathologic phenomena.

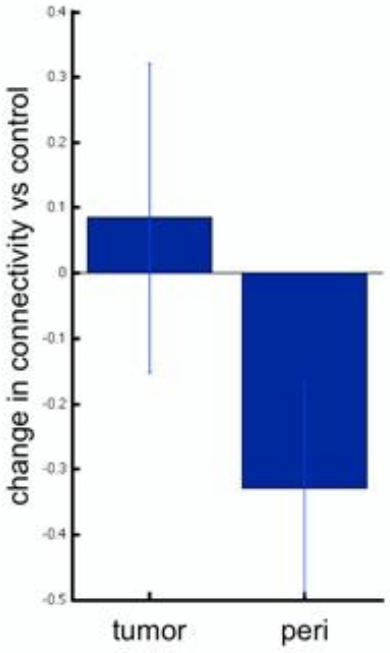
Glioblastoma: Characterization of the Nonenhancing Peritumoral Region Using Resting-State BOLD Functional Connectivity Maps

Chow, D. S.·Filippi, C.·Horenstein, C.·Grinband, J.
Columbia University
New York, NY.

Purpose
Glioblastoma multiforme (GBM) is an invasive and highly aggressive tumor. Though outcomes are highly variable and difficult to predict, there is some consensus that resection provides symptomatic relief and cytotoxic reduction to augment adjuvant therapy. A major limitation for the treatment of GBM has been the ability to differentiate the tumor from surrounding healthy tissue. One means of quantifying the integrity of neural tissue is by assessing the effectiveness of communication between brain regions. Reductions in BOLD functional connectivity have been demonstrated in a wide range of neurologic conditions. In this study, we aim to objectively measure the BOLD functional connectivity, which may represent a potential biomarker for tumor-induced impairment of neural tissue.
Materials & Methods
This was a retrospective review of 13 patients with pathology proven glioblastomas who had resting state BOLD fMRI at 3T prior to tumor resection. Motion correction and slice timing correction was performed on the raw datasets. Functional connectivity (FC) maps were generated. Each voxel time series was correlated to every other voxel in the brain to derive a measure of global functional connectivity. Connectivity maps were coregistered to structural images using FSL. Patterns of functional connectivity within the tumor and peritumoral edema (defined by the peritumoral FLAIR abnormality) were characterized qualitatively and quantitatively.
Results
Peritumoral edema in high-grade gliomas had lower connectivity measures compared to the contralateral normal white matter. The contrast-enhancing tumor region did not show any differences in connectivity when compared to the contralateral normal white matter.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Conclusion
These findings suggest that BOLD functional connectivity maps may provide a potential biomarker for tumor invasion in the nonenhancing peritumoral edema. While the contrast-enhancing tumor region failed to show any differences, this is not unexpected because of loss of vascular regulation in the tumor region. Further study is required to determine whether different classes of tumors are associated with different signatures on these BOLD connectivity maps.

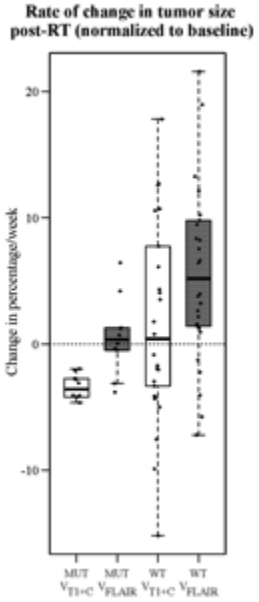
Increased Radiosensitivity of IDH1 Mutant Glioblastomas as Demonstrated by Serial Quantitative MR Volumetry

Tran, A. N.[1,2]·Lai, A.[2]·Pope, W. B.[2]·Nghiemphu, P. L.[2]·Cloughesy, T. F.[2]·Ellingson, B. M.[2]
[1]Duke-National University of Singapore, Singapore, SINGAPORE, [2]David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA.

Purpose
Isocitrate dehydrogenase 1 (IDH1) mutations have been linked to favorable outcomes in patients with glioblastoma multiforme (GBM). A recent study has demonstrated increased radiosensitivity in GBM cell lines that overexpress IDH1 mutant proteins. Therefore, we hypothesized the rate of change in tumor size as measured using serial quantitative MR volumetry would be significantly different between IDH1 mutant (MUT) versus wild-type (WT) GBMs after radiation therapy (RT).

Materials & Methods
All patients in this study signed institutional review board-approved informed consent to have their information in our neuro-oncology database. A total of n = 39 patients were included in this retrospective study with the following criteria: 1) were de novo GBM, 2) had surgery followed by RT and temozolomide only, 3) had IDH1 mutation status sequenced from frozen section samples, 4) had regular postcontrast T1-weighted images (T1+C) and FLAIR or T2-weighted images within six months after starting RT (censored at recurrence). A higher proportion of MUT patients (n = 10) were selected to increase the statistical power. For each serial scan, the regions of contrast enhancement on T1+C and hyperintensity on FLAIR images were manually contoured and the corresponding volumes (VT1+C and VFLAIR) were calculated. Images acquired prior to the start of RT were omitted due to postsurgical edema and swelling. The volumes measured from the scans immediately after RT were used as baseline for normalization. Linear regression models were used to estimate the rate of change in VT1+C and VFLAIR after RT. Kaplan-Meier survival analysis was performed for progression-free survival (PFS).
Results
IDH1 MUT GBMs demonstrated a favorable response to RT as illustrated by 10/10 mutants having a decrease in contrast-enhanced tumor compared to 13/29 wild-types (binomial test p = 0.0003). In the study period, VT1+C and VFLAIR of the IDH1 MUT group changed at -4.8%/week and 0.6%/week respectively, as compared to 4.7%/week and 9.1%/week of the IDH1 WT group (p = 0.0152 for both). Survival analysis showed IDH1 MUT had a significantly longer PFS compared to IDH1 WT GBMs (median PFS of 72.1 months versus eight months, respectively, p = 0.0004).



Conclusion
This study supports the hypothesis that IDH1 MUT GBMs

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

have increased radiosensitivity compared to WT GBMs as evidenced by the decrease in contrast-enhanced volume (VT1+C) and the stable edema volume (VFLAIR).

Association between Volumetric Imaging Features, Genomic Profile, and Patient Outcome in Glioblastoma: A TCGA Glioma Phenotype Research Group Project

Gutman, D. A.[1]·Holder, C.[1]·Cooper, L.[1]·Dunn, W.[1]·Mikkelsen, T.[2]·Jain, R.[2]·Colen, R.[3]·Jaffe, C.[4]·Saltz, J. H.[1]·Flanders, A.[5]·Brat, D. J.[1]·TCGA Glioma Phenotype Research Group
[1]Emory University, Atlanta, GA, [2]Henry Ford, Detroit, MI, [3]M. D. Anderson Cancer Center, Houston, TX, [4]Boston University, Boston, MA, [5]Thomas Jefferson University, Philadelphia, PA.

Purpose
There is growing interest on the integration of gene expression profiles from tumor biopsies to further classify tumors, although gene expression is influenced not only by the underlying molecular abnormalities driving oncogenesis but also micro- and macro-scale properties. For glioblastoma in particular, neuroimaging provides a unique opportunity to characterize macroscale properties which can affect patient survival as well as genomics. We have previously utilized 2-D semiquantitative imaging features extracted from GBM images to explore these associations. We are now integrating 3D volumetric assessments which we hypothesize will provide a more sensitive measure to evaluate radiogenomic-phenotypic associations.
Materials & Methods
Eighty-nine pre-operative MRI image series were obtained from the Cancer Imaging Archive (TCIA). The postgadolinium T1 image and T2 Flair image were annotated using Velocity AI, a radiotherapy treatment planning system. A contrast-enhancing region (any embedded necrosis) was annotated on the T1 series, and a flair "envelope" consisting of adjacent abnormal signal on the T2 flair were marked up. Annotations subsequently were exported and analyzed using a workflow system developed using niPype to perform volume registration, as well as to calculate the volume of necrosis, contrast enhancement, and edema from the image stack. This framework supports extraction of additional 2D and 3D parameters from the imaging volumes. Genetics data was obtained from the MSKCC cBioPortal, and additional clinical data was obtained from the TCGA archives. Correlations were computed using SAM for genetic correlations, or SPSS. Pathway analysis was performed using Ingenuity Pathway Analysis.
Results
We have previously shown high concordance between measurements obtained via velocity (n = 79, p<0.0001) with independent measures using 3D Slicer in a sample of this data set. A number of volumetric features including overall percentage of necrosis (p<0.001), % of edema (p<0.001) as well as the ratio of contrast enhancement to edema (p<0.003) were associated with poor overall survival. Initial genomics analysis indicated a strong gene set enrichment in the hypoxia-inducible factor signaling (HIF, p<0.0001) and anti-apoptosis pathway (p<0.0159) as a function of the percentage of overall necrosis.
Conclusion
This work further establishes a strong association between macroscopic imaging properties and gene expression. Furthermore, the python-based framework supports the integration of additional imaging features for association studies greatly facilitating our radiogenomic work. We currently are exploring gene signatures associated with both contrast enhancement and edema volumes, as well as characterizing whether relative or absolute measures of imaging properties provide greater sensitivity in the identification of gene/imaging features.

Quantitative Susceptibility Mapping of the Motor Cortex in Upper Motor Neuron Disease

Schweitzer, A. D.[1]·Liu, T.[1]·Zheng, K.[1]·Seedial, S.[1]·Shtilbans, A.[2]·Greene, J.[2]·Shahbazi, M.[2]·Lange, D.[2]·Wang, Y.[1]·Tsiouris, A.[1]
[1]Weill Cornell Medical Center, NewYork Presbyterian Hospital, New York, NY, [2]Hospital for Special Surgery, New York, NY.

Purpose
Specific diagnosis of motor neuron diseases often is difficult due to lack of disease biomarkers. For amyotrophic lateral sclerosis (ALS), there currently exists no quantitative laboratory, imaging, or electrophysiologic test that confirms disease presence or correlates with disease severity. Patients with ALS have been shown to have T2 hypointensity in the motor cortex, possibly due to the T2* effect of deposition of paramagnetic species such as iron. Quantitative susceptibility mapping (QSM) is a novel MRI technique whose pixel intensity directly reflects

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

tissue susceptibility. We sought to determine whether patients with motor neuron disease demonstrate increased tissue susceptibility in the motor cortex when compared to a control group.

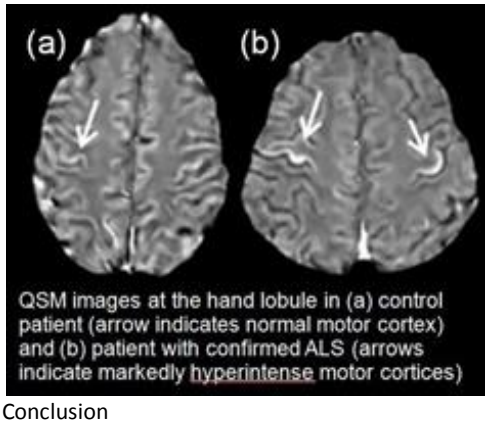
Materials & Methods

Utilizing a 3.0T MRI system, morphology enabled dipole inversion was used to generate QSM images for seven patients with upper motor neuron disease and 23 control patients. Motor cortices were drawn on axial images in a standardized fashion under the guidance of an experienced neuroradiologist. A semi-automatic program was used to refine the segmentation between motor cortices and adjacent white matter/CSF by applying a threshold. Mean motor cortex susceptibility was calculated, and the Wilcoxon rank sum test was used to evaluate for statistical differences between the groups.

Results

Three patients had clinically confirmed ALS, one had confirmed primary lateral sclerosis (PLS), and three had unspecified upper motor neuron disease (possible ALS). In disease and control groups, mean ages were 58.3 and 56.6 years and percent male were 71% and 57%, respectively. Mean motor cortex susceptibility was found to be significantly higher in patients with motor neuron disease than in control patients (41.6 and 28.5, respectively; p = 0.002). Confirmed cases of ALS had the highest susceptibility and the control group had the lowest susceptibility (Table).

Tissue susceptibility in motor cortex by diagnosis	
Confirmed ALS (n=3)	46.2
Motor neuron disease, possible ALS (n=3)	40.7
Confirmed PLS (n=1)	30.3
Control (n=23)	28.5



QSM images at the hand lobule in (a) control patient (arrow indicates normal motor cortex) and (b) patient with confirmed ALS (arrows indicate markedly hyperintense motor cortices)

Conclusion

Quantitative susceptibility mapping has the potential to be a quantitative imaging biomarker for patients diagnosed with motor neuron disease. Further study is necessary to determine whether QSM signal in the motor cortex correlates with disease severity in ALS and other motor neuron diseases.

Cerebral Microbleeds Are Associated with Lower Levels of Cerebrospinal Fluid Beta-Amyloid in Nondemented Elderly Individuals

Chiang, G. C.[1]·Schuff, N.[2]·Weiner, M.[2]
[1]Weill Cornell Medical College-New York Presbyterian Hospital, New York, NY, [2]Veteran Affairs Medical Center, San Francisco, CA.

Purpose

Cerebral microbleeds are four times more likely to be seen in hypertensives than the general population and are associated with white matter hyperintensities on MRI and lacunar infarcts. However, their role in relation to Alzheimer disease (AD) is less clear. A pooled analysis reported that microbleeds are seen in approximately 23% of patients with AD. Pathologically, microbleeds in hypertensives correspond to hemosiderin leakage from abnormal small blood vessels. Conversely, microbleeds in Alzheimer brains are associated with beta-amyloid deposition in vessel walls, or amyloid angiopathy. Furthermore, one study reported that having many microbleeds, greater than seven in this study, correlates with lower beta-amyloid in the cerebrospinal fluid (CSF) and increased brain amyloid deposition, as well as lower scores on the Mini-Mental State Exam (MMSE). The purpose of our analysis was to evaluate the significance of microbleeds in a nondemented cohort without significant vascular comorbidities, for which the Modified Hachinski score was used for screening. Using data from the multicenter Alzheimer's Disease Neuroimaging Initiative (ADNI), we first evaluated whether microbleeds are associated with a hypertensive history, measured blood pressure, age, and APOE4 status. We then evaluated whether microbleeds are associated with CSF biomarkers of Alzheimer disease, namely, beta-amyloid, total tau, and phosphorylated tau. Finally, we evaluated whether microbleeds are associated with memory and overall cognition.

Materials & Methods

Two hundred eighty-six nondemented individuals (90 cognitively normal, 143 with subjective memory complaints, and 53 with mild cognitive impairment) recruited through ADNI underwent a standardized 3T MRI protocol that included 3D MPRAGE and T2* GRE sequences. The number of cerebral microbleeds was visually assessed by a neuroradiologist. All subjects underwent lumbar puncture to determine levels of CSF beta-amyloid, total tau, and phosphorylated tau. Memory

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

was assessed using the delayed recall subscores of the Rey Auditory Verbal Learning Test and Logical Memory II subscale. Overall cognition was determined using the MMSE and Alzheimer's Disease Assessment Scale (ADAS). Hippocampal volumes were calculated using Freesurfer segmentation (version 5.1). Multivariate regression was used to test our three aims, using age, gender, education, hypertensive history, measured blood pressure, APOE4 status, and hippocampal volumes as covariates.
Results
Seventy-five of the 286 (26%) of the cohort had at least one cerebral microbleed. The number of microbleeds was associated with age ($p = 0.004$), but not diagnosis group, gender, education, APOE4 status, hypertensive history, or blood pressure. Adjusting for covariates, including hippocampal volumes, the number of microbleeds was negatively associated with CSF beta-amyloid ($p = 0.04$), but not CSF total tau ($p = 0.58$) or CSF phosphorylated tau ($p = 0.8$). The number of microbleeds was not associated with memory or overall cognition.
Conclusion
Microbleeds were not correlated with hypertension in our cohort. Rather, they increased with age and served as independent predictors of CSF beta-amyloid levels, after accounting for APOE4 status and hippocampal volumes. Further research will determine to what degree these microbleeds, suggestive of underlying amyloid angiopathy, adds to the prediction of future development of Alzheimer disease.

Brain T2-Weighted Lesions in Aging: MR Imaging Overestimates Demyelination in Periventricular and Perivascular Areas

Haller, S.·Kovari, E.·Herrmann, F.·Cuvinciuc, V.·Tomm, A.·Zulian, G.·Lovblad, K.·Giannakopoulos, P.·Bouras, C.
University Hospital Geneva
Geneva, SWITZERLAND.

Purpose
Hyperintense T2-weighted brain MRI lesions frequently are seen in healthy elderly people. Whether or not these radiologic lesions correspond to irreversible histologic changes is still a matter of debate. We report the radiopathologic concordance between T2-weighted lesions and neuropathologically confirmed demyelination in the periventricular, perivascular and deep white matter areas.
Materials & Methods
Fifty-nine very old individuals (mean age 80.5 years ± 9.5 years, 54.2% females) with preserved cognitive abilities and normal pre-mortem brain MRI were evaluated independently by three radiologists (T2-weighted lesions) and two neuropathologists (degree of demyelination). Analyses included inter-rater comparisons both within and between neuropathologists and radiologists, multiple regression models controlling for age and MRI autopsy delay and sensitivity/specificity analyses.
Results
Inter-rater reliability was substantial, almost perfect between neuropathologists (kappa 0.66 - 0.88) and slight-moderate between radiologists (kappa 0.18 - 0.46). Discriminating low versus high lesion scores, sensitivity and specificity values were 0.83 and 0.47 for periventricular, but 0.44 and 0.88 for deep white matter lesions. MR imaging overestimates lesion load in the perivascular and periventricular ($p < 0.001$) areas but underestimates it in the deep white matter ($0 < 0.05$).
Conclusion
These observations indicate that MRI assessment of T2-weighted lesions in periventricular/perivascular areas often lead to false positive cases whereas MRI scans positive for T2-weighted lesions in deep white matter correspond to demyelination. This discrepancy might be related to the relatively high water content in the periventricular and perivascular areas and increasing plasma leakage in the elderly favoring increased T2-weighted signal without necessarily neuropathologically confirmed demyelination.

Susceptibility-Weighted MR Imaging in Extrapyramidal Brain Structures Helps Differentiate Different Types of Gait Disorders

Ng, K.[1]·Schneider, E.[1]·Yeoh, C.[1]·Rumpel, H.[1]·Tan, E.[2]·Chan, L.[1]
[1]Singapore General Hospital, Singapore, SINGAPORE,
[2]National Neuroscience Institute, Singapore, SINGAPORE.

Purpose
Poor gait balance is a frequent clinical diagnostic challenge. Most of these patients have gait disorder parkinsonism (PIGD), although the pathophysiologic differences between idiopathic Parkinson disease (PD) and PIGD remains unclear. Various neurodegenerative disorders associated with parkinsonian syndromes have been found to have increased iron content in the basal ganglia. Susceptibility-weighted MRI (SWI) is sensitive to T2* effects and mineralization. In this study, we evaluated for differences in the extrapyramidal brain structures on SWI between PD and PIGD patients and correlated the SWI values with the degree of gait dysfunction.
Materials & Methods
Patients diagnosed with PD and PIGD were recruited from Movements Disorders Clinics by neurologists. After informed consent, the participating subjects were assessed with the Tinetti score (a validated scale for postural instability), and an MRI brain study at 3T. In addition to conventional MR sequences, an SWI sequence (TE/TR/FA 20/33/15) was included. The MR images were read by a neuroradiologist. Ten ROIs were placed in the

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

midbrain and basal ganglia by two independent raters blinded to subject data and quantitatively evaluated. A multivariate logistical regression analysis was performed with the SWI values as the dependent variable, and age, gender and vascular risk factors as independent variables. P-values of < 0.05 were considered statistically significant. Clinical correlation of the SWI values with the Tinetti score was done using Pearson's correlation.
Results
Forty patients (21 PD, 19 PIGD) were recruited for the study. The mean age of the PD and PIGD patients was 72 years and 74 years, respectively. The inter-rater reliability between the raters was good (ICC >0.8). The SWI intensity values in all regions were on average lower in PIGD than in PD patients, with the lowest results found in globus pallidum. Multivariate analysis showed statistically significant differences for the putamen between PD and PIGD patients ($p < 0.05$), with a similar trend for the other basal ganglia nuclei. Pearson's correlation analysis showed a statistically significant positive correlation between putaminal hypointensity and the Tinetti total score ($r = 0.389$, $p = 0.05$).
Conclusion
We demonstrated that SWI values in PIGD patients were lower compared to PD, providing new clues to the pathophysiologic differences of these conditions. We also showed that there was a positive correlation between the SWI putaminal hypointensity and the Tinetti score, suggesting that this imaging marker may be useful in prospective evaluation for clinical progression.

Caffeine Enhances Task-Related and Functional Connectivity Working Memory Brain Activation in the Elderly

Haller, S.·Rodriguez, C.·Toma, S.·Hofmeister, J.·Sinanaj, I.·Giannakopoulos, P.·Lovblad, K.
University Hospital Geneva
Geneva, SWITZERLAND.

Purpose
Recent evidence indicates that caffeine might be a cognitive normalizer in mild cognitive impairment (MCI) and Alzheimer dementia (AD). Previous studies in young healthy volunteers assessed the complex interaction of caffeine and the BOLD response in fMRI, including cognitive and direct vascular effects. The current investigation in cognitively normal elderly participants complements these previous investigations testing whether caffeine enhances working memory-related brain activation.
Materials & Methods
In a placebo-controlled crossover design, 24 old individuals (mean age 68.8 ± 4.0 years, 17 females) performed a 2-back task. Analyses included task-related general linear model (GLM) and tensorial independent component (TICA) functional connectivity and baseline arterial spin labeling (ASL) perfusion.
Results
There was no significant behavioral difference between caffeine and placebo. Despite a reduction in global perfusion (22.7%, $p<0.001$), caffeine enhanced task-related GLM activation in a distributed network most pronounced in bilateral striatum consistent with the local expression of adenosine receptors. Tensorial independent component functional connectivity was significantly ($p<0.05$) enhanced (Smode + 8.2%) in caffeine versus placebo in a distributed and task-relevant network including working memory and visual areas. The inverse comparison as well as other task irrelevant functional connectivity networks or local perfusion showed no significant change.
Conclusion
Caffeine induced a specific and task-relevant enhancement in both task-related and functional connectivity brain activation. The absence of alterations of task-unrelated functional connectivity networks or local baseline perfusion indicates a specific cognitive effect of caffeine. These results are the basis for further projects in MCI and AD.

Comparison between Parkinson Disease with Dementia and Dementia with Lewy Bodies: Evaluation of White Matter Abnormality with Diffusion Tensor Imaging and Tract-Based Spatial Statistics Study

Kim, D.[1]·Kim, S.[1]·Kim, H.[2]·Choi, C.[1]·Kim, H.[1]·Lee, C.[1]
[1]Asan Medical Center, Seoul, KOREA, REPUBLIC OF, [2]Korea Basic Science Institute, Cheongwon, KOREA, REPUBLIC OF.

Purpose
Cognitive impairment and dementia occur commonly in patients with Parkinson disease (PD). Dementia with Lewy bodies (DLB) and PD with dementia (PDD) are two main categories of dementia associated with PD. Although DLB and PDD have different temporal sequence of symptoms and clinical features, pathologic difference is not well understood and there are no known neuroimaging features to differentiate between the two groups. Our purpose is to compare white matter abnormalities in DLB and PDD using diffusion tensor MR imaging and tract-based spatial statistics (TBSS).
Materials & Methods
Diffusion tensor imaging (DTI) was obtained with a 3.0T MR system in age-matched groups of 53 patients with PD, 27 patients with PDD, and 16 patients with DLB. Patients were selected from our Parkinson disease database on the basis of clinical criteria and consensus guidelines. Patients with history of chronic hypertension, diabetes, stroke or head injury, or prominent high signal in the white matter

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

on T2-weighted images were excluded from the study. Fractional anisotropy (FA) and mean diffusivity (MD) maps were generated using FDT in the FMRIB's Software Library (FSL) package and processed to perform tract-based comparisons of FA and MD among the three groups using TBSS in FSL. To address multiple comparison issue, this result is corrected for family-wise error using threshold-free cluster enhancement (TFCE) method across the white matter skeleton.

Results

Between PDD and PD groups, both FA and MD maps showed difference in both cingulum, frontal and parietal corona radiata, superior longitudinal fasciculus, corpus callosum, and posterior thalamic radiation. In contrast, between DLB and PD groups, both FA and MD maps showed differences only in the right cerebral peduncle and the right internal capsule. Fractional anisotropy was decreased in the corpus callosum, both side anterior, superior, and posterior corona radiate and both tapetums in PDD group compared to DLB group: in contrast, MD map did not showed significant difference between PDD and DLB groups.

Conclusion

Diffusion tensor imaging with TBSS revealed different extent of white matter abnormality between DLB and PDD groups. Parkinson disease with dementia group showed more wide area of white matter abnormality compared to DLB group.

Combined Positron Emission Tomography-MR Imaging for the Evaluation of Suspected Dementia: Initial Experiences and Comparison to Positron Emission Tomography-CT

Shepherd, T. M.·Zhou, Y.·Ding, Y. S.·George, A. E.·Glielmi, C.·Faul, D.·Shulman, M. B.·Boada, F. E.·Friedman, K. P.
New York University Langone Medical Center
New York, NY.

Purpose

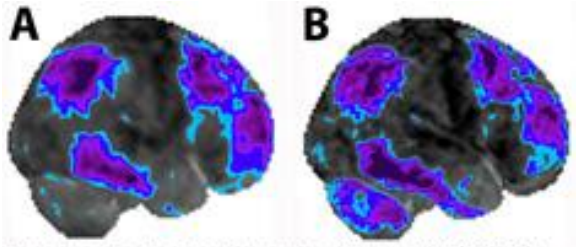
MR imaging of patients with cognitive impairment suspected to have neurodegenerative disease can exclude treatable causes such as hemorrhage, tumor or hydrocephalus. Regional hypometabolism on FDG-PET and group-wise differences observed using advanced MRI techniques appear more specific for neurodegenerative diseases. Simultaneous PET and MRI for cognitively-impaired patients may facilitate shortened examination times, PET coregistration to high-resolution anatomical data, temporally-synchronized data collection and increased diagnostic accuracy. We describe initial experiences evaluating patients with suspected dementia using an FDA-approved 3T mMR combined PET/MRI scanner (Siemens Healthcare, Erlangen, Germany) and compare these results to conventional PET-CT to help validate its routine clinical use.

Materials & Methods

Patients with suspected dementia undergoing clinical ^{18}FDG PET-CT were recruited to undergo PET-MRI at a nearby facility. PET-CT utilized a 15-minute PET acquisition on a Siemens mCT with iterative reconstruction, 512x512 matrix, 1.5-mm slice interval and low-dose CT for attenuation correction. PET-MRI were acquired in list-mode for 60 minutes and reconstructed with OSEM, 512x512 matrix, 1.5-mm slice interval and Dixon MR-based attenuation correction. Diagnostic MRI sequences were obtained simultaneously. PET-CT and PET-MRI were interpreted visually and then reinterpreted using MIM-neuro quantitative analysis (Cleveland, OH).

Results

Sequential brain PET-CT and PET-MRI were obtained from six patients with suspected dementia (71.5±10.6 years, 4 males) after a single IV dose of 9.4±0.5 mCi mCi FDG. Mean uptake time for PET-CT and PET-MRI were 66.3±14.2 min and 180.2±23.8 min respectively. PET-CT visual interpretation and scoring of ^{18}FDG uptake indicated two normal studies, one with moderate and three with severe changes associated with Alzheimer disease (hypometabolism in the precuneus, posterior cingulate & medial temporal lobes). Similar patterns of regional ^{18}FDG accumulation were observed in PET-MRI for all six patients without scoring discrepancies compared to PET-CT, although there was apparent decreased cerebellar ^{18}FDG in four of the six patients (Figure). Quantitative analysis of ^{18}FDG uptake relative to normative data demonstrated no other focal regional differences between PET-CT and PET-MRI although this comparison may be limited by the protracted uptake times for PET-MRI data.



Lateral projection shaded-surface display of PET-CT (A) and PET-MRI (B) data from the same patient with hypo-metabolism relative to normative data in the parietal, temporal and frontal regions. Cerebellar hypometabolism observed in the PET-MRI data (4 of 6 patients) may be from different regional washout kinetics after significantly longer uptake times.

Conclusion

Combined PET-MRI appears feasible and valid for routine clinical evaluation of patients suspected of dementia. Dixon MR-based attenuation correction appears to offer similar quantitative ^{18}FDG uptake results without obvious region-specific limitations. Future work will investigate real-time MRI-based motion correction and further

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

refinement of MR-based attenuation correction. It is hoped combined PET-MRI may increase diagnostic accuracy for neurodegenerative diseases in individual patients.

Internal Structures of Globus Pallidus in Patients with Parkinson Disease: Evaluation with Quantitative Susceptibility Mapping

Ide, S.[1]·Kakeda, S.[1]·Ueda, I.[1]·Watanabe, K.[1]·Murakami, Y.[1]·Moriya, J.[1]·Ogasawara, A.[1]·Futatsuya, K.[1]·Sato, T.[1]·Ohnari, N.[1]·Okada, K.[1]·Tsuji, S.[1]·Liu, T.[2]·Wang, Y.[2]·Korogi, Y.[1]
[1]University of Occupational and Environmental Health, Kitakyushu, JAPAN, [2]Cornell University, Ithaca, NY.

Purpose
The globus pallidus (GP) is subdivided into the medial (GPm) and lateral (GPl) segments, and a thin layer in GP, medial medullary lamina (MML), separates the GPm from the GPl. Deep-brain stimulation has shown therapeutic benefits for several neurodegenerative disorders including Parkinson disease (PD); the GPm is one of the targets. Quantitative susceptibility mapping (QSM) is a novel technique which allows determining the bulk magnetic susceptibility distribution of tissue in vivo from gradient echo magnetic resonance phase images. Our objective is to clarify if the QSM can reveal the GPm in PD patients.
Materials & Methods
The conventional MRI as well as QSM and T2*mapping were performed in 19 patients with PD patients and in 15 age-matched normal control (NC) subjects. For the QSM and T2*mapping, the coronal images were acquired covering the entire basal ganglia. The QSM was performed for various ranges of echo time by using both the magnitude and phase components in the morphology-enabled dipole inversion method. Two neuroradiologists evaluated the GP on QSM imaging, T2*mapping and conventional MRI (T2WI and FLAIR), and classified the delineation of the GP into following four grades; Grade 1= GP is not delineated, Grade 2= GP is delineated, but the differentiation of GPm from GPl is poor, Grade 3= Differentiation of GPm from GPl is good, but delineation of MML is unclear, Grade 4= Delineation of MML is clear.
Results
Regarding the visualization of the GP, the image quality with QSM was scored to be Grade 4 in 15 (79%) of 19 PD patients and in seven (47%) of 15 NC subjects, and Grade 3 in 4 (21%) of 19 PD and in eight (53%) of 15 NC (Figure). All study subjects were scored as grade 1 or 2 on conventional MR images. For the mean qualitative image score, QSM were significantly superior to T2*mapping images in both groups (3.80 versus 2.27 in PD patients, $P < 0.05$; 3.40 versus. 2.27 in NC subjects, $P < 0.05$, respectively).

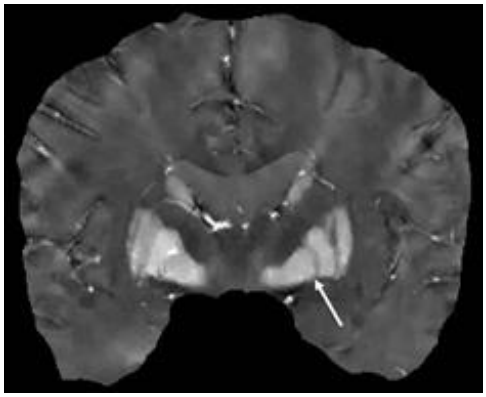

Figure: The QSM image of a parkinson disease patient. On coronal QSM image, the MML separating the GPm from the GPl is clearly seen as a thin low signal intensity layer within the GP (Grade 4).

Conclusion
Quantitative susceptibility mapping technique is able to depict the internal structures of the GP that has been difficult to appreciate on conventional MR imaging; in addition, the QSM showed superior image quality to T2*mapping.

Gait Response to Spinal Tap in Normal Pressure Hydrocephalus Is Independent of Cerebrospinal Fluid Volume Removed

Thakur, S.·Serulle, Y.·Rusinek, H.·Nutanson, I.·Tyagi, V.·Tolete, P.·Golomb, J.·Shepherd, T.·George, A.
New York University School of Medicine
New York, NY.

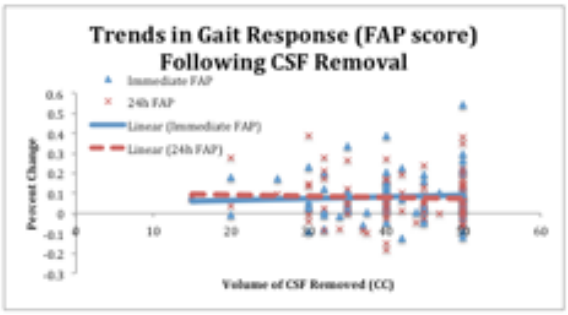
Purpose
Normal pressure hydrocephalus (NPH) is a debilitating disorder characterized by gait instability, cognitive impairment and urinary incontinence. Positive response to cerebrospinal fluid (CSF) removal by spinal tap in NPH patients is an accepted diagnostic marker that predicts positive response to ventricular shunting. To our knowledge, it is unknown whether the amount of CSF removed during the procedure affects gait response. We used longitudinal gait measures to analyze volume of CSF removed as a predictor of gait improvement for a cohort of patients with clinical and imaging findings of NPH.
Materials & Methods
We retrospectively analyzed 72 patients with clinically diagnosed idiopathic NPH who received gait evaluation before and after CSF removal. Patients undergoing spinal tap were placed in prone or prone oblique position. All taps were performed at L2/3 or L1/2 with fluoroscopic assistance using an 18-gauge needle. Evaluation consisted of mean time to walk a fixed distance (WT) and a functional ambulation profile (FAP) score. Evaluation occurred before, immediately after, and 24 hours after CSF

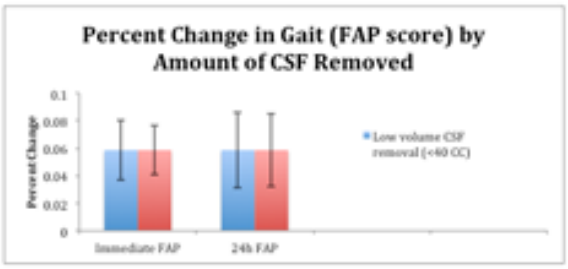
Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

removal. IBM SPSS 19.0 statistical software (paired t-tests, repeated measures, ANOVA, and regression analyses) was used to examine the relationship between volume of CSF removed and longitudinal changes in WT and FAP. WT and FAP were analyzed as recorded and after logarithmic normalization.

Results

The amount of CSF removed ranged from 15-50 mL. Forty-four out of 72 patients (61%) showed improvement following the spinal tap. There was no relationship [N = 72, R2 = 0.004, p = 0.6, regression slope = 0.0009, 95% confidence interval (-0.0024 - 0.0042)] between the volume of CSF removed and either WT or FAP at either time point (Figure). Analysis limited to responsive patients also showed no correlation between volume and gait response.





Conclusion

No relationship was demonstrated between the volume of CSF removed and gait improvement following spinal tap.

Combined Gray Matter Voxel-Based-Morphometry and White Matter Tract-Based Spatial Statistics Analysis in Young First Episode Psychosis Patients with and without Cannabis Consumption

Haller, S.·Curtis, L.·Badan, M.·Bessero, S.·Albom, M.·Chantraine, F.·Alimenti, A.·Lovblad, K.·Giannakopoulos, P.·Merlo, M.
University Hospital Geneva
Geneva, SWITZERLAND.

Purpose

Cannabis consumption is temporally associated with the development of first episode psychosis (FEP). Whether or not the chronic use of this substance induces structural brain changes that may be responsible for the cognitive and psychologic disturbances in this disorder is still a matter of debate. To address this issue, we compared the MRI-assessed gray (GM) and white (WM) changes in young patients with FEP users and nonusers of cannabis.

Materials & Methods

This prospective study included 50 consecutive FEP subjects: 33 users (22.7 ± 4.1 years, four women) and 17 nonusers (23.9 ± 4.2 years, 10 women). Users were further divided into 15 heavy (23.3 ± 4.5 years, two women) and 18 light users (22.2 ± 3.8 years, two women) according to their lifetime cannabis use. Voxel-based morphometry (VBM) analysis of GM and tract-based spatial statistics (TBSS) analysis of WM were performed. Age and gender were used as nonexplanatory coregressors.

Results

There were no suprathreshold differences between user and nonuser groups for both GM and WM parameters. This was also the case when heavy users were considered alone. Multivariate models controlling for age and gender confirmed these findings.

Conclusion

We found no evidence for cannabis consumption-related alterations in GM or WM in FEP subjects. Due to the strict correction for multiple comparisons and sample size, we cannot formally exclude subtle morphometric changes associated with cannabis consumption. However, even if present, such potential alterations would be of low magnitude.

Corpus Callosum on Diffusion Tensor Imaging in Gait Disorders

Ng, K.[1]·Chan, L.[1]·Rumpel, H.[1]·Tan, E.[2]
[1]Singapore General Hospital, Singapore, SINGAPORE,
[2]National Neuroscience Institute, Singapore, SINGAPORE.

Purpose

Poor gait balance is a frequent clinical diagnostic

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

challenge. Most of these patients have gait disorder parkinsonism (PIGD), although the pathophysiologic differences between idiopathic Parkinson disease (PD) and PIGD remains unclear. The integrity of the corpus callosum has been implicated in gait disorders. Diffusion tensor MRI (DTI) is sensitive to microstructural integrity of brain white matter. In this study, we evaluated the integrity of the corpus callosum on DTI between PD and PIGD patients and correlated the DTI values with the degree of gait dysfunction.
Materials & Methods
Patients diagnosed with PD and PIGD were recruited from Movements Disorders Clinics by neurologists. After informed consent, the participating subjects were assessed with the Tinetti score (a validated scale for postural instability), and an MRI brain study at 3T. In addition to conventional MR sequences, a DTI sequence (TR/TE 8200/86, two b values 0 and 800 s/mm2 in 30 noncollinear directions, 128 x 128 matrix, FOV 240 mm) was included. The MR images were read by a neuroradiologist. Regions of interest (ROI) were placed in the genu and splenium of the corpus callosum. In addition, the transcallosal motor tract within the corpus callosum was depicted using the commercially available tractography software based on a deterministic streamline (FACT) approach, connecting two seed regions, one in each right and left motor strip. An ROI also was dropped in the callosal body containing the transcallosal motor tract. The quantitative DTI indices of apparent diffusion coefficient (ADC) and fractional anisotropy (FA) from these ROIs were evaluated and compared between PD and PIGD. Multivariate analysis and clinical correlation of the DTI metrics with the Tinetti score were performed.
Results
Forty patients (21 PD, 19 PIGD) were recruited for the study. The mean age of the PD and PIGD patients was 72 years and 74 years, respectively. The FA values were significantly lower and/or ADC values significantly higher in the callosal body (FA 0.80 versus 0.88, ADC 0.86 versus 0.72 x10-3 mm2/s) and splenium of the corpus callosum (ADC 0.75 versus 0.67 x10-3 mm2/s) in PIGD than in PD patients ($p < 0.05$). Multivariate analysis showed that the FA ($p < 0.05$) and ADC ($p < 0.005$) values in the corpus callosum body differentiated PIGD from PD patients. The callosal body FA values was significantly lower and ADC values significantly higher in PIGD patients with lower Tinetti scores, than those with high scores ($p < 0.05$).
Conclusion
We demonstrated that FA and ADC abnormalities in the callosal body containing the transcallosal motor tract were significantly different between PIGD and PD patients and correlated with the severity of postural instability. This additional differential indicator of gait disability in subjects with parkinsonism may be helpful differentiating PD from those with predominant gait problems.

Angioplasty and Stenting of Symptomatic Severe Stenosis of Vertebral and Subclavian Artery: Quantitative Evaluation of Clinical and Hemodynamic Outcome

Chang, F.·Luo, C.·Lirng, J.·Lin, C.·Wu, H.·Hung, S.·Guo, W.·Teng, M.
Taipei Veterans General Hospital/National Yang Ming University, School of Medicine
Taipei, TAIWAN.

Purpose
Angioplasty and stenting (AS) of the severe stenosis of the subclavian and vertebral arteries was reported to be effective in preventing ischemic stroke and improving symptoms of vertebrobasilar insufficiency (VBI). However, the impact of the AS on the hemodynamic of the territory of vertebrobasilar system and improvement of the components of clinical symptoms was not described. This study was designed to evaluate the influence of AS on: 1) hemodynamic change in the territory of vertebrobasilar system by segmented MR perfusion study; 2) clinical change of life quality by DHI (Dizziness Handicap Inventory) and SF-36 (36-Item Short-Form Health Survey) questionnaire.
Materials & Methods
During the past three years, we performed AS in 25 patients of severe stenosis (60-95%, 76.4 ± 10.6%) of vertebral and/or subclavian arteries associated with VBI. All patients finished a 3-time MR perfusion study and life quality questionnaire, including before the AS, and within one month and about six months after the AS. The quantitative MR perfusion study includes the expectation-maximization (EM) algorithm for brain MR segmentations and multi-tissue hemodynamics. We evaluate the rCBV, rCBF & MTT of the midbrain. The contralateral basal ganglion was taken for comparison. The DHI and SF-36 questionnaire are used to evaluate dizziness and health-related quality of life. All data were collected for statistical analysis.
Results
Angioplasty and stenting was successfully done in all of the 25 patients without complications. They included six females and 19 males with average age of 71.9 ± 10.4 (55-85 years old). All patients showed variable degree of

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

clinical improvement of the symptoms of vertebrobasilar insufficiency after the management. No restenosis was noted in the followup. Complete 3-time MR perfusion studies were done in 22 patients. Complete 3-time life quality questionnaires (SF-36 and DHI) were done in all 25 patients. On MR perfusion study, the average ratio of MTT, rCBF and rCBV of midbrain to contralateral basal ganglion before AS/ within one month/six months after AS were 1.53 ± 0.44/1.26 ± 0.27/1.36 ± 0.36 (MTT), 0.93 ± 0.22/1.13 ± 0.21/1.03 ± 0.21 (rCBF), 1.33 ± 0.40/1.36 ± 0.24/1.27 ± 0.24 (rCBV). For the SF-36 questionnaire, the results within one month after AS showed no significant difference compared with the preprocedural results. Significant clinical improvement was noted in the six month follow-up of bodily pain (P = 0.019). General health perceptions (P = 0.0153), Vitality (P = 0.0462), Social functioning (P = 0.0149), role problem due to emotional problem (P = 0.0186), mental health (P = 0.0213). The DHI questionnaire showed significant improvement of physical function after treatment within one month (P = 0.0068) and about six months (P = 0.008).
Conclusion
Angioplasty and stenting of the symptomatic stenosis of subclavian/vertebral arteries had improved hemodynamic change of the brainstem with more in MTT and rCBF than in rCBV. The clinical improvement was significant in the delayed function of SF-36 (six months) and recent and delayed physical function in DHI (<one month and six months).

Fate of the Penumbra after Endovascular Mechanical Recanalization

Friedrich, B.·Kertels, O.·Prothmann, S.·Wunderlich, S.·Zimmer, C.·Förschler, A.
Klinikum Rechts der Isar, Technische Universität München Muenchen, GERMANY.

Purpose
In the last years endovascular mechanical recanalization (EMR) has developed to a safe and often used method in the treatment of acute ischemic stroke. In the diagnostic phase perfusion CT often is brought up to visualize the so-called ischemic core - which is reckoned as unrescuable - and the penumbra as rescuable tissue-at-risk. The goal of the present study was to assess the evolution of the infarct compared to the performed perfusion CT and to analyze the clinical and interventional factors determining the fate of the penumbra.
Materials & Methods
All patients receiving EMR in the anterior circulation and receiving a perfusion CT beforehand were identified. Perfusion CTs were fused with postinterventional CCTs and the infarct volume was specified. The clinical parameters, short-time outcome and the interventional result were analyzed and correlated to the infarct size and the results of the perfusion CT.
Results
Sixty patients (32 female) were included in the present study. The mean age was 67 +/- 17 years with a NIHSS of 13.4 +/- 5.9. After EMR 76.7% reached a TICI score of 2b or 3. The final infarct volume was significantly smaller in patients with a TICI score of 2b/3 compared to patients with a less sufficient recanalization (17.9 +/- 3.2 cm3 versus 33.1 +/- 6.3 cm3; p<0.05). Also the final TICI score determined significantly the volume of penumbra rescued. Whereafter TICI 2b/3 recanalization 90.4 +/- 6.4% of the potential infarct size (as calculated by the summation of infarct core and penumbra) could be rescued, in patients with TICI score 2a or less only 70.9 +/- 32.3 of the potential infarct was salvaged (p<0.05). Also the volume of salvaged penumbra determined the short-time outcome expressed by the change in NIHSS. Thirty-one patients improved >4 NIHSS points with 72.1 +/- 9.2 cm3 rescued penumbra, in contrast to four patients where only 18.8 +/- 41.9 cm3 could be rescued and subsequently resulting in their death (p = 0.09).
Conclusion
Endovascular mechanical recanalization is a feasible tool to rescue endangered tissue at risk. Additionally infarct volume is a valuable tool in predicting the short- to mid-term outcome.

Does Transfer Status Affect Outcomes in Acute Ischemic Stroke Patients Treated Endovascularly?

Soltanolkotabi, M.[1]·Honarmand, A. R.[1]·Bergman, D.[1]·Shaibani, A.[1]·Hurley, M. C.[1]·Conners, J. J.[2]·Lee, V.[2]·Bernstein, R. A.[1]·Prabhakaran, S. K.[1]·Ansari, S. A.[1]
[1]Northwestern University Feinberg School of Medicine, Chicago, IL, [2]Rush University Medical Center, Chicago, IL.

Purpose
Access to intra-arterial therapy (IAT) for acute ischemic stroke (AIS) is limited to comprehensive stroke centers (CSCs) with timely access deemed critical for success. Inter-hospital transfers represent a growing subset of patients in which outcomes have not been well studied.
Materials & Methods
We retrospectively analyzed consecutive anterior circulation AIS patients that underwent IAT at four institutions from 2006-2011. We excluded patients selected using perfusion imaging. Patient demographics, medical risk factors, presentations, technical, and clinical (NIHSS and mRS scores) outcomes, complications, and mortality were studied. Symptom-onset, groin puncture, and end-of-procedure times were recorded. THRIVE scores were calculated. Successful recanalization was defined as TICI ≥2b. Good functional outcome was defined as mRS 0-2 at 90 days. Patients were categorized into those who were

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

transferred from outside institutions and those who presented directly to the CSCs.
Results
Of 116 patients studied, 68 (58.6%) were transferred from outside institutions. Transfers and nontransfers were similar in THRIVE scores (p = 0.300), median symptom-onset to groin puncture times (306 versus 315 minutes; p = 0.572), successful recanalization (p = 0.574), and symptomatic ICH (13.2 versus 10.4, p = 0.776), but differed by age (59 versus 69 years; p = 0.002), prior stroke (3% versus 22%, p = 0.002), cardiac history (17.9 versus 36.6%, p = 0.040), baseline NIHSS (20 versus 17, p = 0.005), and location of occlusion (45.6% versus 22.9% ICA, p = 0.012). Transfer patients had significantly worse outcomes at 90 days (mRS 0-2: 16.2% versus 60.4%, p<0.001). In multivariate analysis, transfer status was an independent predictor of poor functional outcome (adj. OR 0.05, 0.011-0.222), adjusting for relevant covariates.
Conclusion
Transferred AIS patients have worse functional outcomes at 90 days than nontransfers, independent of baseline risk factors, stroke severity, time to IAT, and procedural success/complications. Further investigation should focus on residual factors that may contribute to our findings such as baseline/final infarct volumes, premorbid functional status, and poststroke care including rehabilitation.

Outcome after Mechanical Thrombectomy by Stent Retriever under Conscious Sedation: Comparison between Tandem and Single Occlusion of the Anterior Circulation

Pierot, L.·Soize, S.·Kadziolka, K.·Estrade, L.·Barbe, C.·Serre, I.
Hopital Maison-Blanche
Reims, FRANCE.

Purpose
In acute ischemic stroke patients, tandem ICA/MCA (internal carotid artery/middle cerebral artery) occlusion predicts poor outcome after systemic thrombolysis. We aimed to compare patient's outcome after mechanical thrombectomy of tandem and single anterior circulation occlusion.
Materials & Methods
Consecutive patients with acute ischemic stroke of the anterior circulation who underwent mechanical thrombectomy performed with a stent retriever under conscious sedation in six hours from the symptoms onset were included in a prospective study. Data were collected on clinical, imaging and endovascular findings. Tandem and single occlusions were compared with functional outcome and mortality at three months for primary outcome.
Results
From May 2010 to January 2012, 42 patients with an acute ischemic stroke attributable to MCA and/or ICA occlusion were treated. Eleven patients (26.2%) presented a tandem occlusion and 31 patients (73.8%) a single anterior circulation occlusion. Baseline characteristics were similar between the two groups. Recanalization status did not differ significantly (p = 0.76) but patients with tandem occlusion had a worse functional outcome (p = 0.01), a higher mortality rate at three months (p = 0.03) and higher symptomatic intracranial hemorrhages at 24 hours (p = 0.01).
Conclusion
Tandem lesions predicts poor outcome after mechanical thrombectomy by stent retriever under conscious sedation.

Acute Stroke Patients Treated with Stent Retrievers in Carotid "T" Occlusions Have Improved Recanalization and Outcome

Lum, C.·Orton, T.·Alhazzaa, M.·Iancu, D.·Lesiuk, H.·Santos, M.·Sharma, M.·Ottawa Stroke Research Group
University of Ottawa
Ottawa, ON, CANADA.

Purpose
Higher recanalization rates have been found with stent-retriever use in acute large vessel stroke compared to prior techniques. We sought to evaluate the efficacy and outcomes in acute stroke patients treated with stent retrievers compared to a previous cohort of patients treated with multiple other recanalization strategies.
Materials & Methods
A retrospective chart review was performed in 60 consecutive patients who underwent intra-arterial therapy for acute stroke at an academic stroke referral center between Jan. 2010-Nov. 2012. The cohort prior to this interval was previously analyzed. We divided this cohort into two groups based on treatment with a stent retriever as first-line strategy (group 1) compared to a nonstent retriever multimodality cohort (group 2). Patient baseline demographic information, recanalization rates, recanalization times and post-treatment morbidity and mortality data were compared between the two groups. A good outcome was defined as a 30-day modified Rankin score $\leq$ 2 or 10-point decrease in NIHSS.
Results
There was no significant difference between the two groups in patient age, gender, intravenous tissue plasminogen activator use or stroke risk factors (diabetes, hypertension, dyslipidemia, smoking, peripheral vascular disease, coronary artery disease, prior stroke or transient

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

ischemic attack, severe internal carotid stenosis or atrial fibrillation). Intravenous tPA was administered in 65% and 68%. In group 2, 27% had only ia-tPA, 49% were primarily treated with Penumbra, 16% angioplasty, 3% stent only (ICA dissection) and 5% had failed target lesion access. There was a higher baseline median NIHSS score in the stent-retriever group (18 versus 16, p = 0.034). Twenty-three patients treated primarily with stent retrievers were compared to 37 with a multimodality approach. Overall, there were higher recanalization rates in the stent-retriever group (87% versus 51% group 2, p = 0.005). Good outcomes at 30 days were higher in the stent-retriever group (78% versus 43% group 2, p = 0.008). There was lower mortality in patients treated with stent-retrievers (4% versus 32% in group 2, p = 0.011). There was no significant difference in median time to recanalization (68 versus 79 mins). There was lower mortality (4% versus 32%, p = 0.011) and fewer symptomatic hemorrhages (none versus 11%, p = 0.036) in the stent-retriever group. Terminal carotid "T" occlusions comprised 52% of the stent-retriever cases versus 30% in the group 2 cohort. The proportion of "T" lesions was higher than other reported studies (16%-32%). Recanalization rates were higher in the stent-retriever group (83% versus 38%, p = 0.0123). There were more good outcomes in the stent-retriever group (67% versus 22%, p = 0.036). Mean recanalization times were shorter in patients treated with stent retrievers (69 versus 191 mins, p = 0.0023).

Conclusion

An endovascular strategy employing stent retrievers as the first line revascularization technique improves recanalization rates and good outcomes with reduced morbidity and mortality. In a series with a substantial proportion of carotid "T" occlusions, stent retrievers had higher rates of recanalization, shorter recanalization times and better good outcomes compared to a previous multiple modality approach.

Characteristics and Outcomes of Acute Ischemic Stroke Patients Not Selected for Intra-Arterial Intervention by Perfusion Imaging

Soltanolkotabi, M.·Honarmand, A. R.·Prabhakaran, S. K.·Hurley, M. C.·Shaibani, A.·Ansari, S. A.
Northwestern University Feinberg School of Medicine Chicago, IL.

Purpose

Perfusion imaging has been proposed as an effective modality in selecting acute ischemic stroke (AIS) patients who may benefit from intra-arterial (IA) intervention. We investigated the characteristics and outcomes of patients that were deemed ineligible for IA intervention based on perfusion imaging as compared to those who underwent intervention at our institution.

Materials & Methods

A multicenter retrospective review of all AIS patients who underwent perfusion imaging from February 2010 to August 2012 was conducted. Inclusion criteria were the following: symptom-onset to presentation ≤ eight hours, anterior circulation large vessel occlusion as determined by CT/MR angiography (MCA/ICA occlusions), baseline National Institute of Health Stroke Scale (NIHSS) score ≥ 8. Patients selected or excluded for IA intervention based on CT/MR perfusion imaging profiles (CBV/DWI infarct core < 1/3 MCA territory and mismatch of ischemic penumbra > 20% infarct core) were separated into subgroups for analysis. Patient demographics, cardiac and stroke risk factors, intravenous (iv) tPA utilization, location of occlusion, time from symptom-onset to perfusion imaging, NIHSS and modified Rankin Scores (mRS) scores (baseline, discharge, and 90 days), discharge disposition (home, rehabilitation/nursing home, hospice), and mortality rates were recorded. Good functional outcome was defined as mRS 0-2 at 90 days. Statistical analyses were performed with SPSS 20.0.

Results

One hundred ten eligible AIS patients underwent perfusion imaging of which 62 were excluded from IA intervention (56.4%) based on CT/MR perfusion imaging profiles. Table 1 details patient characteristics and outcomes in the intervention versus nonintervention subgroups.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Conclusion

Among a large cohort eligible for intervention, mismatch was present in younger patients and fewer vascular risk factors. These data suggest that advanced age and atherosclerotic risk factors may influence rate of progression from ischemia to infarction through decreased cerebrovascular reserve and collateral flow in response to arterial occlusion. Despite earlier time to presentation (imaging) and greater receipt of iv tPA, those without mismatch were six-fold less likely to be discharged to home and half as likely to have independent functional outcomes. However, nearly one third of nonintervention patients achieved functional independence at three months suggesting the need to refine patient selection strategies for IA intervention.

Perfusion-Based Selection Leads to Improved Outcomes Compared with Time-Based Selection for Endovascular Reperfusion Therapy in Acute Ischemic Stroke

Soltanolkotabi, M.[1]·Prabhakaran, S. K.[1]·Honarmand, A. R.[1]·Shaibani, A.[1]·Hurley, M. C.[1]·Curran, Y.[1]·Bernstein, R. A.[1]·Alberts, M. J.[1]·Lee, V. H.[2]·Conners, J. J.[2]·Ansari, S. A.[1]
[1]Northwestern University Feinberg School of Medicine, Chicago, IL, [2]Rush University Medical Center, Chicago, IL.

Purpose

Controversy exists on the role of perfusion imaging-based selection of patients with acute ischemic stroke (AIS) for endovascular reperfusion therapy (ERT). Our hypothesis was that perfusion imaging-based selection would improve functional outcomes at three months compared to time-based selection alone.

Materials & Methods

We reviewed data from consecutive AIS patients treated with ERT at four centers between 2006 and 2011. We excluded patients with initial NIHSS score < 8 and those with posterior circulation occlusions. We collected data on demographics, initial NIHSS score, intravenous tissue plasminogen activator (iv tPA), use of perfusion imaging (CT or MRI), time from onset to groin puncture, initial and final reperfusion grade using the modified TICI scale, procedural complications using ECASS criteria, and functional outcome defined as modified Rankin Scale (mRS) 0-2 at three months. Using univariable statistics and multivariable logistic regression, we assessed whether patients who underwent perfusion imaging had better outcomes than those selected based on time alone. We estimated odds ratios (OR) and 95% confidence intervals (CI) in the final model.

Results

One hundred eighty-five patients (mean age 66.7 years; median NIHSS score 19; MCA occlusion 73% and ICA occlusion 27%) were included. TICI 2b or 3 reperfusion grade was achieved in 49.7% while symptomatic hemorrhage (PH1, PH2, or perforation) occurred in 10.8%. Good outcome at three months was seen in 41.7%. Perfusion imaging was used in 69 (37.3%) patients (45 CT and 24 MRI) and was associated with increased onset-to-groin puncture time (359 versus 298 minutes, P = 0.019). Patients who underwent perfusion imaging also were older (73 versus 63 years, P<0.001). Those who underwent perfusion imaging were more likely to have good outcome (53.6 versus 34.5%, P = 0.011). In multivariable analysis, perfusion imaging remained a predictor of good outcome (adj. OR 2.35, 95% CI 1.17-4.72), independent of initial NIHSS score (adj. OR 0.91, 95% CI 0.86-0.97), TICI 2b or 3 reperfusion (adj. OR 4.94, 95 CI 2.50-9.76), and iv tPA use (adj. OR 2.50, 95% CI 1.26-4.94).

Conclusion

In this multicenter study, AIS patients who underwent perfusion imaging were over two-fold more likely to have good outcome following ERT despite a delay in time to

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

treatment and age imbalance between groups. Further studies should continue to address the optimal perfusion imaging thresholds for patient selection for ERT.

Metabolic Syndrome and Outcomes in Patients with Acute Ischemic Stroke Undergoing Endovascular Treatment

Gleason, A. K.[1]·Nahabet, E.[1]·Devulapalli, K.[2]·Hsu, D.[3]
[1]Case Western Reserve University School of Medicine, Cleveland, OH, [2]University Hospitals Case Medical Center, Cleveland, OH, [3]Goodman Campbell Brain and Spine Indiana University, Indianapolis, IN.

Purpose
Previous studies have investigated metabolic associations with regards to stroke presentation and stroke outcomes in patients undergoing stroke treatment with intravenous tissue plasminogen activator (tPA); however, associations between metabolic risk factors and outcomes for patients with acute ischemic stroke treated endovascularly are unknown. The purpose of this study is to identify if metabolic syndrome or its components are predictive of stroke severity and outcomes in patients who underwent endovascular treatment for acute ischemic stroke.
Materials & Methods
A retrospective analysis of a single institution's stroke database collected between January 2008 and March 2011 was conducted. Inclusion criteria included patients undergoing endovascular treatment of acute ischemic stroke through mechanical thrombectomy (MT) and/or intra-arterial tPA (IA-tPA). Metabolic syndrome and its components, as defined by the International Diabetes Federation (IDF) was recorded. Severe stroke was defined as severe if National Institute of Health stroke scale (NIHSS) > 15. Outcome measures included successful vessel recanalization defined by TIMI scores ≥ 2, favorable neurologic outcome (FNO) defined by immediate postprocedural change in NIHSS ≥ 8, and mortality. Outcomes were compared between groups using Chi-Square contingency table analysis. Binary logistic regression models were created to assess predictors of outcome with independent variables chosen if Chi-Square analysis yielded P<0.100.
Results
One hundred fifty-one patients presenting with acute ischemic stroke treated endovascularly. Of these, 32 (21.2%) patients had metabolic syndrome and 91 (60.3%) patients presented with severe stroke. No statistically significant associations were found between incidence of severe stroke and metabolic syndrome or its components. Successful recanalization was achieved in 117 (77.5%) patients. Factors associated with successful recanalization included absence of CHF (OR 0.326, 95% CI: 0.126-0.847), HDL less than 40 (OR 3.32, 95% CI: 1.26-8.75), and combination IA-tPA and mechanical thrombectomy (OR 4.56. 95% CI: 1.36-15.3). Thirty-five (23.2%) patients were found to have an improvement of NIHSS ≥ 8 after treatment. Factors associated with improvement of NIHSS included no prior history of diabetes mellitus (DM) (OR 0.238, 95% CI: 0.060-0.954) and high-density lipoprotein (HDL) less than 40 (OR 3.152: 1.18-8.43). Mortality in this study was 50 (33.1%), with history of DM being predictive of mortality (OR 3.35, 95% CI: 1.28-8.76).
Conclusion
No significant associations between metabolic syndrome and initial stroke severity, recanalization, FNO or mortality were observed. Statistical associations regarding components of metabolic syndrome including HDL and DM were observed in that HDL<40 and no prior history of DM was associated with both successful recanalization and FNO. Only DM was predictive of mortality. To our knowledge, this is the first study to investigate associations between metabolic risk factors and immediate stroke outcomes in patients undergoing endovascular treatment.

Relationship between Diffusion-Weighted Imaging-ASPECTS before Endovascular Reperfusion Therapy and 90-Day Clinical Outcome in Acute Ischemic Stroke Patients

Nakazaki, M.·Mori, T.·Iwata, T.·Iwata, Y.·Takahashi, Y.
Shonan Kamakura
Kamakura, JAPAN.

Purpose
The purpose of our study was to investigate the relationship between Alberta Stroke Programme Early Computed Tomography Score of MRI/diffusion-weighted imaging (DWI-ASPECTS) before endovascular reperfusion therapy and favorable clinical outcome at 90 days in acute stroke patients.
Materials & Methods
Included in our retrospective analysis were consecutive acute ischemic stroke patients: 1) who admitted one single hospital from January 2004 to March 2012 inclusive with severe neurologic deficit, 2) who underwent emergency MRI screening including DWI, and MRA, which suggested acute internal carotid artery (ICA) or middle cerebral artery (MCA) occlusion, and 3) who underwent emergency endovascular reperfusion therapy from three to eight hours from onset. We evaluated the relationship between DWI-ASPECTS before treatment and favorable clinical outcome defined with a modified Ranking Scale (mRS) of 0 to 2 at 90 days.
Results
Fifty-two patients were included, median age was 80 years old, 24 patients were female, and median NIHSS score was 17. Median DWI-ASPECTS before reperfusion therapy was

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

seven (interquartile rage = 5.25-9). Successful recanalization, defined as Thrombolysis in Cerebral Infarction grade 2B or more, was 53%. Diffusion-weighted imaging-ASPECTS before reperfusion therapy was correlated with mRS at 90 days (P<0.001), the higher DWI-ASPECTS was, the better score of mRS at 90 days was. Logistic regression analysis identified DWI-ASPECTS (OR= 1.96, 95% CI=1.08 to 4.45, P= 0.024) as an independent significant predictor of favorable clinical outcome.
Conclusion
Higher DWI-ASPECTS before endovascular reperfusion therapy was an independent determinant for favorable clinical outcome at 90 days in acute ischemic patients with occlusion of the ICA or MCA.

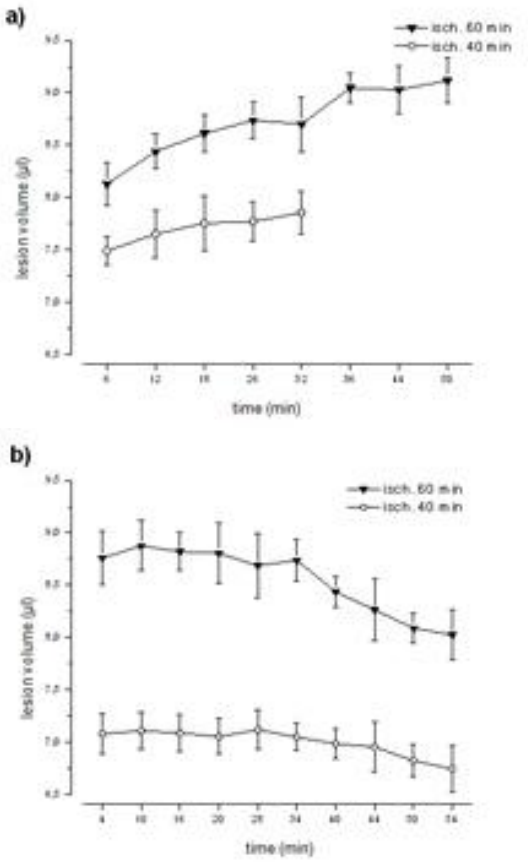
T2*-Weighted MR Imaging Reveals Hyperacute Lesional Dynamics after Temporal Occlusion and Reperfusion in a Murine Model

Gersing, A. S.[1]·Eisenbeis, A.[2]·Leypoldt, F.[2]·Siemonsen, S.[2]·Magnus, T.[2]·Zimmer, C.[1]·Fiehler, J.[2]
[1]Klinikum Rechts Der Isar, Technical University Munich, Munich, GERMANY, [2]Universitätsklinikum Hamburg-Eppendorf, Hamburg, GERMANY.

Purpose
We aimed to analyze the growth dynamic of T2*-WI signal intensities under experimental conditions. Onion skin-like lesion expansion was hypothesized, the lesion center exhibiting greatest T2*signal decreases.
Materials & Methods
Thirty mice were i.p. anesthetized and temporal occlusion of middle cerebral artery (MCAO) was induced with occlusion time varying between 40 and 60 minutes. Subsequently, early dynamic T2*-signal changes were examined chronologically utilizing a 3T vertical magnet with a scan every two minutes until 60 minutes after recanalization. Baseline imaging of T2*, qT2 and DWI was acquired. Recanalization was conducted by retracting the occluding filament. Infarct volume were evaluated histopathologically with triphenyltetrazolium chloride (TTC) staining.
Results
Continuous volume growth of the outer layer has been observed during MCAO, while the center layer volume was constant within four or 60 minutes after ischemia (Figure a.). Reperfusion lead to further gradual signal increase with initial signal abnormality in the affected hemisphere compared to the vital hemisphere by 8.8%. Degree of signal increase was associated with occlusion time. Continuous reduction of outer layer volume was found after reperfusion by 8.6% after 60 Minutes (Figure b.). Triphenyltetrazolium chloride staining of final penumbra location correlated with T2*-signal loss. Histologically, the total T2*-lesion was larger than infarct core in 16/18 mice (46.9%).



Conclusion
As acute decrease in T2*-signal is attributed to increased local deoxyhemoglobin concentration and is hypothesized to reflect the penumbra on a metabolic level. In the original penumbra concept, the penumbra shrinks from the center by infarct growth while its outer extent is constant. Instead, we observed an increase of the T2*-lesion volume after MCAO and a decrease after reperfusion. The T2*-lesion was larger than the infarct core. It is likely that T2*-WI reflects differences in pathophysiologic states of tissue during ischemia.

Achieving Better and Faster Recanalization in Patients with Acute Ischemic Stroke with Dedicated Intra-Aterial Stroke Tool

Shankar, J. J. S.·Conrod, J.
QE II Hospital
Halifax, NS, CANADA.

Purpose
Outcome of patients with acute ischemic stroke (AIS) with proximal occlusion is poor with intravenous thrombolytic therapy. These patients have better outcome with intra-arterial mechanical thrombolysis. The proper tool for mechanical thrombolysis has been debated as more labor-intensive, complicated and much more costly. Despite all the literature available in favor of mechanical thrombolysis, the cost incurred is a big factor in acquisition of these mechanical tools in many institution including ours. This delayed the acquisition of this tool called stent retriever. We assessed the recanalization rate, cost incurred and the outcome of the patients with AIS in our institution in the last two years.
Materials & Methods
From July 2010 to July 2012, we treated 11 patients with acute ischemic stroke with intra-arterial treatment. We procured the stent retriever in November 2011. We treated six patients before November 2011 and six patients after that. Before November 2011 the intra-arterial thrombolysis was done using tPA, microcatheter, microguidewire, intracranial stents and balloons. After November 2011, the intra-arterial thrombolysis was performed using only the stent retriever. We analyzed the recananalization rate, procedure time and equipment cost in all these patients.
Results
The mean procedure time after stent retriever was shorter compared to before stent retriever but it failed to reach significance ($p = 0.076$). The equipment cost before and after stent retriever was not significantly different ($p = 0.69$). The rate of recanalization of the occluded artery after stent retriever was significantly higher ($p = 0.036$).
Conclusion
Adding a dedicated intra-arterial stroke tool improved the outcome of the patients with shorter recanalization time, procedure time, shorter hospital stay, better clinical outcome and with no significant increase in the cost. This suggests that a dedicated mechanical tool for recanalization in selected patients result in better patient outcome without adding any significant cost.

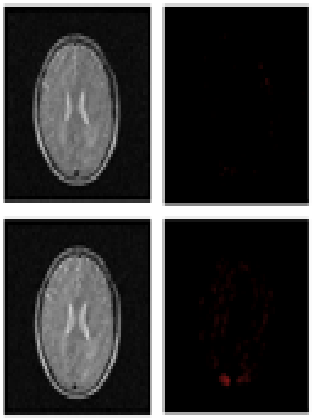
More Direct Method for Functional MR Imaging

Tailor, D. R.
University of Pittsburgh
Pittsburgh, PA.

Purpose
Functional MR imaging (fMRI) of the brain has traditionally consisted of T_2^*-weighted imaging which relies on the susceptibility effect of deoxyhemoglobin (the BOLD effect). Since the BOLD signal is several biochemical steps removed from actual metabolism, its use for studying brain function relies on statistical mapping of the imaging data by correlation with the functional stimulation paradigm to indirectly infer neuronal activation. A more direct and perhaps more reliable approach would involve high spatiotemporal resolution brain mapping of oxidative metabolism in response to stimulation. However, there are no techniques presently available that can accomplish this goal. The purpose of this study is to introduce a novel MR approach for high spatiotemporal imaging of relative cerebral metabolic rate of oxygen ($CMRO_2$) and to apply for direct visualization of brain activation without reliance on statistical inference relative to the activation paradigm.
Materials & Methods
Based on our model, the subtraction of high-frequency spin-locked ("high B_1") and low-frequency spin-locked ("low B_1") $T_{1\rho}$-weighted images of the brain directly yields relative $CMRO_2$ on a pixel-by-pixel basis. In accordance with an IRB-approved protocol, three human subjects (two males and one female, ages 23 to 35 years) were visually stimulated using LED goggles flashing at 10Hz for 5s. Both the high and low B_1 images were obtained (TR = 1s, TE = 14 ms, 0.2 x 0.2 x 0.5 mm pixels, NEX =1, ETL = 45, high B_1 frequency = 500 Hz, low B_1 frequency = 250 Hz) within the final 3.2 sec of our five sec visual stimulus, immediately following a control study without stimulation, with an imaging temporal resolution of 3.2s.
Results
Representative data are provided in the graphic file, which consists of a figure demonstrating the control (top left) and experimental (bottom left) $T_{1\rho}$-weighted images of a subject with the color-rendered subtraction of the high and low B_1 images, which is equivalent to the relative

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

$CMRO_2$ value in each respective pixel (right column). As expected, the bilateral medial occipital regions consisting of the visual cortex demonstrate elevated relative $CMRO_2$ values in response to visual stimulation. In this particular subject, there appears to be right-side dominance (left side of image) of the visual function.



Conclusion

In conclusion, our novel fMRI technique based on $T_{1\rho}$-weighted imaging is capable of high-resolution mapping of brain activation in humans without reliance on statistical inference. This method may provide a more robust alternative to conventional fMRI.

Reproducibility of Cerebral Blood Flow Values from Arterial Spin Labeling in Patients with Cognitive Impairment

Karmonik, C.·Pascual, B.·Dulay, M. F.·Spann, B. M.·Grossman, R. G.·Roman, G. C.·Fung, S. H.
The Methodist Hospital Neurological Institute
Houston, TX.

Purpose

To establish confidence limits for longitudinal arterial spin labeling (ASL) perfusion studies in elderly patients evaluated for cognitive impairment by means of test-retest reliability analysis.

Materials & Methods

In a prospective study, two sets of pseudo-continuous ASL (pCASL, post-labeling image delay 2.5 sec to account for possibly increased arterial transit times, GE MR750 3T) image sets were acquired from 30 subjects (patient repositioned during examination, age-range: 62-84 years). Cerebral blood flow (CBF) maps were registered to gray matter (GM, segmented with FSL) maps from 3D anatomical scans and transformed into Talairach space (AFNI) enabling qualitative voxel-based comparisons (entire GM and selected regions from MNI structural atlas) using scatter-plots, quantile-quantile (QQ) plots and box-percentile (BP) plots. Test-retest reliability was quantified with intraclass correlation coefficient (ICC) and standard deviation (SD). Statistical significance of CBF distribution differences were assessed with the Student *t*-test (for mean) and Kolmogorov Smirnov (KS) tests (R statistical language).

Results

Scatter and QQ plots showed good qualitative agreement between both measurements. Box-percentile plots revealed differences in CBF distribution shapes for investigated brain regions (Figure 1). Average ICC values were consistent between entire GM [average: 0.77 (range: 0.9 - 0.5)] and assessed regions (frontal lobe: 0.78 (0.92 - 0.51), parietal: 0.78 (0.91 - 0.40), occipital: 0.74 (0.90 - 0.45), temporal: 0.69 (0.93 - 0.30) and cerebellum: 0.72 (0.91 - 0.41). Average SD was lowest for occipital lobe (7.0 ± 1.7 ml/min/100g) and highest for cerebellum (8.7 ± 2.5 ml/min/100g). Average SD for entire GM was 8.1 ± 2.0 ml/min/100g). P-values for KS tests did not exceed 0.0033 with two exceptions (0.0014 for cerebellum in subject #13 and 0.007, frontal, #15). P-values for Student *t*-test exceeded 0.05 for frontal and parietal lobe each in one subject, for temporal lobe in two subjects and for cerebellum in three subjects.

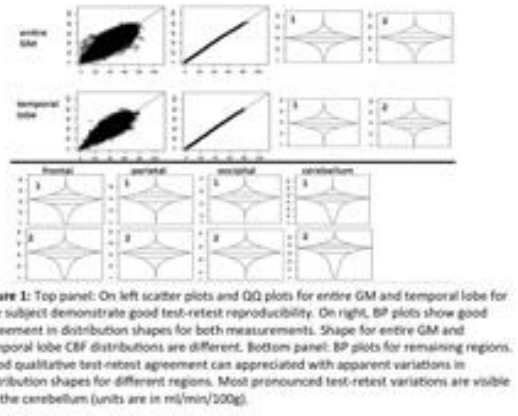

Figure 1: Top panel: On left scatter plots and QQ plots for entire GM and temporal lobe for one subject demonstrate good test-retest reproducibility. On right, BP plots show good agreement in distribution shapes for both measurements. Shape for entire GM and temporal lobe CBF distributions are different. Bottom panel: BP plots for remaining regions. Good qualitative test-retest agreement can appreciated with apparent variations in distribution shapes for different regions. Most pronounced test-retest variations are visible for the cerebellum (units are in ml/min/100g).

Conclusion

Good test-rest reproducibility was found in the investigated patient population. Our results suggest that for statistical significance in longitudinal perfusion studies, observed differences have to exceed 8 ml/min/100g (one standard deviation).

Quantitative Perfusion Changes in Functional Arterial Spin Labeling MR Imaging during Language and Motor Tasks

Ross, A. B.·Watts, R.·Nickerson, J. P.
University of Vermont/Fletcher Allen Health Care
Burlington, VT.

Purpose
Although arterial spin labeling (ASL) is a well established technique for perfusion brain imaging, it has not yet been used widely for functional imaging paradigms despite certain advantages over traditional BOLD MRI. Specifically, ASL provides quantitative information regarding changes in cerebral blood flow (CBF), is relatively insensitive to signal drift, and may provide more statistical power for certain functional imaging experimental designs. This study compares ASL to the standard of BOLD in classic language and motor tasks and provides normative data regarding quantitative CBF changes within the relevant regions of interest.
Materials & Methods
Seventeen healthy adult volunteers have been recruited to date with the functional tasks consisting of word generation and finger tapping. A simple two-condition block design was used for each sequence. For each functional task, traditional BOLD images were acquired followed by a pseudo-continuous arterial spin labeling acquisition (pCASL) using a protocol similar to Aslan et al. Arterial blood in a slab 20 mm inferior to the imaging volume is magnetically labeled with a labeling duration of 1650 ms and post-labeling delay of 1525 ms. Axial slices are acquired using a 2D echo-planar readout acquisition matrix of 80x80x10 and a resolution of 3x3x5mm3 using a SENSE factor of 2.5. Background suppression and vascular crushers are used to minimize sensitivity to subject motion and intravascular blood. 90 pairs of control and tag images are acquired with a TR of 4s (acquisition time 12 minutes) and TE of 20ms. Data were analyzed using FSL FEAT with full perfusion signal modeling. The BOLD activation maps were used as a guide for generating masks over the hand motor cortex and Broca's area for the finger tapping and word generation tasks, respectively. The masks then were registered into the ASL scan using the SPM suite of tools for Matlab and the quantitative change within the ROI calculated in FSL.
Results
Subject recruitment and data analysis are ongoing with results to date showing that cerebral blood flow increased by 42.83% +/- 15.66 (Mean, Std. Dev.) in the right motor strip and by 44.57% +/- 17.56 in the left motor strip. Broca's area demonstrated a 23.05% +/- 6.13 increase in cerebral blood flow.
Conclusion
Perfusion-based functional imaging using pCASL provides robust and consistent quantitative perfusion information when used for functional activation mapping in motor and language paradigms when compared to BOLD MRI. Normative data for quantitative CBF changes in Broca's area and the motor strip are presented for healthy adult volunteers during word generation and finger tapping tasks respectively. A technique for directly comparing BOLD and ASL scanning paradigms is described in detail. Validation of this quantitative technique may allow for the application of functional MRI in the research setting across differing populations to a greater degree than has been previously achievable with BOLD imaging.

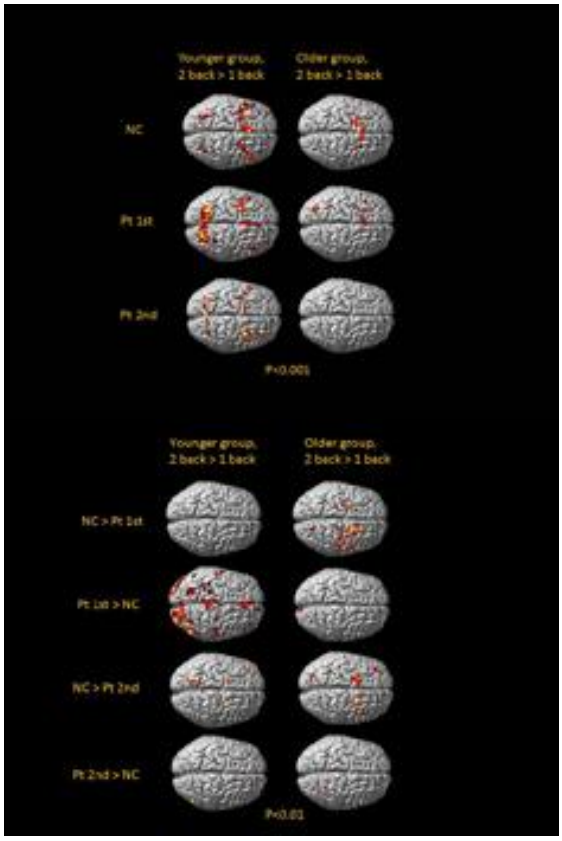
Age Influence in Functional MR Activation during Working Memory after Mild Traumatic Brain Injury

Chen, D.·Wang, W.·Liao, Y.·Hsu, H.·Tseng, Y.·Chen, C.
Taipei Medical University/Shuang Ho Hospital
Taipei, TAIWAN.

Purpose
Mild traumatic brain injury (mTBI)-induced differences in working memory functional activity is observed in several studies. This study aims to evaluate the influence of age on working memory activation in functional MRI after mTBI.
Materials & Methods
Research ethics committee approval and patient written informed consent were obtained. We collected two groups of mTBI patients (age > 50 years and age < 30 years). The older group contains 13 patients (51~68 years; average 57.7 years) and the younger group contains 13 patients (21~29 years; average 24.7 years). Nine normal controls (NC) for the older group (51~68 years; average 60.1 years) and 13 normal controls for the younger group (21~29 years; average 26.1 years) were recruited. Brain activation patterns in response to a working memory task (n-back; 1 and 2-back conditions) were assessed with functional MRI on a 3.0T MR system. Each mTBI subject underwent the first scan within one month after injury. The second scan was repeated at six weeks after the first scan.
Results
In the younger group, the patients had more activations than the controls (2-back>1-back, p-value < 0.01) in the first scan. In the second scan, the working memory activation of the patients returned to be similar with the controls. In the older group, the patients had less activations than the controls (2-back>1-back, p-value < 0.01) in the first scan. In the second scan, however, the working memory activation of the patients further decreased from the first scan.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Conclusion

After mTBI, working memory activation of the younger patients increased in the first scan and returned to the baseline after six weeks. The older patients had decreased working memory activation than the controls and did not recover. The result may suggest that younger group has more potential to recover after mTBI while the older group did not.

Default Mode Network Assessment in Patients with Neuromyelitis Optica: A Resting-State Functional MR Imaging Study

Rueda-Lopes, F. C.[1,2]·Miraldi, F.[1]·Domingues, R.[2]·Alves-Leon, S.[1]·Gasparetto, E. L.[1,2]
[1]UFRJ, Rio de Janeiro, BRAZIL, [2]DASA, Rio de Janeiro, BRAZIL.

Purpose

Neuromyelitis optica (NMO) spectrum is an autoimune demyelinating disease usually related to optical neuritis and extensive myelitis. Diffuse white matter damage has been shown, but the cortex was poorly studied in such disease. Our objective was to investigate NMO patients using the resting-state functional magnetic resonance imaging (RS fMRI) compared to the controls, regarding the default-mode network in order to evaluate the cortical adaptations in NMO.

Materials & Methods

We studied 28 NMO spectrum patients (including myelitis, neuritis optica and/or both) mean age 38 years (SD +/- 3,2, 18 female), and also 19 sex- and age-matched controls. All participants signed informed consent. MR imaging was performed in a 1.5T scanner, including 3D T1-weighted images (postprocessed by SIENAX to obtain gray matter (GM), white matter (WM) and total brain volume (BV) and RS fMRI was performed during rest. Functional MRI data were postprocessed using MELODIC, part of FMRIB's Software Library. The fMRI data set was decomposed using independent component analysis (ICA) to identify large-scale patterns of functional connectivity. After that, a "dual-regression" approach was carried out allowing voxel-wise comparisons of resting functional connectivity between both groups. Threshold-free cluster enhancement (TFCE) and p-corrected maps of comparison between both groups were analyzed. Also, the extracted synchronization values of the default-mode network (DMN) of patients and controls were compared and their correlaction with GM volume, WM volume and BV was assessed using Pearson technique. A p-value of 0.05 was considered statistically significant.

Results

Fourteen components were computed in the entire subject group by ICA. Default-mode network was detected clearly among the subjects and was compared between both groups. The evaluation of TFCE maps showed areas of significantly higher synchronization in NMO patients compared to healthy controls in the parietal lobes, precuneus region and also in the right hippocampus ($p<0.01$), which remained after p-correction. Also, controls had areas of higher synchronization in the frontal areas compared to patients in the TFCE maps, which were markedly reduced but still detected after p-correction. The synchronization average value for DMN in patients was 1.373588 (2.429656 SD) and for controls 2.483234 (2.258987 SD) with a p-value of 0.12. These synchronization values had a negative weak correlation with GM volume (-0.03) and a positive correlation with WM volume (0.13) and BV (0.03).

Conclusion

Neuromyelitis optica patients have an increased synchronization during rest in the parietal and precuneus areas of DMN as a form of compensation for the decreased synchronization in the frontal area. The weak correlation of the synchronization values with GM volume is probably due to the maintenance of the cortical and subcortical areas in such disease. The main damage is probably located in the WM tracts, as shown by TBSS and volume studies, corroborating for the correlation between DMN values and WM volume.

Motor Tongue Representation at the Base of a Novel Sagittal Landmark in the Precentral Gyrus: Introducing the "K"

Tyndall, A. J.[1]·Hartwigsen, G.[2]·Karwacki, G.[1]·Stenzel, F.[1]·Ahlhelm, F.[1]·Stippich, C.[1]
[1]University Hospital Basel, Basel, SWITZERLAND, [2]Language and Aphasia Laboratory, Leipzig, GERMANY.

Purpose
Knowledge of topographical brain anatomy is mandatory in clinical routine and research interpretation, thus identification of characteristic landmarks is fundamental. Landmarks have been described in the axial and sagittal planes, however, the latter is less commonly used in functional studies. The inferior frontal gyrus has a typical M-shape easily identified on sagittal MR images. Adjacent to the pars opercularis, the base of the sensorimotor area abuts this configuration, which typically forms a "K" consisting of the anterior subcentral and inferior precentral sulci, the precentral gyrus, posterior subcentral sulcus, postcentral gyrus and postcentral sulcus that abuts the angular gyrus. Based on the concept of the homunculus, the motor tongue area is located inferior to the motor hand area on the precentral gyrus. As of now, no typical landmark for this area has been described. We aimed to: a) localize the motor tongue area using fMRI and b) describe its anatomical configuration to reliably enable clinicians to identify the base of the precentral gyrus in the sagittal plane based on the resultant anatomical description only.
Materials & Methods
Ten healthy subjects underwent fMRI examination with a tongue motor paradigm using a block design. The M1activation was defined using Spm5. From a cohort of patients of a dementia study (n=33), MPRage datasets were used for morphologic depiction of the "K" performed by two neuroradiologists in consensus. A screenshot with its best depiction was acquired in both hemispheres, which then were presented to three physicians (neurosurgeon, neuroradiology resident and consultant cardiothoracic radiologist), who were requested to locate the precentral gyrus, without further assistance. After this read-out they were informed about the fMRI results of healthy controls and the anatomical formation of the base of the lower convexity ("K"). This read-out then was repeated four weeks later.
Results
In the 10 healthy volunteers, group analysis showed BOLD activation at the base of precentral gyrus in the upper right "arm" of the "K" for the motor tongue paradigm (x=45, y=-7, z=25, MNI space). For the dementia study cohort (n=33), the mean sagittal degree (first lateral slice depicting the cortical surface = 0%; mid-sagittal plane of the brain = 100%) of the chosen sagittal slices best depicting the K-formation was 31.5% (±4.2SD) and 30.4% (±3.8SD) for the right and left hemisphere, respectively. Before anatomical instruction of the "K" formation, the neurosurgeon, neuroradiologist and cardiothoracic radiologist located the precentral gyrus with 91%, 85% and 69% accuracy, respectively. After anatomical instruction, this increased to 100%, 100% and 98%, implying a statistically significant improvement of 10% (p=0.013), 18% (p=0.001) and 44% (p<0.001), respectively.
Conclusion
The motor tongue representation (M1) is found at the base of the lower convexity in the precentral gyrus in the upper arm of a "K" formation. The precentral gyrus can be identified in the sagittal plane via the K-shaped gyral formation with a high accuracy. We consider this a valuable diagnostic asset, especially if other established landmarks are insufficiently identifiable, such as in anatomical deformation due to underlying pathologies.

Altered Resting-State Network Connectivity as a Potential MR Biomarker in Spinocerebellar Ataxia Type 6

Pereira, L. P.·Airan, R.·Sair, H.·Ying, S.
Johns Hopkins Hospital
Baltimore, MD.

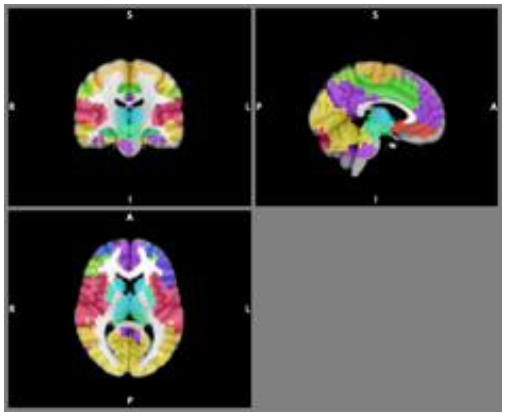
Purpose
The cerebellum is known to demonstrate functional co-activation not only with cortical motor areas but also with cognitive networks. In order to test this relationship, we evaluated brain resting state network connectivity in a relatively "pure" cerebellar model of degeneration, spinocerebellar ataxia type 6 (SCA6). Spinocerebellar ataxia type 6 is characterized by both progressive motor impairment and mild cognitive impairment. Patients are expected to demonstrate altered efficiency of internetwork connections between functional modules, in correlation to disease severity.
Materials & Methods
Sixteen patients (age 45 to 70 years) with SCA6 underwent 3T MRI including T1 MPRAGE and seven min BOLD fMRI (TR = 2.5 sec) sequences. Data were preprocessed using FSL (FMRIB, Oxford, UK), SPM8 (Wellcome Trust, UK) and custom MATLAB (Mathworks, MA) scripts to complete slice-timing correction, rigid-body motion correction, segmentation and normalization to a standard template (MNI, 2mm), COMPCOR nuisance regression, bandpass temporal filtering (0.01-1Hz), and spatial smoothing (6 mm Gaussian kernel). Whole-brain gray matter was automatically parcellated into 875 regions of interest (ROIs). For each ROI, the first eigenvariate of voxel timecourses was extracted. Pearson correlation coefficients between each pair of ROI timecourses were calculated across the 875 ROIs. The set of average control correlation coefficients were fed as an undirected weighted adjacency matrix (thresholded at r2 = 0.08) into the infomap modularity algorithm. For each network, the

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

intra-network efficiency of the thresholded adjacency sub-matrix was calculated, with a similar measuring applied to the inter-network efficiency. Efficiency was correlated with functional staging for ataxia (FSFA) score, a scale from 0 to 6 that emphasizes mobility.

Results

Functional staging for ataxia is correlated with altered efficiency of internetwork connections within the following functional modules: attention, both inferior and superior cerebellar and pons, limbic, right frontoparietal, ventromedial temporal and inferior temporal gyrus and pons, and medial prefrontal cortex. Of note, the motor network is not involved.



Conclusion

In SCA6, there is altered efficiency of internetwork connections in the cerebellum, brainstem, and frontal and temporal lobes that is consistent with the clinical presentation and is correlated with disease severity. With further validation, resting state network connectivity could have promise as an MR biomarker for functional staging in this genetic model of cerebellar ataxia.

Resting-State Activity in the Left Executive Control Network Is Associated with Behavioral Approach and Is Increased in Substance Dependence

Tanabe, J. L.[1]·Krmpotich, T. D.[1]·Thompson, L. L.[1]·Banich, M. T.[2]·Klenk, A. M.[1]·Tregellas, J. R.[1]

[1]University of Colorado Denver, Aurora, CO, [2]University of Colorado Boulder, Boulder, CO.

Purpose

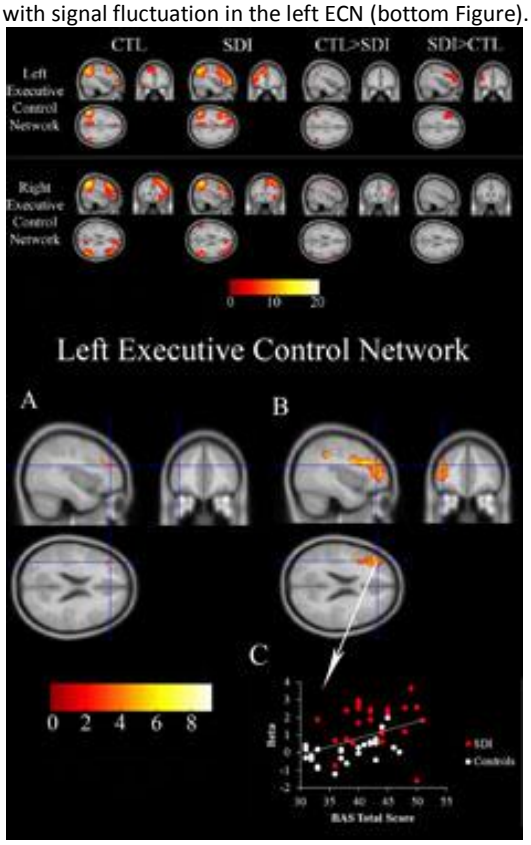
Individuals with drug addictions report increased willingness to approach rewards. Approach behaviors are thought to involve executive control processes and are more strongly represented in the left compared to right prefrontal cortex. A link between approach behavior and left prefrontal activity has not been shown in the resting brain. We hypothesized that compared to controls, substance-dependent individuals (SDI) would have greater left prefrontal activity in a left executive control network (ECN) at rest.

Materials & Methods

Twenty-five SDI and 25 controls completed a Behavioral Inhibition System/Behavioral Activation System (BIS/BAS) questionnaire and underwent a resting fMRI scan. Group independent component analysis was performed. We used template matching to identify a left ECN component and right ECN component, respectively. Corresponding components were compared across groups using a 2-sample t-test. Maps were set at a threshold of $p<0.005$, uncorrected, with an extent threshold of 35 voxels, corresponding to a whole-brain cluster-corrected level of $p<0.01$. Next, BAS scores were correlated with the magnitude of signal fluctuations in the left ECN and BIS scores with right ECN.

Results

Substance-dependent individuals showed significantly greater activity than controls in the left prefrontal cortex of the left ECN. In contrast, SDI showed less activity than controls in the right prefrontal cortex of the right ECN (top Figure). Behavioral Activation System scores correlated with signal fluctuation in the left ECN (bottom Figure).



Conclusion

Results from this study suggest that approach tendencies may be related to a left hemispheric ECN at rest. Higher resting-state signal in the left ECN may play a role in heightened approach tendencies that contribute to drug-seeking behavior.

Is the Normal-Appearing Cerebellum Really Normal?: A H-MR Spectroscopy Study at 3T

Azagra, A.[1]·Beltran-marin, M.[1]·Sadeghi, N.[1]·Manto, M.[1]·Jissendi-Tchofo, P.[2]
[1]Hopital Erasme, Bruxelles, BELGIUM, [2]C.H.U. Lille, Lille, FRANCE.

Purpose
In patients suspected of having a brain lesion on the basis of the neurologic examination, the brain MRI might appear normal, or disclose supratentorial abnormalities whereas the cerebellum is described as normal. Going beyond the morphologic appearance, spectroscopy is the only technique that allows detecting tissular biochemical anomalies, which precede morphologic changes. We aimed at describing metabolic alterations found in the normal-appearing cerebellum of patients with altered neurologic functions, and suggest metabolic ratios thresholds to be used when reading spectra in clinical practice.
Materials & Methods
The study included 32 patients (18F/14M, aged 10-78 years old, mean 37,12) who underwent a brain assessment at 3T. All showed normal-appearing cerebellum on MRI using predefined criteria of reading (two readers). Spectroscopy was performed in all patients and included a single voxel PRESS sequence at short echo time (TE 30-36 msec) within the cerebellum (encompassing the dentate nucleus). The metabolites ratios (Naa/Cr, Cho/Cr, mI/Cr, GlxT/Cr) were calculated and compared with the values obtained in 14 aged-matched controls (group 1), by means of t- and Z score tests. Presence or absence of lactate also was recorded.
Results
The indications for MRI/MRS assessment were: metabolic disease (n = 15; 14 mitochondriopathy, 1 PKU), neurodegenerative processes (n = 5; two Parkinson disease, three cerebellar ataxia), epilepsy (three), cognitive disturbances (two) (1 MCI, one developmental delay), vascular encephalopathy (n = 2), one supratentorial tumor, and three nonspecific neurologic impairment. Eighteen patients showed a totally normal brain (group 2) while 14 patients had supratentorial involvement (group 3). We found significant differences between group 1 and groups 2 and 3 for all the ratios ($p<0.05$). In comparison with the controls, group 2 showed unexpected higher levels of Naa/Cr and mI/Cr ratios ($p<0.01$), with corresponding z scores means at 0.22 and 0.35, while group 3 showed lower Cho/Cr and mI/Cr ($p<0.01$), and strikingly increased GlxT/Cr ($p<0.01$) with z scores means at 0.24, 0.46, and 0.59 respectively.
Conclusion
These findings suggest a probable hyperactivation of the cerebellum in neurologic disturbances with no signal abnormality in the brain, as revealed by an increase of all the metabolites ratios (group 2). In the presence of supratentorial lesions, there is likely an imbalance of the neurotransmitters in the cerebellum as revealed by the striking increase of GlxT/Cr levels. The z scores means may be used as threshold values to interpret the metabolites ratios as abnormal in comparison with a control group.

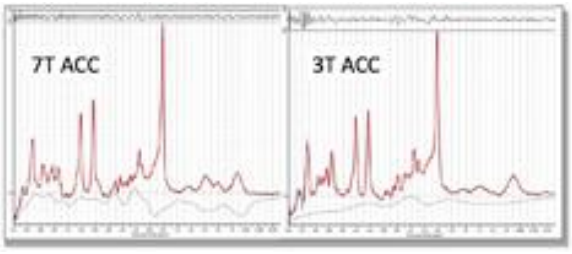
Comparison of Single Voxel MR Spectroscopy at 3T and 7T

Barker, P. B.[1]·Wijtenburg, S. A.[2]·Gillen, J.[1]·Bonekamp, S.[1]·Rowland, L. M.[2]·Edden, R. A. E.[1]
[1]Johns Hopkins University, Baltimore, MD, [2]University of Maryland, Baltimore, MD.

Purpose
MR spectroscopy (MRS) is believed to benefit from the use of high magnetic field strengths such as 7T; however, to our knowledge, there have been no direct comparisons of 7T MRS to the current clinical standard of 3T. The purpose of this study was to compare 7T to 3T MRS in the same subjects using near identical methodology.
Materials & Methods
Four healthy normal volunteers (2M, 35 ± 7 years) were scanned at both 3T and 7T within a seven-day time period. Spectra were recorded from the anterior cingulate cortex (ACC) and dorsolateral prefrontal cortex (DLPFC) using Philips 3T and 7T scanners running the same operating system, and both equipped with 32-channel head coils. Spectra were recorded with the semi-LASER (sLASER) pulse sequence with the following parameters (3x3x3 cm, TR/TE 3000/32 ms, VAPOR water suppression, 3 kHz adiabatic refocusing pulses, 32 averages). Spectra were analyzed at both field strengths using LCModel software.
Results
Figure 1 shows representative ACC spectra from one subject at both 3T and 7T. Average ACC and DLPFC signal-to-noise ratios (SNR) were 50.1 and 54.8 at 7T, and 33.8 and 35.5 at 3T, respectively. Average line widths were 0.030 ppm (8.9 Hz) and 0.035 ppm (4.5 Hz) at 7T and 3T, respectively. For the major resonances in the spectrum (tCho, tCr, tNAA, mI), average Cramer-Rao lower bounds (CRLB, a measure of the uncertainty of the estimated metabolite concentration) at 7T were between 71-98% of the 3T values, consistent with the improved SNR and resolution at 7T. Some (but not all) other compounds also were more reliably determined at 7T, including glutamate, NAAG, taurine and glutathione.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Conclusion
Spectra acquired from cortical gray matter regions show the expected benefit in SNR and reduced uncertainty (CRLBs) at 7T compared to 3T, as well as the ability to accurately detect more compounds at 7T compared to 3T.

MR Proton Spectroscopy of the Brain: Metabolic Imaging Findings in the 1.3 ppm Region Utilizing Ultrashort TE

Boyko, O. B.·Shiroishi, M.·Kim, P. E.·Rajamohan, A.·Rajamohan, A.·Go, J. L.·Lerner, A.·Law, M.
University of Southern California
Los Angeles, CA.

Purpose
To compare the clinical findings in the 1.3 ppm region of ultra-short TE single voxel proton MR spectroscopy (MRS) with standard short TE single voxel proton MRS using either STEAM or PRESS in imaging diseases of the brain.
Materials & Methods
Twenty patients underwent single voxel MR spectroscopy at 1.5T using either STEAM or PRESS for water and fat suppression. MR spectroscopy was acquired with ultrashort STEAM (12-15 msec) and ultrashort PRESS (20, 25 msec) with standard short TE STEAM (20 msec) or standard short TE PRESS (30, 35 msec). The shortest default TR allowed by the scanner was utilized in most cases . The peak heights and/or area under the heights of metabolites identified in the 1.3 ppm region were compared with each TE. TE 144 msec was utilized to identify J-coupling features of metabolites which would indicated lactate.
Results
Ultrashort TE proton MRS was acquired successfully in all patients including the supratentorium and posterior fossa. Outer saturation bands prior to shimming could only be prescribed for ultrashort TE PRESS acquisitions and not STEAM acquisitons. Peak height variability was noted in the 1.3 ppm between the ultrashort STEAM and PRESS compared to standard TE STEAM and PRESS acquisition. Short T1 metabolite such as lipid demonstrated the highest peak height on the ultrashort TE acquisitions both STEAM and PRESS, slightly more apparent with STEAM. Lactate doublet was resolved more readily on standard TE PRESS acquisition.
Conclusion
Brain lesion metabolite such as lipid having a short T1 appears to have the highest peak height with ultra short TE acquisitions. Lactate doublet peak was identified on both ultra short and standard TE MRS. In disease processes of the brain where MRS, delineates a lipid peak at 1.3 ppm, utilization of short TE MRS acquisition may detect the highest peak height.

Diagnosis and Surgical Treatment of the Brain Tumors

Murodova, D.·Ahmediev, M. M.
Republican Scientific Center of Neurosurgery
Tashkent, UZBEKISTAN.

Purpose
One of the main trends of modern neurosurgery, is to minimize surgical trauma and improve the quality of life of patients after surgery. The aim of the study. Comparative evaluation of the results of surgical treatment of brain tumors of supratentorial localization method using DT-MRI tractography.
Materials & Methods
We analyzed the results of treatment of 90 patients who were operated under identical conditions. Age of patients was 5-62 years. Surgery was performed under the control of intraoperative monitoring. For noninvasive and more complete removal of the tumor with maximum preservation of pathways using data mechanogram, which allows the surgeon to more accurately determine the amount of tumor resection.This technique made it possible to identify possible ways to access and surgical planning of tumor resection.
Results
These DT-MRI tractography, found that nearly half (56.5%) of primary surgery ended with subtotal removal of the tumor, total tumor removal was possible in 34.8% of cases, the biopsy in 8.7% of cases. Border security resection of the tumor tissue adjacent to the pathways should be at a distance of 5-10 mm from them. However, when the data mechanogram intraoperative monitoring, tracking boundaries resection should be considered intraoperatively shift occurs in the brain. Due to a "shift of the brain" dislocation pathways occurs mainly due to resection and tissue edema, and changes in intracranial pressure. Thus, during the operation the displacement of the center of the white substance formed resection cavity, and the distance from the area of operations to the point of passing the white matter pathways is reduced. Information about the localization pathways and conducted intraoperative monitoring, help plan and implement a more precise surgery, avoiding destruction deployed, as well as swollen and infiltrated tumor tract, increases confidence when working in areas, where the white matter bundles.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Conclusion
Thus, removal of intracranial tumors under the control of intraoperative monitoring using data from MR tractography, the conditions of intraoperative accuracy and safety of surgery to minimize surgical trauma, helps reduce the risk of neurologic deficit, which determines the efficiency of the operation and the quality of life of patients.

Health Policy and Imaging Reimbursement Cuts: How Will You Be Affected and What's Coming Next?

Rehani, B.[1]·Rosman, D.[1]·Romero, J.[1]·Schaefer, P.[1]·Gonzalez, R.[1]·Hirsch, J.[1]·Sherin, C.[2]·Cooper, J.[2]
[1]Massachusetts General Hospital, Boston, MA, [2]American College of Radiology, Washington, DC.

Purpose
Radiology has been affected by decreases in reimbursement for advanced imaging that has been enacted through both federal legislation and regulations. Our aim was to review the decreases that have most affected radiology since 2006 with a specific focus on the current regulations and ongoing health reform.
Materials & Methods
A detailed analysis of the timeline of federal imaging policy starting from the Deficit Reduction Act in 2006 was performed. The existing data and literature concerning the legislation affecting radiology were surveyed. The cumulative impact of decreases in reimbursement was summarized and outlined.
Results
There have been several legislative and regulatory actions since 2006, which have led to decreased reimbursements. These include Multiple Procedure Payment Reduction (MPPR), Medicare Improvements for Patients and Providers Act (MIPPA) and PPACA (Patient Protection and Affordable Act). These legislative and regulatory actions affect reimbursement both directly and indirectly through changes to the Utilization Rate, and the technical and professional components of the Medicare Physician Fee Schedule (MPFS). In addition, the Centers for Medicare and Medicaid Services has mandated code bundling. The cumulative impact of these is significant and is well demonstrated in the attached table (Courtesy: ACR and the Access to Medical Imaging Coalition). For example, the approximate reimbursement for MRI Brain in 2006 was $1118 and is predicted to be $439 dollars in 2013. In neuroimaging, the impact of MPPR may be high due to contiguous organ imaging (e.g., head and neck) as well as imaging of stroke and trauma patients (who are relatively sick and usually undergo multiple exams in a day). On the near horizon are potentially severe cuts to Medicare reimbursement of approximately 30% due to implementation of the Sustainable Growth Rate. On the somewhat more distant horizon are further bundling cuts as CMS turns its screen from codes used together 90% of the time to those used together 75% of the time. Much less predictable are the consequences of at-risk contracts such as Accountable Care Organizations.

Conclusion
Multiple legislative measures in the federal imaging policy have led to a cumulative impact in decreased reimbursements. It is important for neuroradiologists to understand legislation that impacts radiology so that they can appropriately manage their practices and advocate for radiology.

Transitioning from a Denial to Nondenial Approach to Radiology Benefit Management: Impact on the Utilization of Neuroimaging

Hiatt, M. D.[1]·Johnstad, T. R.[1]·Boyko, O. B.[2]
[1]HealthHelp, Houston, TX, [2]University of Southern California, Los Angeles, CA.

Purpose
In managing the utilization of neuroimaging, traditional pre-authorization, as administered by radiology benefit managers (RBMs), has incorporated payment denial for lack of medical necessity. A new approach in which no denials are issued offers the advantages of diminished

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

acrimony between provider and payer and reduced costs and delays related to an appeals process that is no longer needed. Reluctance to adopt a nondenial approach centers on the assumption that the threat of denial is necessary to compel physicians to comply. The aim of this study is to quantify the impact on neuroimaging utilization of replacing a denial approach with a nondenial one.
Materials & Methods
A major health insurance company transitioned from one RBM embracing denials to another eschewing them for its ~80,000 beneficiaries (half of whom were Commercial subscribers and the other half Medicare) in one state in the southwestern U.S. on 1/1/2011. When a procedure request diverged from RBM guidelines, it was denied under the old schema, but approved under the new paradigm. This study focused on CT and MRI of the brain, defined by CPT codes 70450, 70460, 70470, 70551, 70552, and 70553. Utilization, derived from claims data and expressed as units per 1,000 members (UPK), was calculated in the year before (2010) and the year after (2011) implementing the nondenial approach. This same analysis was performed for a contiguous state that employed a nondenial approach in both years.
Results
For the total population, 2,991 neuroimaging procedures were performed in 2010 and 2,861 in 2011, yielding UPKs of 4.63 in 2010 and 4.23 in 2011 for CT and 10.36 in 2010 and 10.13 in 2011 for MRI in the Commercial population, representing decreases of 9 and 2%, respectively, and 26.88 in 2010 and 22.84 in 2011 for CT and 34.36 in 2010 and 32.65 in 2011 for MRI in the Medicare population, representing decreases of 15 and 5%, respectively. Utilization did not similarly decrease in the comparison state.
Conclusion
Transitioning to a nondenial approach yielded no increase in utilization. Providers working in a collaborative environment in which the result of disagreement is to defer to the treating clinician did not cause greater utilization than when they worked in an environment in which the payer retained the "final say". A collaborative approach to utilization management can still "bend the cost curve" without the confrontational atmosphere traditionally associated with such efforts.

Effect of Direct Neuroradiologist Participation in Physician Marketing on Imaging Volumes in Outpatient Radiology

Grignon, L.[1]·Vavricek, J.[1]·Horsley, W.[2]·Murphy, R.[2]·Keiper, M.[1,2]
[1]University of Nebraska Medical Center, Omaha, NE,
[2]Scottsdale Medical Imaging, Scottsdale, AZ.

Purpose
Referring clinicians are the key referral source of imaging studies to an outpatient radiology center. Marketing to referring physicians may have a profound impact on referral patterns, whether marketing is performed by a radiologist or a radiology sales representative. The purpose of this study is to determine the relative impact of direct neuroradiologist participation in marketing on imaging study volumes in outpatient radiology.
Materials & Methods
Baseline monthly physician referral data of CT and MR scans of 19 referring clinicians (neurologists, neurosurgeons and anesthesiologists) to an outpatient radiology group were collected over a six-month period from January to June of 2009. During that time, a nonphysician radiology sales representative made personal visits to the referring physicians' offices every two weeks providing support, substantive education material and personal encounters with clinicians to maximize radiology referrals. From January to June 2010, the same radiology sales representative visited the same referring clinician offices every two weeks but accompanied by a neuroradiologist once a month. The neuroradiologist provided educational lectures, imaging examples, advice and additional substantive personal interaction with referring clinicians during the visits. Monthly CT and MRI referral volumes were collected during this time period as well. The time periods were separated by a year to control for typical seasonal variations of referral patterns. No significant changes or improvements in the radiology group's service parameters such as telecommunications equipment, scheduling or authorization personnel, or quantity of scanners or imaging centers available for scheduling. In addition, no change in the individual referring clinicians' practices occurred between the time periods. The monthly referral volumes of CT and MRI examinations collected for both time periods were compared with the identical month of the corresponding time period for statistical analysis to control for additional potential monthly variations.
Results
The generalized estimating equation (GEE) negative binomial regression with log link was used to fit the scan data to adjust for correlation among the repeated interventions on a single referring clinician. The Tukey post-hoc method was used for pairwise comparisons of results between months in the different time periods. The results demonstrate the relatively dramatic effect of the

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

use of a neuroradiologist in garnering increases in imaging referral volumes. Cross-sectional imaging referral volumes were approximately 2.5 times greater during the six-month period utilizing the neuroradiologist for direct physician to physician marketing when compared with the volumes achieved with the sales representative alone. Moreover, this difference was statistically significant for all six months evaluated (p<0.0001).

	Mean scan volume **Year 2009**	Mean scan volume **Year 2010**	
	Sales Representative	Sales Representative + Neuroradiologist	P-value
January	8.47	19.53	<0.0001
February	8.29	20.35	<0.0001
March	8.35	21.00	<0.0001
April	7.65	20.12	<0.0001
May	7.59	18.71	<0.0001
June	5.65	16.12	<0.0001

Conclusion
Direct radiologist participation in physician marketing is an essential tool in creating and maintaining imaging volumes in outpatient radiology.

KEYWORDS: Economics, Marketing

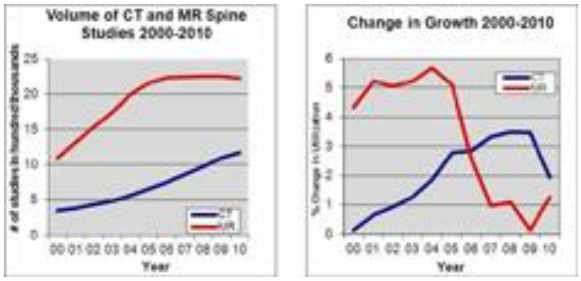
Trends in Advanced Spinal Imaging in the Medicare Population from 2000-2010: Slowing Down the Runaway Train

Zoltani, Z. A.·Zohrabian, V. M.·Parker, L.·Friedman, D. P.
Thomas Jefferson University Hospital
Philadelphia, PA.

Purpose
To examine trends in utilization of spine CT and MR in the Nationwide Medicare population from 2000-2010.
Materials & Methods
The Nationwide Medicare Part B databases for 2000-2010 were queried. Current Procedural Terminology (CPT)® codes were obtained for CT and MR imaging of the cervical, thoracic, and lumbar spines without, with, and with and without contrast. All nine CT CPT codes were combined and all six MRI CPT codes were combined, and analyzed separately. Fee-for-service beneficiary denominators were calculated from the Medicare Advantage market penetration files. Study volume for fee-for-service beneficiaries, utilization rates per 1,000 beneficiaries, and growth rates were calculated. The 2000-2010, pre-Deficit Reduction Act (2000-2005), and DRA/post-DRA (2006-2010) time periods were examined.
Results
The overall volume of spine CT increased by 235% from 2000-2010. There was positive year-to-year growth in overall volume of spine CT throughout the study period, and the rate of growth peaked in 2005 (16.6%), at which point the rate of increase slowed. However, from 2005-2010, the total volume of CT still nearly doubled (655,408 to 1,172,959). The total utilization rate of CT was 11 per 1,000 beneficiaries in 2000 and 33 per 1,000 beneficiaries in 2010 (+212%). The compounded annual growth rate (CAGR) in the pre-DRA and DRA/post-DRA period was nearly uniform, and the CAGR from 2000-2010 was 12.1%. From 2000 to 2010, the overall volume of spine MR increased by 103%, and although positive growth was seen each year from 2000-2009, a drop in total volume was observed in 2009-2010. Nearly all the increase in MR volume was seen from 2000-2005 (1,096,809 to 2,154,589), with flattening of the volume increase from 2006-2010. The total utilization rate of MR was 33 per 1,000 beneficiaries in 2000 and 63 per 1,000 beneficiaries in 2010 (+89%). The CAGR in the pre-DRA period was 10.2% and in the DRA/post-DRA period was 0.3%. The CAGR from 2000-2010 was 6.7%.



Conclusion
The rate of growth of CT spine in the Medicare population began to slow in 2005, although volume continued to substantially increase. While the rate of growth of spine MR in the Medicare population also grew from 2000-2005, the number of studies performed after 2005 largely reached a plateau. It is speculated that the impending passage of the DRA in early 2006, in combination with increased awareness of the risks of radiation exposure and cost consciousness on the part of patients and physicians, contributed to these trends.

Pilots to Publications: An Analysis of Preliminary Research Follow-Up in the American Journal of Neuroradiology

Chin, M. S.·Castillo, M.
University of North Carolina
Chapel Hill, NC.

Purpose
There are perceptions, possibly anecdotal, that "pilot" studies lack follow-up to address initial articles' limitations or reinforce its findings. Our purpose was to assess the rate of relevant follow-up publications, whose initial pilot studies were published in the American Journal of Neuroradiology (AJNR).
Materials & Methods
Over a 12-year period (2001 - present), a list of publications from the AJNR electronic archives was obtained with one or more of the following "keywords" in their titles: pilot, initial, preliminary, experimental, and/or exploratory. Using this list, MEDLINE and EMBASE were searched for relevant preceding or subsequent publications, written by one or more of the original authors. Any relevant follow-up papers written by different authors yet based on the original authors' pilot research, were excluded from consideration.
Results
Of 194 pilot articles, 64 (33%) follow-up publications addressed a limitation or expanded upon the preliminary paper. Two or more relevant follow-up publications were seen in 26 (13%) of pilot studies. An additional 29 (15%) follow-up papers applied the pilot research in a different disease and/or clinical setting. Of the 70 translational (animal/in vivo/cadaver) pilot papers, 39% (n = 27) resulted in a follow-up publication, with 10% (n = 7) having two or more follow-up publications. Comparing translational and non-translational research, no statistical significance was seen in percentage of follow-up publications (single follow-up paper, p = 0.27; multiple follow-up papers, p = 0.24). Twenty-five percent (n = 48) of pilot papers were preceded by smaller, yet relevant "pre-pilot" papers by one or more of the same authors, yet lacked one of the "keywords" in their titles. The majority (95%) of pilot papers reflected "positive" results in their findings. The average time to follow-up publication was 19.5 months (SD: 16.2), with an average of 17.7 months (SD: 14.1) for translational research papers. A weakness of this study is the exclusion of potential pilot papers that did not include one of the specified keywords in its title. This paper also does not assess the number of relevant subsequent papers by different authors (based on these authors' pilot papers) or examine the reasons for the lack of follow-up publications in the remaining "pilot" studies (despite reported positive results in the pilot papers).
Conclusion
One third of published AJNR papers with certain "pilot" keywords in their title resulted in follow-up publications and 13% resulted in two or more subsequent papers. No statistical significance was seen between rate of follow-up publications between translational and non-translational research articles.

KEYWORDS: AJNR, Long-term followup, Pilot

O-250 **11:25 AM - 11:33 AM**

Bringing the Reading Room to the People: Evaluation and Efficacy of Relocating the Head & Neck Radiologists Directly into the ENT Clinic

Peterson, R. B.·Corey, A.·Aiken, A.·Baugnon, K. L.·Mattox, D. E.·Hudgins, P. A.
Emory University
Atlanta, GA.

Purpose
At our academic institution, the Head & Neck (HN) radiology reading room recently was integrated into the newly renovated Otolaryngology Outpatient Clinic in an attempt to improve multidisciplinary interaction, customer service, patient treatment planning and appropriateness of radiology examination ordering. The goal of this investigation was to evaluate the referring clinician's perceptions after this change. Additionally, radiology residents, fellows and faculty were surveyed to evaluate the educational benefits and/or deficits to the change.
Materials & Methods
A 10-question survey was designed for health care practitioners, including physicians (MD), nurse practitioners (NP), and physician assistants (PA) involved in our institutional HN Tumor Board (ENT, Hematology/Oncology, Radiation/Oncology, Pathology, Oral Maxillofacial Surgery) as well as other support staff (Nursing, Audiology, Speech Pathology, Social Work, Research, Scheduling, etc). The survey identified the individuals by their specialty, role and whether they were directly affiliated with our institution or an outside referring clinician. Both qualitative and quantitative benchmarks were included to evaluate the daily interaction with radiology before and after the move, the effects of the change on multidisciplinary tumor board/treatment planning and overall practice workflow (exam appropriateness and report turnaround time). Additionally, radiology residents, neuroradiology fellows and HN radiology faculty completed a separate survey to evaluate the educational value of the integration.
Results
Thirty-five responses were returned via an electronic survey from the clinical services. Approximately 58% were from the Department of Otolaryngology at our institution. Ninety-four percent responded that the move was extremely beneficial to their practice. The greatest improvements were in the availability of the HN radiologist for prompt consultation and interpretation of outside images. ENT clinicians reported an increased interaction with the radiologists from 6% to 31%, in the

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

"frequently" (defined as multiple times per day) and "regularly" (defined as at least once a day) categories. The most commonly reported interaction with a radiologist was multiple times per week. Respondents also reported a 37.5% improvement in the tumor board productivity after the move into the clinic. More importantly, even though the move was most favorable to the department of Otolaryngology, the other specialties indicated no significant hindrance to their interaction with radiology. Sixteen radiologists responded to our survey with 100% indicating an increase in daily interaction with clinicians (from once per day on average to multiple times a day) compared to other diagnostic subspecialties. The results also indicate an increase in direct patient interaction compared to other nonprocedurally based subspecialties.
Conclusion
Preliminary results demonstrate a significant improvement in the interaction between HN radiologists and referring clinicians without deterring the interaction with other subspecialties. Radiology trainees and faculty report an increased improvement in clinical correlation and educational value of the rotation. Overall, the move has been beneficial for both radiologist and clinician.

Effects of Installing an MR Scanner in the Emergency Department on the Emergency Department Length of Stay for Patients Admitted with Symptoms of Stroke

Babiarz, L. S.·Zan, E.·Urrutia, V.·Hill, P.·Leigh, R.·Lewin, J. S.·Yousem, D. M.
Johns Hopkins Hospital
Baltimore, MD.

Purpose
Patients presenting with stroke-like symptoms (SLS) often undergo MRI. We assessed the effects of installing an MR scanner in the ED on the emergency department length of stay (EDLOS) of patients admitted through the ED with SLS. We hypothesized that MRI availability in the ED increases EDLOS for patients with SLS because of the additional time for the completion o f MR studies prior to admission.
Materials & Methods
Our study was HIPAA compliant and approved by the IRB. We compared patients with SLS seen in the ED and admitted between July 1st and August 15th 2011 and 2012, before (2011) and after (2012) ED MR scanner installation. The overall EDLOS for patients who did and who did not have MRI in the ED was determined. Time intervals between ED registration and MR exam order and completion of MR exam were measured. Comparative statistics and t-tests were computed.
Results
Sixty-seven patients (mean age = 57.8 years, range = 21-87 years; male = 33) with SLS in July/August 2011 and 48 patients (mean age = 59 years, range = 24-87 years; male = 22) in 2012 were seen in the ED. Twenty-one MRs were performed for 10 patients in the ED (14.9%) in 2011 and 28 MRs for 14 patients (29.2%) in 2012. Mean overall EDLOS was 5.17 hours in 2011 and 5.94 hours in 2012 (p-value=0.33, NS). Mean EDLOS for patients who did and did not have an MR in the ED were 6.44 and 4.95 hours (p-value=0.12, NS) in 2011 and 5.90 and 5.91 hours in 2012 (p-value= NS), respectively. The 2012 patients who had MRI in the ED had shorter EDLOS (p-value=0.0006). ED registration to MR exam order time was 138.8 in 2011 and 144.3 minutes in 2012 (p-value=NS). MR exam order to MR exam completion time was 124.2 in 2011 and 97.3 minutes in 2012 (p-value=NS). Patients with SLS seen in the ED in 2011 were diagnosed with: 26 ischemic strokes, 22 TIAs, five hemorrhagic strokes, five migraines, three vertigo, one acute pressure palsy, one retinal artery occlusion, one complex partial seizure, one cranial nerve palsy, one migraine versus TIA, one optic neuritis, one postconcussive syndrome. In 2012, ED patients with SLS were diagnosed with: 21 ischemic strokes, 18 TIAs, three retinal artery occlusions, one hemorrhagic stroke, one conversion disorder, one new intracranial mass, one migraine, one migraine veersus TIA, one venous infarct/sinus thrombosis, one vertigo versus Meniere's disease.
Conclusion
Although not statistically significant, there was an overall trend for patients who presented with SLS in 2012 to have longer EDLOS than those who presented in 2011, before installation of the MR scanner. However this difference was not attributable to performing MR exams in the ED setting as those who had an MR were scanned more quickly and had a shorter LOS in 2012 than in 2011. Further analysis of larger patient samples is needed for confirmation of the benefits of prompt and accurate diagnosing of patients with SLS in the ED with MRI.

KEYWORDS: Actue stroke, Utilization management

O-252 **11:41 AM - 11:49 AM**

Emerging Trends in Critical and Semi-Urgent Notification of Radiologic Findings

Aamodt, D.·Hunt, C. H.·Knudsen, J. M.·Schwartz, K. M.·Diehn, F. E.·Eckel, L. J.·Wood, C. P.
Mayo Clinic
Rochester, MN.

Purpose
To describe trends in communication of critical and semi-urgent findings in a neuroradiology practice using both the telephone and an automated semi-urgent report system.
Materials & Methods
A retrospective review was made of all neuroradiology reports by modality from 1/2005 to 12/2011. Telephone communication of critical findings always has been documented directly within the radiology report at our institution. From 4/2007, an automated process was put in place where a report with a semi-urgent finding could be

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

flagged and the clinician notified electronically with verification of receipt. For this study, the number of reports each month in which direct telephone communication was documented and the number of reports that were flagged with the semi-urgent notification system was recorded.
Results
A total of 391895 neuroradiology reports were reviewed from 2005 through 2011 (CT: 1865+/-134; MR: 2800+/-348 per month). Telephone communications for all findings increased from 3.4%+/-0.47 of reports per month in 2005 (CT: 6.3%+/-1.0; MR: 1.8%+/-0.3) to 4.3%+/-0.50 of reports per month in 2011 (CT: 7.1%+/-1.0; MR: 2.1%+/-0.4) ($p<0.0002$). Since successful implementation in 2007, the semi-urgent automated notification system has been used fairly consistently on 1.4%+/-0.3 of reports per month (CT: 0.7%+/-0.3; MR: 1.9%+/-0.5). Interestingly, a telephone call was made to the ordering clinician in 14.2%+/-5.5 of neuroradiology reports per month, in which the automated notification system also was utilized (CT: 21.2%+/-13.2; MR: 12.9%+/-7.3).
Conclusion
There is an increasing trend of telephone communication with clinicians to convey important radiologic findings. A semi-urgent notification system has demonstrated significant sustained use in our busy clinical practice. In a small percentage of reports, both the semi-urgent notification system and direct telephone communication are utilized, potentially leading to inefficiency in the radiologist's and clinician's practice.

Effects of Installing an MR Scanner in the Emergency Department on the Hospital Length of Stay for Patients Admitted with Symptoms of Stroke

Babiarz, L. S.·Zan, E.·Urrutia, V.·Hill, P.·Leigh, R.·Lewin, J. S.·Yousem, D. M.
Johns Hopkins Hospital
Baltimore, MD.

Purpose
Patients presenting with stroke-like symptoms (SLS) often undergo MRI evaluation which may be performed in the emergency department (ED) or inpatient setting. We assessed the effects of installing an MR scanner in the ED on the hospital length of stay (HLOS) of patients admitted with SLS through the emergency department. We hypothesized that MRI availability in the ED expedites patient evaluation resulting in shorter HLOS.
Materials & Methods
Our study was HIPAA compliant and approved by the IRB. We compared patients admitted through the ED with SLS between July 1st and August 15th 2011 and 2012, before (2011) and after (2012) ED MR scanner installation. The overall HLOS and HLOS for SLS patients who did and did not undergo MRI evaluation in the ED was determined. Comparative statistics and t-tests were computed.
Results
Sixty-seven patients (mean age = 57.8 years, range = 21-87 years; male = 33) with SLS in July/August 2011 and 48 patients (mean age = 59 years, range = 24-87 years; male = 22) in 2012 were admitted through the ED. Twenty-one MRs were performed for 10 patients (14.9%) in the ED in 2011 and 28 MRs for 14 patients (29.2%) in 2012. Mean overall HLOS was 3.52 days in 2011 and 2.63 days in 2012. Mean HLOS for patients who did and who did not have an MR in the ED was 3.01 and 3.61 days in 2011 and 2.43 and 2.71 days in 2012. For patients seen in 2011, the final diagnoses were: 26 ischemic strokes, 22 TIAs, five hemorrhagic strokes, five migraines, three vertigo, one acute pressure palsy, one retinal artery occlusion, one complex partial seizure, one cranial nerve palsy, one migraine versus TIA, one optic neuritis, one postconcussive syndrome. For 2012 patients, the final diagnoses were: 21 ischemic strokes, 18 TIAs, three retinal artery occlusions, one hemorrhagic stroke, one conversion disorder, one new intracranial mass, one migraine, one migraine versus TIA, one venous infarct/sinus thrombosis, one vertigo versus Meniere's disease.
Conclusion
There was nearly a full day reduction in HLOS for patients admitted through the ED with SLS before (3.52 days) and after (2.63 days) installation of an MRI scanner in the ED with the greatest benefit occurring in those patients in 2012 who had an MR in the ED (HLOS 2.43 days). Further analysis of larger patient samples is needed to confirm the benefits of prompt and accurate diagnosing of patients with SLS in the ED with MRI.

Demographics of Providers Who Order Neuroimaging Procedures for Medicaid Patients

Boyko, O. B.[1]·Hiatt, M. D.[2]·Malkan, P. R.[2]
[1]University of Southern California, Los Angeles, CA,
[2]HealthHelp, Houston, TX.

Purpose
To characterize the types of providers who order neuroimaging for Medicaid patients.
Materials & Methods
Requests for pre-authorization of neuroimaging under the utilization management of a radiology benefit manager since the inception of such management in the state of New York for its approximately 875,000 Medicaid beneficiaries were reviewed retrospectively to ascertain the proportion of requests initiated by (a) physician assistants (PAs) and nurse practitioners (NPs), (b) family and general practitioners (FPs and GPs, respectively), and (c) neurologists, neurosurgeons, and psychiatrists to

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

understand how Medicaid patients are being served. The time period spanned from April 2011 to October 2012. The neuroimaging procedures of interest were comprised of CT and MRI of the brain, defined by CPT codes 70450, 70460, and 70470 for CT and 70551, 70552, and 70553 for MRI.
Results
During the 1.5 years of review, 17,691 requests for neuroimaging, comprised of 4,593 CTs and 13,098 MRIs, were initiated for 14,876 unique patients. Considering those requests submitted by providers pertaining to just the three categories of interest, 7% were from PAs and NPs, 30% from FPs and GPs, and 63% from neurologists, neurosurgeons, and psychiatrists.
Conclusion
The recent preponderance of PA, NP, FP, and GP involvement in ordering neuroimaging for Medicaid patients may be a harbinger of the nature of care to come under the Affordable Care Act, which may largely rely on Medicaid to provide health insurance coverage to over 30 million more Americans. This initial analysis also may serve as a baseline against which to compare presumed even greater reliance on PAs and NPs in the future.

KEYWORDS: Utilization management, Utilization rates, Radiology benefit management

Patient Protection and Affordable Care Act: What You Need to Know as a Radiologist?

Rehani, B.·Rosman, D.·Romero, J.·Schaefer, P.·Gonzalez, R.·Hirsch, J.
Massachusetts General Hospital
Boston, MA.

Purpose
To understand the basics of health care reform, mechanisms by which PPACA expands health care coverage and how PPACA pays for its coverage. To outline in comprehensible terms PPACA's effect on consumers, on neuroradiologists specifically and radiology at large.
Materials & Methods
The PPACA legislation was studied extensively and key elements of health reform are summarized. The pertinent legislation that has a potential to directly impact radiologists was studied.
Results
PPACA expands coverage to nearly all U.S. citizens and legal residents through two principle mechanisms: a mandate to require most U.S. citizens and legal residents to purchase health insurance; and an expansion of Medicaid. Each of these mechanisms achieves approximately half of the 30+MM people who will be newly insured due to the Act. The insurance products are made available on a state by state basis through insurance exchanges and the mandate is enforced through the tax code. Individuals who do not meet the expanded criteria for Medicaid and who meet other income eligibility criteria (from 133%-400% of federal poverty level) will be given subsidies for purchase of insurance on the exchange. Other important components of PPACA include cost controls, incentives to form Accountable Care Organizations and health plan regulation. Specific to radiology is legislation that includes utilization rate, self-referral, appropriateness criteria and a 2.3% excise tax on medical devices.
Conclusion
There are many unanswered questions regarding the implementation of PPACA and a general lack of awareness about how health reform will impact radiology. After detailed study of the legislation, there are specific key points which can help simplify the understanding of PPACA for neuroradiologists both in academic and private practice settings.

Alzheimer: Clues, Causation and Clues

Small, S.
Columbia University
New York, NY.

After graduating from NYU with a BA in experimental psychology, Dr. Small began the MD/PhD program at Columbia University in Eric Kandel's laboratory. Discovering that he enjoyed patient care more than he

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

anticipated, he decided to focus exclusively on his medical training. After completing a medical internship at UCLA, a neurology residency and chief residency at Columbia, and a fellowship with Richard Mayeux, Dr. Small "returned" to research. Informed by his prior experience studying neuronal physiology and pathophysiology he began a research program at Columbia dedicated to investigating intractable disorders of the brain. Taking a decidedly top-down approach, he optimized brain imaging tools designed to pinpoint brain dysfunction in human patients and mouse models of disease. More recently, Dr. Small has combined brain imaging with gene-expression technologies to uncover novel molecular defects underlying Alzheimer disease and aging. Dr. Small is the recipient of numerous awards, including the Beeson Scholar Award in Aging Research from the American Federation on Aging, the McKnight Neuroscience of Brain Disorders Award, the Derek Denny-Brown Young Neurological Scholar Award from the American Neurological Association, and the Lamport Award for Excellence in Clinical Science Research from Columbia University.

Presentation Summary
Alzheimer disease, like all diseases of the brain, manifests with regional vulnerability. Pinpointing brain regions vulnerable and resistant to a disease is important for understanding underlying mechanisms. In this presentation I will begin by briefly reviewing a variant of fMRI that uses "cerebral blood volume" to map brain metabolism, and which has features well suited for identifying anatomical patterns of hippocampal vulnerability in patients and animal model. Then, I will discuss how this fMRI variant has been applied to patients, nonhuman primates, and mouse models to identify a pattern of hippocampal vulnerability that distinguishes Alzheimer disease from aging. Next, I will review recent imaging studies in humans and mice, which suggests how the disease spreads over time. Finally, I will show how the pattern of vulnerability has been used to uncover a pathogenic molecular pathway that has opened up a novel avenue of drug discovery.

Translational Imaging Strategies for Therapy in AD

Petrella, J. R.
Duke University Medical Center
Durham, NC.

Presentation Summary
As neuroradiologists, our role in the workup of the dementia patient has been limited. This is primarily driven by the lack of effective treatment options and limitations of our imaging tools. Over the past 100 years, we have made tremendous strides in our understanding of the genetic, molecular, cellular basis of AD. We now know that the pathology underlying AD is present years, if not decades, prior to development of symptoms. Unfortunately, current therapies are symptomatic only, directed at slowing progression of cognitive decline for a limited time. The search for a true disease-modifying therapy continues and many clinical trials are underway. Current outcome measures are based on cognitive tests which are relatively insensitive to disease progression, requiring long trials with large numbers of participants. Biomarkers, including neuroimaging, have great potential to increase the power of clinical trials through greater effect sizes. This approach is based on matching the imaging methodology with therapeutic mechanism. The multicenter ADNI trial aims at identification and characterization of such biomarkers for clinical trials. Perhaps one of the most important advances over the past decade has been the development of in vivo imaging probes targeted to amyloid beta protein. One such agent has been approved by the FDA and other similar agents are in late stage clinical trials. These agents show great potential for enriching samples in clinical trials of anti-amyloid agents. Volumetric imaging measures to quantitate cerebral volume loss in a variety of critical brain structures correlate well with cognitive decline as well as with tau pathology, suggesting that they might serve as accurate surrogate markers of neurodegeneration. Recent development of automated, highly reproducible volumetric methods has increased the availability and practicality of these tools. Use of such techniques in early phase clinical trials is expected to significantly decrease the duration and number of subjects in such trials and greatly increase the rate at which candidate drugs can be brought to testing in larger phase III trials.Though recent failures of several phase III trials employing anti-amyloid therapies in patients with AD has thrown the amyloid hypothesis in question, this approach may still be effective earlier in the disease, before significant neurodegeneration has taken place. The National Institute on Aging is currently funding three national trials of anti-amyloid therapies in asymptomatic, at-risk subjects, in which neuroimaging biomarkers will be used for sample enrichment and outcome measures.

Diffusion Imaging of the Brain: My BFF Sequence

Filippi, C. G.
Columbia University Medical College of Physicians and Surgeons
New York, NY.

Learning Objectives
Upon completion of this presentation, participants will be able to:
1) Describe diffusion-weighted imaging (DWI) techniques and define the quantitative parameters derived from these sequences including age-related and normative, regional-related values.
2) Demonstrate key diagnostic applications of DWI beyond stroke imaging, specifically intracranial infections, neoplasm, and demyelinating diseases.
3) Explore the emerging use of DWI in novel applications such as the analysis of brain tumor histopathologic grade and assessment of treatment response.
Presentation Summary
Diffusion-weighted imaging has become an important part of routine brain magnetic resonance (MR) imaging. The molecular motion of protons within brain tissue is impeded or influenced by interactions with cell membranes as well as intracellular and extracellular structures. Within any given voxel, average diffusion can be quantified by apparent diffusion coefficient, the volume-averaged rate of propagation of water molecules as they interact with cellular structures within that voxel. In ordered anatomical structures like axons and white matter fiber tracts, diffusion is highly oriented, or anisotropic, and can be exploited for diffusion tensor imaging (DTI). By acquiring diffusion-sensitized images along multiple noncollinear directions, at least six and typically up to 32, one can determine the fractional anisotropy of white matter as well as its major and minor eigenvalues (or equivalently, axial and radial diffusivity). Together these parameters can be used to make inferences about the integrity of white matter microstructure. Quantitative DTI is an intense focus of ongoing neuroimaging research because more accurate quantitative in vivo neuroimaging biomarkers are necessary for prognostication and as outcome measures for treatment management and efficacy in a number of neurologic disorders. The high sensitivity and specificity of diffusion imaging for the detection of acute infarction has fundamentally altered neuroimaging practice. Diffusion-weighted imaging is not simply a stroke-related sequence, however, as DWI and DTI are helpful in the diagnosis of many other neurologic diseases. Diffusion-weighted imaging is particularly useful in the diagnosis of intracranial infections like pyogenic abscess, septic embolism, herpes encephalitis, and prion disease. The role of DWI in the evaluation of brain tumors also is evolving rapidly. Not only can DWI readily distinguish epidermoid from arachnoid cysts, but the technique also is being increasingly used to aid in the histologic grading of pediatric and adult tumors. There is heightened interest in the use of DWI and DTI as a way to monitor therapeutic response to treatment, assess recurrence of brain neoplasms, and better predict the long-term course of disease. Diffusion-weighted imaging also plays an important role in the evaluation of inflammatory, dysmyelinating, and demyelinating diseases. This presentation will briefly define DWI and DTI and the quantitative metrics derived from these sequences, and discuss age-related and regional variations in mean diffusivity and fractional anisotropy. Characteristic examples of DWI in intracranial infections, brain tumors, and demyelinating diseases will be presented along with novel uses and applications of DWI in these and other neurologic disorders, which will highlight emerging advances in this technique.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

What Does Diffusion Mircroscopy Tell Us About Diffusion In Vivo?

Shepherd, T. M.
New York University Medical Center
New York, NY.

Presentation Summary

Diffusion microscopy of ex vivo nervous tissue enjoys several important experimental advantages that have proven useful to investigate the biophysical basis for water diffusion observed during clinical diffusion MRI. Unlike MRI in clinical practice, isolated tissue samples without motion are well suited to time-intensive, complex acquisitions using high-field narrow-bore research magnets, gradients and optimized coil designs without tissue heating limitations. Quantitative 3D data obtained from diffusion microscopy are less time- and labor-intensive to obtain than histology, and more amenable to modeling of nervous tissue properties and connectivity in normal and diseased states. This presentation will summarize the key underlying biophysical determinants of diffusion and discuss how these features should color the interpretation of clinical MR diffusion imaging studies. Landmark MR microscopy studies in specimens demonstrate that water diffusion in nervous tissue is affected by a number of biophysical properties of tissue, including the distribution of water within the intra and extracellular compartments (and their respective T2 values), extracellular tortuosity, restriction or hindrance from semi-permeable membranes and the rate of water exchange across the cell membrane. While it is not entirely incorrect to ascribe diffusion changes observed during ischemia, to simple cell swelling, for example, it should be recognized that this simple process alone most likely affects all these properties simultaneously. Determining the precise contributions from each of these factors to the diffusion signal during ischemic stroke is difficult and potentially intractable given the dynamic changes that occur in real time. The contribution from different factors also varies significantly across disease states. Importantly, diffusion microscopy also has proven that the coherent ordering of intact axonal membranes, not myelin, is the dominant contribution to diffusion anisotropy observed with clinical diffusion MRI in large bundles of white matter. It follows that observed microstructural coherences, such as from the ordered orientations of large pyramidal neurons and their dendritic arborization, also result in significant diffusion anisotropy. Thus, diffusion microscopy may be able to investigate the functional organization of clinically important structures, such as the cortex or hippocampus, and thereby provide a standard by which to better interpret normal and abnormal organization of these structures in the individual patient. This exciting development has the potential to enable diffusion MRI detection of early changes in connectivity related to neurologic disease.

Diffusion Imaging Outside the Brain: Challenges and Applications

Hess, C. P.
University of California, San Francisco
Mill Valley, CA.

Presentation Summary

The past two decades have seen MR diffusion imaging transform from laboratory curio to standard of practice for a number of routine indications for clinical brain imaging. However, the application of this technique outside of the brain has yet to gain widespread acceptance.
Although there exist many scenarios for which diffusion imaging is helpful or even necessary to establish a diagnosis in the spinal cord, peripheral nervous system, soft tissues, or osseous structures, diffusion-weighted imaging (DWI) and diffusion tensor imaging (DTI) are more technically challenging to acquire and frequently difficult to interpret in these areas of the body. Similar to its use in the brain, diffusion imaging in other body regions can be integrated with other conventional MR contrast mechanisms to enhance tissue contrast and/or by itself to provide a quantitative probe of tissue microstructure. The most widely used quantitative diffusion parameter, apparent diffusion coefficient, represents an important adjunct for distinguishing between benign and aggressive soft tissue masses, permits accurate identification of recurrent cholesteatoma in the postoperative temporal bone, and serves as a valuable benchmark for assessing treatment response in head and neck oncologic imaging. Beyond these applications, DWI and DTI are also useful for improving visualization and characterization of nerve and spinal cord lesions, and for enhancing sensitivity to osseous and soft tissue metastatic disease. This presentation will focus on current and emerging extracranial applications of diffusion imaging in neuroradiology, using case studies to illustrate how the technique can be effectively implemented in the clinical setting and used for head and neck, spine, and nerve imaging. In this context, the relative strengths and limitations of different presently available approaches for DWI and DTI, including single-shot and multi-shot, PROPELLER, reduced field-of-view, and other volume suppressed echo-planar pulse sequences will be presented.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Radiology Value Chain - 2013 J. Arliss Pollock, MD Memorial Lecture Award Recipient

Enzmann, D. R.
David Geffen School Of Medicine at UCLA
Los Angeles, CA.

Presentation Summary
A simplified view of the diagnostic radiology value chain defines components vulnerable to significant change. Some of these changes are disruptive and some are opportunities to improve productivity, to add value, or to mitigate the risk of commoditization. The radiology business model must define new ways to add value either by increasing productivity or by creating new services. This may initiate an evolution of diagnostic radiology from a professional service into an information business. These two models differ fundamentally. Areas of symbiosis between diagnostic and interventional radiology are proffered as a potential for expanding radiology's value proposition by reframing image-guided therapy into image information-guided interventions (iiGI). Overall the value chain in radiology's business model is evolving from a technical orientation to an image-based, personalized precision diagnostic and therapeutic patient care orientation.

O-263 **1:50 PM - 2:15 PM**

Cost Centers and Service Lines

Rasmussen, P. A.
Cleveland Clinic Foundation
Cleveland, OH.

Dr. Rasmussen is director of the Cerebrovascular Center, Cleveland Clinic. He received his education, Medical Degree, Neurosurgical Training at the University of Wisconsin. Dr. Rasmussen is Fellowship-trained in cerebrovascular microsurgery and endovascular neurosurgery. His current interests include systems development for comprehensive stroke care.

Presentation Summary
Cerebrovascular disease and stroke care demands a multidisciplinary approach to deliver high-quality and cost-effective care. One model of such health are delivery, a disease-based center concept, sharing a unified service line reporting model will be discussed. As a real life example, our experience at the Cleveland Clinic will be presented.

Patient H.M. and the UCSD Digital Brain Library

Annese, J.
The Brain Observatory
San Diego; Department of Radiology University of California San Diego
San Diego, CA.

Presentation Summary
The Digital Brain Library project is an effort to catalog the morphologic variability of human brains in relation to cognition and behavior and understand how aging and disease affect the dynamics of structure-function relationships. Subjects that are recruited in the local community undergo annual neuroimaging sessions and neuropsychologic assessments. Intelligence and personality tests also are administered in the context of the longitudinal evaluation. The impact of the study is maximized by the consent of research participants to donate their brains for follow-up postmortem examination. These cases provide the extraordinary opportunity to combine noninvasive neuroimaging (conducted in vivo) with postmortem neuropathologic analyses; and consequently afford the direct correlation of neuroimaging and behavioral markers and cellular-level

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

structural information. This success is in part due to the fact that research subjects also are given the choice to participate in a personal autobiographical interview that covers major elements of the patients life experience. The distinguishing feature of the "Digital Brain Library" is the fact that it collects 2-dimensional (2D) and 3-dimensional (3D) data from multiple neuroimaging modalities and spanning a very wide range of file sizes and levels of resolution. Given the sheer size of the image collection relative to each individual brain, it is obvious that the resource cannot be utilized efficiently by any single researcher or clinician; instead, it is essential to create the infrastructure for a larger collaborative environment. We present new strategies in data sharing and data visualization that are poised to maximize the use and scientific impact of a novel multimodal neuroimaging archive. One of the Digital Brain Library's most notable archived cases is that of the amnesic patient H.M. who underwent a medio-temporal lobotomy in 1953 to alleviate his severe epileptic seizures; unexpectedly, the operation created a profound state of anterograde amnesia while all other cognitive functions were preserved. His case became a landmark in the behavioral sciences, because for the first time it was clear that the hippocampus and medial temporal lobe structures were essential to store and retrieve memories. A complete histological atlas of the brain of patient H.M. was created representing a centralized archive of information that would be available to researchers worldwide. The goal of the digital collection is to provide a commensurate scope of neuroanatomical data relative for corroborating an unprecedented amount of neurobehavioral investigations that spanned over 50 years.

O-266 **1:45 PM - 2:15 PM**

Computational and Visualization Strategies Involved in the Correlation of Multimodal Neuroimaging at Multiple Levels of Resolution

Bartsch, H.
University of California San Diego
San Diego, CA.

Hauke Bartsch studied computer science in Germany and got his PhD in 2003 with work on computations of lateral connection in primary visual cortex. He has since worked in the medical industry on 3D image processing and PACS/HIS/RIS systems. Since 2011 he shares his passion for advanced image analysis between The Brain Observatory and the Multi-modal Imaging Laboratories at the University of California San Diego, Department of Radiology. In his spare time he enjoys reading and building robots with his two kids.

Presentation Summary
The correlation between different neuroimaging modalities that entail qualitatively different image data and at different scales of resolution presents serious computational challenges. Nevertheless, the correct integration of information obtained from non invasive clinical MRI and histological features underlying MRI signal is crucial for the interpretation of clinical radiologic scans and proper diagnosis and treatment (Annese, 2012). We have developed a computational workflow that operates in 2D and 3D for the processing, analysis, and visualization of neuroimaging data. The workflow is intended to organize cellular-level parameters contained histological images based on the original geometry of the brain. In practice, each individual patient who participates in The Digital Brain Library undergoes regular MRI scans (longitudinal imaging) and behavioral testing. When the patient dies, the brain undergoes a series of postmortem scans (in situ and ex-situ) before it is processed, in one piece, histologically (Bartsch et al., 2012). The process generates a series of stacked anatomical images (blockface imaging) and corresponding tissue slices. The latter are stained to reveal neuropathologic features and digitized at approximately 0.4 µm/pixel. Therefore the image size to contend with varies from matrices of 256x256 pixels (clinical MRI; < 100 MB on disk) to over 400,000x400,000 pixels (50GB on disk). In addition, the bit depth and information contained in the image vary considerably (gray scale radiologic images versus 16 bit color anatomical and histological images). The pipeline developed at The Brain Observatory includes processing steps that convert 2D blockface and histological images into 3D volume data sets. These are registered to the original MRI via nonlinear registration techniques, so that quantitative analyses conducted at the microscopic level can be "projected" onto the clinical images. For example, we quantify age- and disease-related changes in microscopic fiber architecture underlying regions of white matter hyper-intensities localized by MRI and DTI. Finally, the inspection of radiologic scans, anatomical structures, and large-scale histological montages is achieved by 2D and 3D visualization strategies that feed into a web-based resource accessible to other investigators. The portal also contains cognitive and behavioral measures together with a large number of imaging-related parameters (neuroimaging markers) derived by atlas-based image processing tools like FSL and FreeSurfer. The portal was designed to evaluate correlations between the diverse imaging data and scores obtained with previous neuropsychologic testing.

O-267 **2:15 PM - 2:45 PM**

Exploring Correlations between Neuroimaging Markers and Complex Traits in Essential Tremor

Klaming, R.
University of California San Diego
San Diego, CA.

Ruth Klaming graduated cum laude with a Master of Science in Neuropsychology from Maastricht University in the Netherlands. She currently works as a research

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

associate at The Brain Observatory, University of California San Diego where she is responsible for neuropsychologic assessments and neuroimaging for the Digital Brain Library project. Mrs. Klaming is a PhD candidate at the Vrije University of Amsterdam working on a collaborative longitudinal study on healthy aging conducted by The Brain Observatory and the Vrije University of Amsterdam.

Presentation Summary
Essential tremor (ET) is one of the most common movement disorders yet its underlying pathophysiology is still unclear making a correct diagnosis and effective treatment extremely difficult (Louis, 2005). In addition to motor symptoms, mild cognitive deficits are common in ET patients. Although ET can occur at any age, it is more prevalent amongst elderly; hence, dissociating age-related brain atrophy and cognitive decline from changes that are specific to ET is challenging. The cerebellum is implicated in motor and higher cognitive functions, supported by its extensive connections with several brain regions, including the prefrontal cortex. This makes the cerebellum a likely area affected by ET. However, the precise nature of cerebellar involvement in the pathophysiology of ET and the possibility that imaging the cerebellum might provide specific noninvasive biomarkers of the disease remains to be established. We have explored a novel MRI parameter in a cohort of well characterized ET patients who are enrolled in the Digital Brain Library project. The gyrification Index (GI) is defined as the ratio between the cortex that lies on the surface and that which is buried in the depth of the sulci. The GI is therefore an index of gray matter loss, separate from overall changes in volume (which could be due to gray and/or white matter atrophy). The comparison of the GI of the cerebral cortex with that of the cerebellum could reveal abnormal rates of atrophy distinct from age-related cerebral structural changes. The analysis of specific neuroimaging markers like the GI is associated with the results of neuropsychologic assessments and individual measures of tremor symptomatology. Complex behavioral scores are combined with neuroimaging data in the framework provided by the Digital Brain Library, making it possible to explore the relationship between behavioral and structural changes specific to ET.

Anatomy, Pathology and Post-Treatment Appearance of the Skull Base: The Basics

Connor, S. E. J.
King's College Hospital
London, UNITED KINGDOM.

Dr. Steve Connor is a consultant neuroradiologist and head and neck radiologist at King's College Hospital and Guy's and St Thomas' Hospital, London, UK. He underwent a neuroradiology fellowship at King's College Hospital and gained head and neck radiology subspecialty training at the Royal National Nose, Throat and Ear Hospital. He has a busy head and neck radiology practice with a particular interest in otology, skull base and maxillofacial imaging. He is deputy editor for three journals and has written three book chapters. He has written over 20 original papers as first author, and has published over 90 peer-reviewed articles. He is vice-chairman of the British Society of Head and Neck Imaging. He has given numerous invited lectures at ENT and radiology meetings, and he reviews the national ENT imaging guidelines and training curriculum.

Presentation Summary
CT and MRI are the principle imaging modalities used to evaluate the skull base, and they are complementary in the diagnosis and staging of skull base lesions. A detailed understanding of the skull base anatomy helps the radiologist predict the likely origin of pathologic tissue, anticipate patterns of disease spread and identify critical

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

anatomical structures at risk. The skull base is traditionally divided into anterior, central and posterior parts and there are numerous associated important neurovascular structures. The radiologic differential diagnosis can be formulated by identifying the specific location of the lesion within the skull base, and then can be refined by recognizing typical imaging appearances. Some examples at specific sites will be used for illustration. There are some lesions which have specific or highly suggestive imaging findings which will obviate biopsy whilst there are some entities which should be identified as “don’t touch” lesions, either because they are normal variants/pseudolesions or because biopsy will be perilous. Even if the imaging findings are nonspecific, there are important generic aspects, such as cystic/solid or benign/aggressive imaging features which are likely to influence treatment planning. The radiologist should identify the anatomical structures adjacent to the lesion, and in particular those which offer potential pathways for spread or which may be endangered by the disease or its treatment. There are some useful imaging criteria which may be used to assess the involvement of such structures (e.g., vascular⋯). The extent of pathologic tissue is critical for staging and planning of appropriate therapies, and an awareness of the potential patterns of spread and the differing appearances of invaded tissues (e.g., bone marrow, dura, perineural) will help the radiologist define the extent of pathology. Pretreatment imaging helps define tumor volumes for radiotherapy planning and guides the appropriate surgical approach (e.g., external versus endoscopic resection . Post-treatment imaging of the skull base is used for the detection of residual or progressive disease or to demonstrate complications of treatment. It is particularly challenging to evaluate since reconstructions and foreign substances, together with the distorted and altered post-treatment tissue (e.g., secondary to scarring, denervation or irradiation) may mimic disease. Normal post-treatment imaging appearances will be presented, together with imaging features of treatment complications (e.g., ??? radionecrosis,cephalocele) and some imaging features which may be helpful in more difficult cases.

O-270 **2:15 PM - 2:45 PM**

Post-Treatment Sinus: The Basics

Joshi, V. M.
Apollo Hospital
Hyderabad, INDIA.

Presentation Summary
Interpretation of CT and MRI scans showing post-treatment changes in the paranasal sinuses often is a diagnostic challenge. Knowledge of the basic disease process, the type of treatment or surgery performed on the patient, and the anticipated imaging appearances of the sinuses after the therapy allow accurate assessment and may prevent misinterpretation of post-treatment changes as recurrent disease. In this talk, we will review the various treatment options for sino-nasal diseases, the choice of imaging modalities to assess the post-treatment sinus, the CT and MRI acquisition protocols and the optimal time interval after the therapy to perform the imaging study. We will discuss the spectrum of expected surgical changes found on postoperative imaging of paranasal sinuses after various functional endoscopic procedures and their common surgical complications. The talk also will focus on the anticipated imaging appearances after surgery and irradiation for sinonasal tumors and the postoperative imaging evaluation of myocutaneous flaps used for reconstructive surgery. The sole intent of the discussion will be to familiarize ourselves with the basic expected imaging changes in the paranasal sinuses following therapy to enable optimal interpretation and differentiate post-treatment changes from recurrent disease.

Flow Diverter Stents in Bifurcation Aneurysms: Is It Safe?

Saleme, S.·Ayoub, D.·Ponomarjova, S.·Mounayer, C.
University Hospital of Limoges
Limoges, FRANCE.

Purpose
We report our experience with flow diverters (FD) in the treatment of aneurysms in artery bifurcations beyond the level of the circle of Willis.
Materials & Methods
A total of 21 bifurcation aneurysms were treated with FD, 42.8% (9/21) at the middle cerebral artery bifurcation, 28.6% (6/21) at the anterior communicating complex, 14.3% (3/21) at the pericallosal artery, and 14.3% (3/21) at the internal carotid bifurcation. Twenty-eight flow diverter stents were deployed (1.3 FD/aneurysm). Aneurysm sizes varied from 1 mm to 20 mm (6 mm average). Nine out of 21 aneurysms (42.8%) have been treated previously by coiling or stent+coiling. All patients but four (17/21, 81.0%) had MRI 24-48 hours after the procedure. MR imaging at six months was performed in 8/21 (38%) patients. Control angiography at six months was obtained in 13/21 (62.0%).
Results

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Twenty-one aneurysms were treated flow diverters in artery bifurcations (19/21, 90.5% saccular; 2/21, 9.5% blister-like). There were no failures of stent deployment but in one case (4.8%) balloon angioplasty was necessary for the perfect opening of the stent. Reversible neurologic complications were noted in 9.5% (2/21), and permanent neurologic complications in 4.8% (1/21, mRS of 2). There was no mortality. MR imaging at 24-48 hours showed micro embolic spots at diffusion in 35.3% (6/17), all asymptomatic, and ischemic lesions in the territory of the shunted branch in 17.6% (3/17), two of which had reversible symptoms. MR imaging at six months showed no new ischemic lesion in 87.5% (7/8) and a junctional infarct (12.5%, 1/8) responsible for a transient facial paralysis due to occlusion of the MCA frontal branch covered by a FD , probably in relation to flow competition. Control angiography at six months showed complete occlusion of the aneurysm in 92.3%(12/13) and residual sac in 7.7%(1/13).
Conclusion
Aneurysms in artery bifurcations beyond the level of the circle of Willis are amenable to treatment by flow diverters in selective cases.

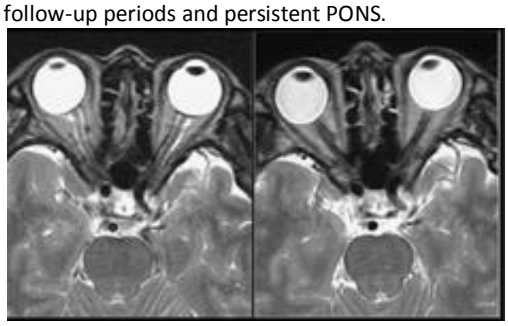
KEYWORDS: Flow diverter, Aneurysm treatment, Bifurcation

O-272 **3:23 PM - 3:31 PM**

MR Imaging Findings of Intracranial Dural Arteriovenous Fistula with Venous Hypertension

Ting, W.[1]·Tsai, F.[2,3]·Guo, W.[1]·Pan, H.[1]·Shiau, C.[1]
[1]Taipei Veterans General Hospital, Taipei, TAIWAN, [2]Taipei Medical University, Taipei, TAIWAN, [3]University California at Irvine, Irvine, CA.

Purpose
The study was aimed to correlate the digital subtraction angiography (DSA) and magnetic resonance imaging (MRI) findings of intracranial dural arteriovenous fistula (ICDAVF) focusing on their relation to intracranial venous hypertension and to find out the feasibility of using the imaging findings as a predictor of therapeutic effects.
Materials & Methods
From 2003 to 2010, totally 91 cases of intracranial dural arteriovenous fistula treated by Gamma Knife radiosurgery were included, (Cognard classification: 24 type I, 24 IIA, 15 IIB, 9 III, 19 IV). Integrated stereotactic MRI and DSA were used for radiosurgical targeting. Follow-up MRI at a six-month interval was undertaken after radiosurgery. Once the ICDAVF became regressed on MRI, DSA was performed to verify the therapeutic result. The patients were followed up 122 (6-122) months. Two neuroradiologists reviewed all DSA and MRI, retrospectively, and recorded the imaging findings on consensus.
Results
Three abnormal MRI findings were observed: Prominent Peri-Optic Nerve Subarachnoid Space (PONS) in 75% (68/91), mesial temporal lobe swelling (MTS) in 19% (17/91), and venous hypertension-related subcortical white matter changes (SWM) in 32% (31/91) of the cases. Stratified by the Cognard classification, type IIB ICDAVF had the highest incidence of PONS (13/15, 87%) and MTS (6/15, 40%). Type III had the highest incidence of SWM (9/9, 100%). But there was no significant difference in incidence of the imaging findings among the types and locations of ICDAVF. Three abnormal DSA findings were observed, namely, internal jugular vein hypoplasia (IJVH), sinus thrombosis (ST), and anterior drainage (AD). Cases with all three abnormal findings showed higher incidence of PONS (81.1% versus 70.4%; 77.2% versus 70.6%; 92.9% versus 45.7%) and MTS (32.4% versus 9.3%; 26.3% versus 5.9%; 19.6% versus 17.1%). Subcortical white matter changes occurred more in cases with IJVH (54.1% versus 16.7%) and AD (35.7% versus 25.7%) but less in cases with ST (29.8% versus 35.3%). In the 68 cases presented PONS, three cases lost followup, among the rest, 54 cases showed regression of ICDAVF by TOF MRA or DSA and 52 of them showed regression of PONS (Figure). The other 11 cases showed, yet, no improvement of ICDAVF in the follow-up periods and persistent PONS.



Conclusion
Peri-optic nerve swelling (PONS) depicted by MRI was a highly specific finding of ICDAVF. It was most likely related to the venous hypertension that stemmed from the associated IVJH, ST or AD. PONS is also a good predictor of radiosurgical effects in ICDAVF.

KEYWORDS: dAVF, Gamma knife, Venous hypertension

O-273 **3:31 PM - 3:39 PM**

Brain Arteriovenous Malformation Treatment by Venous Approach

Saleme, S.·Ponomarjova, S.·Ayoub, D.·Mounayer, C.
University Hospital of Limoges
Limoges, FRANCE.

Purpose
We report our experience in the treatment of brain AVMs by Onyx using the venous approach.
Materials & Methods
From February 2008 to December 2012 a total of eight brain AVMs (BAVM) were treated by Onyx via the venous approach. This technique was chosen when there was no other therapeutic solution for hemorrhagic BAVMs with

small nidus and, for almost all cases (7/8, 87.5%) with deep venous drainage. There were four men and four women with a mean age of 39.5 years (range, 12-57 years). In 50.0% (4/8) of cases the BAVM was treated by venous approach alone and in 50.0% (4/8) by both venous and arterial approach.
Results
The complete obliteration of the nidus was achieved in 75% (6/8). We deplored one (1/8, 12.5%) procedure-related complication by venous perforation during microcatheterism that was immediately controlled by Onyx injection, resulting in intraventricular hemorrhage with no clinical consequence. All patients remained clinically stable with unchanged modified Rankin Scale.
Conclusion
The transvenous approach using Onyx for the management of BAVMs is shown to be an efficient and safe alternative treatment in cases with no other conventional therapeutic choice and when some anatomical considerations are respected.

KEYWORDS: Arteriovenous malformation, Treatment assessment, Onyx

O-274 **3:39 PM - 3:47 PM**

Pretreatment Predicting Factors of Symptomatic Adverse Effects with Linear Accelerator or Gamma Knife Treatment of Arteriovenous Malformations

Machnowska, M. H.·Taeshineetanakul, P.·Geibprasert, S.·Menezes, R.·Agid, R.·Schwartz, M.·Krings, T.·Terbrugge, K.
University of Toronto
Toronto, ON, CANADA.

Purpose
To identify the angioarchitectural, dosimetric and vascular predictors of symptomatic post-radiation T2 signal change in patients with arteriovenous malformations treated with radiosurgery.
Materials & Methods
The charts of 211 consecutive patients with arteriovenous malformations treated with either gamma knife radiosurgery or linear accelerator radiosurgery between 2000-2009 were reviewed retrospectively. One hundered sixty-eight patients had a minimum of 12 months of clinical and radiologic followup following the procedure and complete dosage data. A symptomatic adverse effect was considered as new or worsening focal or global neurologic deficits including worsening of headaches, visual symptoms, increased seizure frequency, worsening of seizure activity, or motor and sensory symptoms. Pretreatment characteristics and dosimetric variables were analyzed to identify predictors of adverse radiation effects.
Results
One hundred forty-one patients had no clinical symptomatic complications. Twenty patients had global or focal neurologic deficits attributed to symptomatic edema; four patients had a hemorrhagic complication; two patients had arterial ischemia, one in the region of the AVM and the other remote from the AVM; one patient was diagnosed with radiation necrosis. We found that the variables associated with development of symptomatic edema included an asymptomatic or nonhemorrhagic symptomatic presentation compared to presentation with hemorrhage, $p = 0.001$, the presence of venous rerouting compared to the lack of venous rerouting, $p = 0.031$; OR (95% CI) = 3.25 (1.20, 8.80); radiosurgery with GKS compared to radiosurgery with LINAC $p = 0.012$; OR (95% CI) = 4.58 (1.28, 16.32); and the presence of more than one draining vein compared to a single draining vein $p = 0.032$; OR (95% CI) = 2.82 (1.06, 7.50). Sex, AVM size, flow rate through the AVM, the number of dominant feeders, perinidal angiogenesis, nidus type, drainage pattern, focal venous pouches, and eloquence did not correspond statistically to the presence of symptoms.
Conclusion
We postulated that the greater number of isocenters used with gamma knife radiosurgery may be responsible for the greater number of adverse radiation effects with this modality compared to linear accelerator radiosurgery. We found that AVMs with greater venous complexity and therefore instability resulted in more adverse treatment outcomes, suggesting that AVM angioarchitecture should be considered when making treatment decisions.

Posterior Fossa Arteriovenous Malformations More Frequently Present with Prenidal Aneurysm Rupture

Kouznetsov, E.·Raymond, J.·Weill, A.·Ghostine, J.·Roy, D.
l'Hôpital Notre-Dame du CHUM
Montréal, QC, CANADA.

Purpose
A controversy exists regarding natural history and treatment of AVM-related prenidal aneurysms. We conducted a retrospective review of 233 consecutive AVM cases in order to examine whether or not we could corroborate previously reported findings, suggesting that posterior fossa AVMs more frequently presented with a prenidal aneurysm rupture.
Materials & Methods
Medical records of all patients with cerebral AVMs seen at Notre Dame Hospital (Montreal, QC, Canada) between April 2001 and August 2012 were reviewed. All fossa and only two of those had a nonhemorrhagic presentation. Twelve out of 22 hemorrhagic posterior fossa AVMs (55%) had a prenidal aneurysm-related hemorrhage, whereas only five out of 135 (3.7%) hemorrhagic supratentorial AVMs presented with a prenidal aneurysm hemorrhage ($Z = 7$; $p < 0.001$).
Results

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Out of 233 AVMs, 24 (10%) were in the posterior cases with a prenidal aneurysm as the main hemorrhagic source were identified. We compared prenidal aneurysm-related rupture rates between supra and infratentorial AVMs.
Conclusion
Posterior fossa AVMs present much more frequently with a prenidal aneurysm rupture than supratentorial AVMs. Our data support more aggressive management of these aneurysms, especially when complete AVM excision is not possible.

KEYWORDS: Aneurysm rupture, AVM, prenidal aneurysms

Endovascular Treatment of Hypoglossal-Clival Dural Arteriovenous Fistula

Liu, H.[1]·Hsu, Y.[2]·Lee, C.[1]·Wang, Y.[1]
[1]National Taiwan University Hospital, Taipei, TAIWAN, [2]Cheng-Hsin Hospital, Taipei, TAIWAN.

Purpose
To report our experience about the treatment of hypoglossal-clival DAVF.
Materials & Methods
From the databank of our institute, we found a total of 17 patients suffered from hypoglossal-clival dural arteriovenous fistula (AVF). They were eight males and nine females and their ages ranged from 43 to 77 years old (mean = 56 years old). Two of them associated with transverse sinus dural AVF. Sixteen patients had pulsating tinnitus and one mainly presented with dementia which may be caused by her transverse sinus DAVF. Three of them associated with eye congestion symptoms due to drainage to the cavernous sinuses.
Results
Of the 17 patients, seven were treated with transvenous approach alone, three with transarterial approach alone (one with onyx and one with coiling), and five with transvenous approach with adjuvant transarterial approach with NBCA or particles. Two patients received no treatment but the lesion had obliterated spontaneously on the follow-up images. The immediate post-treatment was excellent. No evidence of clinical or imaging residual/recurrence in 16 patients, while one treated with onyx had minimal residual without subjective symptom.
Conclusion
Endovascular treatment provides is safe, feasible, and excellent treatment for hypoglossal-clival AVF. Transvascular coiling is a better approach in long-term aspect.

KEYWORDS: Dural arteriovenous fistula, Endovascular management

Comparative Efficacy of Intra-Arterial Cone-Beam CT Angiography Relative to Biplane Digital Subtraction Angiography in the Evaluation of Intracranial and Spinal Arteriovenous Fistulas

Honarmand, A. R.[1]·Gemmete, J. J.[2]·Soltanolkoltabi, M.[1]·Hurley, M. C.[1]·Chaudhary, N.[2]·Pandey, A. S.[2]·Shaibani, A.[1]·Ansari, S. A.[1]
[1]Northwestern University Feinberg School of Medicine, Chicago, IL, [2]University of Michigan Health System, Ann Arbor, MI.

Purpose
Digital subtraction angiography (DSA) is considered the standard for characterization of intracranial/spinal arteriovenous fistulas (AVFs). Although DSA offers superior spatial and temporal resolution, it is limited by 2D planar imaging. Prior reports described the value of intra-arterial cone-beam CT angiography (IACBCTA) in the anatomical localization of intracranial/spinal dural AVFs, but a comparative analysis is lacking. We directly paralleled these modalities to assess the relative IACBCTA efficacy in the anatomical identification/localization of AVFs and utility for surgical/endovascular treatment planning.
Materials & Methods
Patients with intracranial/spinal AVFs underwent biplane DSA and IACBCTA procedures (AXIOM-Artis FlatDetector Biplane-Angiosuite, Siemens) at two institutions with identical contrast injection, radiation exposure, and postprocessing techniques. Images were reviewed retrospectively and independently by two neurointerventionalists on a de-identified PACS workstation. Observers were blinded to clinical information and reviewed both DSA and IACBCTA images in tandem, obtained from the same IA injection. Qualitative image analysis was performed based on the level of delineation on a scale of 1-3 (3: Excellent/Good with minimal attenuation; 2: Moderate, relevant visibility with restrictions; 1: Poor, nondiagnostic). The following parameters were scored: a) Arterial feeders, b) Venous drainers and course, c) Fistula site, d) Adjacent anatomical landmarks for cross-sectional localization, and e) Overall diagnostic value for interpretation. Differences between the scores were defined as the IACBCTA efficacy value. For evaluation of IACBTA treatment planning efficacy, observers described the treatment strategy at the end of DSA and IACBCTA grading respectively and scored its adjunctive value: altered or more confident treatment plan versus no value. Wilcoxon signed rank and Mann-Whitney U tests compared scores of image quality parameters. Interobserver agreement was assessed using Spearman correlation coefficient. P value <0.05 was considered statistically significant.
Results
Thirty-two consecutive patients [22M/10F, mean age 60.9±12.4 years (29-83 years)] were studied. Intracranial AVFs were classified as Cognard type I (n=3), type II (n=11),

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

type III (n=3), type IV(n=1) and metameric dural/pial (n=5). Spinal AVFs were limited to Anson-Spetzler type I (n=9). Despite moderate interobserver agreement for IACBCTA overall efficacy value (rho=0.4, P=0.02), no significant difference was observed between efficacy values (P = 0.6). Both observers assigned significantly higher scores to IACBCTA for overall diagnostic value (both observers: P<0.001). No significant differences were observed between DSA and IACBCTA scores while evaluating arterial feeders (observer 1: P=0.3, observer 2: P=0.6) or venous drainers (observer 1: P=0.08, observer 2: P=0.15). Both readers assigned higher scores to IACBCTA when evaluating the fistula site (observer 1: P <0.0001, observer 2: P=0.0003) and adjacent anatomical landmarks/cross-sectional localization(both observers: P<0.0001). In 30/32 cases, both observers noted that IACBCTA did not alter the treatment plan; but provided a more confident endovascular or surgical treatment approach. Both observers altered their treatment plan from an endovascular approach to microsurgery in one case based on IACBCTA.

Conclusion

IACBCTA adjunctively improves the anatomical delineation of AVFs, particularly in terms of fistula site and localization; biplane DSA may be equally sensitive for arterial feeder and venous drainer identification. IACBCTA confers a more confident endovascular or surgical treatment approach when performed in conjunction with DSA.

Ophthalmic Artery Patency and Clinical Followup after Placement of Pipeline Embolization Device

Raz, E.·Tanweer, O.·Becske, T.·Shapiro, M.·Zumofen, D.·Riina, H.·Nelson, P. K.
New York University
New York, NY.

Purpose

Flow diversion of aneurysms with the pipeline embolization device (PED) has been shown to be an effective treatment option for intracranial aneurysms. Concerns for patency of branch arteries that are covered by a PED have been raised. We aim to examine the patency of the ophthalmic artery and clinical sequelae of occlusion in treatment of intracranial aneurysms with PEDs.

Materials & Methods

A prospective study was performed for all patients undergoing treatment of an internal carotid artery aneurysm where a PED was used and covered the neck of the ophthalmic artery and followup was available. Age, gender, type of aneurysm, number of PEDs used, ophthalmic artery flow on follow-up angiograms, P2Y12 platelet function test results and ophthalmologic exam data were collected. At the followup, the time interval from the procedure, the complete or partial aneurysm occlusion, P2Y12 and ophthalmologic exam were recorded.

Results

The study included 58 patients (M/F ratio = 6/52; mean age 60.2 ± 11.9 years) who had at least one PED placed covering the ostium of the ophthalmic artery. A total of 127 PED were implanted successfully in the 58 patients covering the ophthalmic artery (median 2; range 1-4). The last followup available was performed at 14.5 (11.5) months on average (range 1.9-59.6 months). At followup, 47 out of 58 (81.0%) aneurysms were occluded. Functional impairment of the ophthalmic artery was noted in 12 cases (20.7%): in seven cases the flow within the ophthalmic artery was noted to be slow, in four cases the ophthalmic artery was closed and in one case, proximal stenosis was noted. In all cases of occlusion, reconstitution of the ophthalmic artery was noted via external carotid supply and in one case from the meningohypophyseal trunk. No new visual deficits or complaints were noted in patients with occlusions. No significant difference on the number of PED covering the neck of the ophthalmic artery was present between the two patient groups(p=0.354). No correlation was found between monitoring platelet functionality and ophthalmic artery patency (p=0.782).

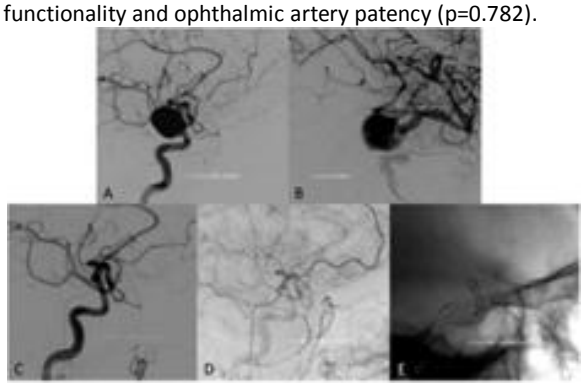

Figure: Baseline images (A-B) demonstrating a paraophthalmic aneurysm with preserved ophthalmic artery flow. One year followup after PED (C-D-E): complete occlusion of the aneurysm; ophthalmic artery origin occluded; reconstitution of flow via the left middle meningeal artery.

Conclusion

In our case series, 20.7% of the ophthalmic arteries were found to be occluded or exhibiting diminished flow on follow-up angiography. None of these changes were found to have clinical sequelae.

Bigger Is Not Always Better: Unexpectedly High Radiation Doses Using Flat Panel Detectors with Increasing Magnification

Lin, S. J.[1]·Badve, C.[2]·Vidal, L. L. M.[2]·Jordan, D. W.[2]·Blackham, K. A.[2]
[1]Case Western Reserve University School of Medicine, Cleveland, OH, [2]University Hospitals, Case Western Reserve University, Cleveland, OH.

Purpose
Flat panel detector units (FPDs) are a new alternative to image intensifiers (II) and ostensibly have a number of advantages; however, the design and operation of the technology is not commonly understood. The large field of view of the detector may result in excessive magnification to visualize small structures. This study evaluates the dose performance of an FPD at various magnification levels which also are known as fields of view (FOV) to quantify dose changes. A small field of view indicates a higher magnification.
Materials & Methods
Measurements were performed on a biplane Philips Allura Xper FD 20/20 (flat detector) system in the AP plane only at different FOV: 42 cm, 22 cm and 15 cm, utilizing clinically typical modes: fluoroscopy (15 frames/second) and digital subtraction angiography modes of 3, 4, and 6 frames/second. Skin-entrance dosimetry was performed with an Unfors Xi R/F detector placed under a CTDI head phantom. Secondly, simulated dosimetry at various locations on the head was measured using thermoluminescent dosimetry (TLD) chips placed on a RANDO head phantom. A fluoroscopic system resolution test tool was used to visually evaluate image resolution at the three levels of magnification.
Results
For FPD fluoroscopy, skin dose rates increased by factors greater than the predicted scaling of 1/FOV with increasing magnification. For acquisition modes, the skin dose effect of magnification paralleled the predicted values of $1/FOV^2$ that is typical for image intensifiers. This resulted in skin dose rates much higher than the predicted scaling of 1/FOV typically associated with FPD-based equipment. Measurements at multiple locations on a head phantom indicated that for fluoroscopy at magnification factors of 1.0-1.9, the increase in radiation output is partially offset by the irradiation of less tissue (i.e., smaller FOV), including minimizing irradiation of the eyes and areas potentially overlapped by the lateral plane. At magnification factors of 2.0 and higher, however, the summed dose from the measurement locations still increases dramatically despite the smaller region of irradiation. The fluoroscopic image spatial resolution check demonstrated expected results for magnification modes that do and do not used pixel binning. As to how this relates to a particular clinical use: an acquisition run performed at six frames/sec with a 15 cm FOV (i.e., for evaluation of arteriovenous fistula) results in a skin dose 16.8 times larger than a run at three frames/sec with a 42 cm FOV (i.e., routine diagnostic run). Not including the effect of the increased frame rate, this is three times the dose increase that commonly would be predicted for an FPD at this magnification using 1/FOV scaling.
Conclusion
Radiation dose rates increase much more than predicted when using FPD at high magnification. Optimal use of this equipment requires operator awareness of the dose-magnification relationship for a given FPD technology. As with any system, the performance and dose delivery should not be assumed optimal by solely relying on factory settings; imaging preferences at the operator level may need to be revised.

Long-Term Followup in a Consecutive Series of Patients with Intracranial Aneurysms Treated by Flow Diverter Stents

Biondi, A.·Pomero, E.·Macovei, I.·Jirari, M.·Cattin, F.
Besancon University Hospital
Besancon, FRANCE.

Purpose
To evaluate long-term follow-up clinical and angiographic results in a consecutive series of patients with intracranial aneurysms treated using a flow diverter stent.
Materials & Methods
Sixty-three patients (ranging in age from 16 to 79 years, mean age 52 years) with 76 unruptured or recanalized intracranial aneurysms treated by a flow diverter stent were included in the study. Thirty-four out of 63 patients were symptomatic. Seventy-seven percent of lesions were large or giant. At total, 78 stents were deployed (from 1 to 3 per patient). Six patients with adjacent aneurysms (from 1 to 4) were treated by only one stent. Flow diverter stents were Silk Stent (Balt company) in 10 aneurysms, Pipeline Stent (ev3 company) in 50 and Surpass stent in 16. In four cases, coils also were positioned within the aneurysm sac immediately before the deployment of the stent. After the procedure and at one-year followup, angiographic results were evaluated using the Kamran score (Grade 0 - no change in endosaccular flow; Grade 1 - residual contrast filling, greater than 50%; Grade 2 - residual sac filling, less than 50% of pretreatment aneurysm volume; Grade 3 - residual filling confined to the neck region, and not extending beyond the width of neck; Grade 4 - no residual filling (i.e., complete obliteration of the aneurysm). Technical and clinical complications were recorded systematically. All patients underwent long-term MR follow-up studies.
Results
At 1-3-year followup, improvement or cure of the

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

compressive syndrome was observed in 80% of patients. Complete occlusion was observed in 92 % of patients. At three month followup, asymptomatic parent artery stenosis (>50%) was observed in three patients. Occlusion of small aneurysms seems to need more time in relation to large/giants lesions. Immediate complications included one regressive hemiparesis in a patient with a severe groin hematoma. Transient worsening of mass effect syndrome in eight patients with one case of persistent ophthalmoparesis. At one month, one patient died because of cataclysmic hemorrhage during surgical treatment of a tumor. Due to worsened clinical conditions, the patient underwent surgery only 10 days after the discontinuation of the antiplatelet treatment. One patient had a regressive hemiparesis and speech disturbances at one year after stopping aspirin. Five days after the intervention, one patient bled and died. Correlations with long-term follow-up MR studies are under analysis.
Conclusion
Our results confirm that the use of flow diverter stents is a very promising technique in some configurations of intracranial aneurysms, especially in large or giant lesions. However, more experience and long-term followup is needed in order to define the indications of these new stents.

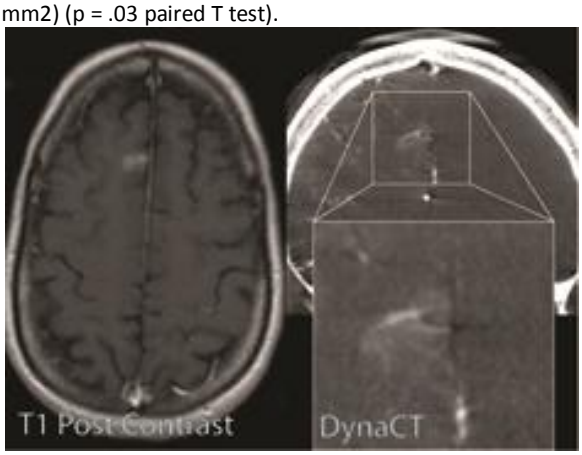
Association of Intralesional and Juxtapositioned Developmental Venous Anomalies in Patients with Capillary Telangiectasia: Observations from a Large, Single Center Series

Trimble, C. R.·Gandhi, D.
University of Maryland School of Medicine
Baltimore, MD.

Purpose
Capillary telangiectasias are “angiographically occult” vascular lesions and often identified incidentally as small areas of blush-like enhancement primarily within the pons on postcontrast brain MR imaging. Though generally considered benign entities, there is controversy regarding their etiology and clinical significance. In our experience, we have noted that many of the capillary telangiectasias may harbor an intralesional developmental venous anomaly (DVA). We hypothesize that there is a significant and perhaps causal association between DVA and capillary telangiectasia.
Materials & Methods
Forty-four patients (16 male and 28 female) with capillary telangiectasia were identified from a phrase search of a diagnostic MRI database during a 24-month period. Following retrospective image analysis, 20 patients were excluded due to lack of identification of the capillary telangiectasia, presence of co-existent demyelinating disease, or intracranial malignancy. The 24 remaining patients had lesions that had imaging appearance consistent with capillary telangiectasias. A detailed review of imaging studies was performed by two radiologists with specific attention to the presence of DVA within or adjacent to the capillary telangiectasia.
Results
Capillary telangiectasias were seen primarily in the pons (15/24 cases), but also in the basal ganglia (2/24), thalamus (1/24), subcortical white matter (3/24), tectum (1/24), and superior cervical spinal cord (1/24). Developmental venous anomalies were visualized within the capillary telangiectasia in 13/24 cases and juxtaposed to the capillary telangiectasia in 2/24 patients. Capillary telangiectasias with high diagnostic confidence of associated DVA demonstrated larger cross-sectional areas (average 54.4 mm2) compared with capillary telangiectasias without associated DVAs (average 12.2 mm2) ($p = .03$ paired T test).



Conclusion
This retrospective case analysis demonstrates that association between DVAs and capillary telangiectasias may be stronger than previously reported. Our data also lend support to the possibility that capillary telangiectasias may represent a manifestation of local venous hypertension from DVAs.

Predicting Recurrent Glioma versus Treatment-Related Necrosis Using Multiparameter Advanced MR Imaging: Accurate and Cost-Effective Clinical Decision-Making

Hamilton, J. D.·Jackson, E. F.·Leeds, N. E.·Ketonen, L.·Schellingerhout, D.·Jones, J.·Tatum, L. S.·Hou, P.·Evans, D. T.·Underwood, M. L.·Jones, J. R.·Reed, B. J.·Hash, S.·Steele, J.·Albright, H. W.·Kumar, A. J.
The University of Texas M. D. Anderson Cancer Center
Houston, TX.

Purpose
To reduce the amount of unnecessary brain surgeries or biopsies of patients with treatment-related brain necrosis and no residual viable high-grade glial tumor by utilizing physiologic MRI sequences, and doing so in an efficient and cost-effective manner.
Materials & Methods
As part of an on-going clinical protocol, patients 1) with history of histologically proven glioma brain tumor, 2) treated with radiation therapy >six months prior and often surgery/chemotherapy, 3) who developed a new enhancing lesion within the radiation field, were prospectively imaged to determine recurrent glioma versus treatment-related brain necrosis. For this study, we concentrated on the patients with 4) biopsy or resection within 60 days of imaging. The protocol, which began in 2009, includes dynamic contrast-enhanced (DCE) and dynamic susceptibility contrast (DSC) perfusion, diffusion tensor and multivoxel spectroscopy in addition to conventional imaging (scan time <75 minutes, postprocessing ~30 minutes). At the beginning of 2011, multiple changes to the protocol occurred based on review of earlier results, this included changes to our techniques (e.g., DSC perfusion), data processing (e.g., for DCE perfusion), and novel cut-off values. We also learned which values were important in which situations (e.g., Avastin makes DCE values less reliable). To evaluate the refinements of the prospectively prescribed imaging protocol, data from January 2009 -September 2010 were gathered for the baseline and compared to June 2011-June 2012 after the refinements. Pathology and radiology reports were graded on a five-point scale from pure tumor (1) to mixture to pure treatment effects (5). Radiologist reports were considered accurate if within a point of pathology. The cost of all care (surgery, chemotherapy, hospitalization, etc.) for patients beginning from the date of MRI scan through 90 days follow-up was tabulated. Inflation estimates derived from U.S. Department of Labor Statistics adjusted the line item costs. Fisher exact test compared group differences by pathology.
Results
In the baseline group, 110 patients were imaged, 33 fulfilled the inclusion criteria including biopsy/surgery within 60 days of imaging and 11 of those were found to have no residual brain tumor with only treatment effects. After the protocol was refined, 103 patients were imaged, 29 had biopsy/surgery and 1 of those were found to have no residual brain tumor but only treatment changes (p = 0.003 between baseline and after refinements). Similarly, the accuracy of radiology reports increased from 72% (24/33 cases accurate) to 97% (28/29). After costs were adjusted for inflation and outliers were censored, the average total cost for the 110 baseline patients imaged was $28,447 and $24,507 for the 103 patients imaged after the refinements, a cost savings of about $3,900 per patient.
Conclusion
Refining a physiologic MRI protocol improved the accuracy of imaging diagnosis to >95% making surgical intervention for treatment effect unnecessary and reducing the overall patient care costs. This required an experienced team (MR technologists, physicists and neuroradiologists) with a small additional scanning and postprocessing time (<1 hour more than conventional imaging). This data provide justification for a prospective multicenter clinical trial.

Evaluation of T2* Dynamic Susceptibiliy-Based Contrast-Enhanced and T1 Dynamic Contrast-Enhanced Perfusion and Permeability Imaging in Glioma Grading

Santarosa, C.·Castellano, A.·Politi, L. S.·Terreni, M. R.·Leoncini, G.·Falini, A.·Anzalone, N.
Ospedale San Raffaele
Milano, ITALY.

Purpose
T2*-weighted dynamic susceptibility-based contrast-enhanced (DSC) MR perfusion technique offer an estimate of relative cerebral blood volume (rCBV), established to predict glioma grading. Nevertheless limitations of DSC technique due to high sensitivity to susceptibility effects are well known. Our purpose was to evaluate, in comparison with DSC, a more recent T1-based perfusion technique, dynamic contrast-enhanced (DCE). Two parameters are derivable from DCE: fractional plasma volume (fVp) and volume transfer coefficient (Ktrans), respectively, an estimate of vessel compartment volume and an estimate of vessel permeability. Dynamic

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

susceptibility-based contrast-enhanced and DCE-derived parameters were correlated with WHO histologic grading.
Materials & Methods
Ten patients affected by glioma (including both astrocytic and olidendroglial histotypes) underwent DSC and DCE perfusion MR imaging with a 3.0T scanner (Achieva, Philips). NordicIce software was used for postprocessing. Parameters were measured through hotspot-based method, from region of interest (ROI) of the maximal abnormality within the lesion, and through histogram-based method, from ROI including the whole lesion volume. Mean-Median-Standard deviation-Skewness-Kurtosis were considered as distribution frequency descriptive indices. Spearman rank correlations evaluated associations beetween rCBV-fVp-Ktrans parameters and histologic WHO grade.
Results
Through "hotspots-based" method, correlation WHO grade-fVp ($p = 0.001$) and WHO grade-Ktrans ($p = 0.001$) from DCE was more significant than correlation WHO grade-rCBV from DSC ($p = 0.067$). Through "histogram-based" method, for each parameter all the frequency distribution descriptive indices resulted to be almost equally correlated with WHO grading.
Conclusion
Our preliminary results seem to indicate that: 1. Vp parameter is more related than rCBV to WHO grading, with both measurement method; 2. Ktrans parameter correlates with WHO grading too. If confirmed by a larger sample, these results could lead to consider DCE preferable to DSC in noninvasive grading of gliomas.

Spatial Variation of Apparent Diffusion Coefficient and Fractional Anisotropy within Nonenhancing Components of Glioblastomas as a Function of Distance from Enhancing Tumor: Predicting Clinical Outcome - A TCGA Glioma Phenotype Research Project

Hwang, S. N.[1]·Holder, C. A.[2]·Gutman, D.[2]·Jain, R.[3]·Wintermark, M.[4]·Colen, R. R.[5]·Saltz, J.[2]·Brat, D. J.[2]·Jaffe, C.[6]·Flanders, A. E.[7]·The TCGA Glioma Phenotype Research Group
[1]St Jude Children's Research Hospital, Memphis, TN, [2]Emory University, Atlanta, GA, [3]Henry Ford Hospital, Detroit, MI, [4]University of Virginia, Charlottesville, VA, [5]M. D. Anderson Cancer Center, Houston, TX, [6]Boston University, Boston, MA, [7]Thomas Jefferson University, Philadelphia, PA.

Purpose
Explore the variation of apparent diffusion coefficient (ADC) and fractional anisotropy (FA) within the nonenhancing component of glioblastomas as a function of distance from enhancing tumor. MR diffusion parameters of glioblastomas have been described previously in the literature; however, the goal of the current work is to more completely characterize the spatial variation of these parameters to improve the classification of glioblastomas and to predict clinical outcome.
Materials & Methods
As part of The Cancer Genome Atlas (TCGA) MRI characterization project of the National Cancer Institute, the multi-institutional TCGA Glioma Phenotype Research Group has been investigating MRI, including diffusion and diffusion tensor imaging, as a means of predicting clinical outcomes for glioblastoma patients. For the current work, a previously described interactive machine learning method for segmenting MRI of glioblastomas into various components, including nonenhancing and enhancing tumor, was applied. A Euclidian distance transform was performed to compute the distance from enhancing tumor. Volumes of interest (VOIs) containing nonenhancing tumor were generated at increasing distances from enhancing tumor: 0 to 2 mm, 2 to 4 mm, 4 to 6 mm, and 6 to 8 mm from enhancing tumor. Fractional anisotropy and ADC were computed for the VOIs. Thirty-five of the tumors have been processed thus far. Clinical outcomes including days of survival were obtained from the publicly available TCGA data. Analysis of variance and Kaplan-Meier survival analysis were performed. For initial analysis, tumors were divided into two groups based on the medians of the parameters (e.g., high ADC versus low ADC).
Results
A suggestion of a minimal increase in ADC was noted with greater distance from enhancing tumor, but was only statistically significant ($p<0.05$) between the volumes of tumor 0 to 2 mm compared to 4 to 6 mm and between 2 to 4 mm compared to 4 to 6 mm. In the subset of tumors currently evaluated, no significant difference in survival was identified between tumors with high FA versus low FA. However, tumors with high ADC in enhancing tumor demonstrated significantly longer survival ($p = 0.004$, 543 days versus 187 days). High ADC in nonenhancing tumor adjacent to enhancing tumor (within 0 to 2 mm) also was associated with longer survival ($p = 0.03$, 654 versus 357 days). In the next layer of nonenhancing tumor (2 to 4 mm from enhancing tumor), there was only a suggestion of improved survival with higher ADC ($p = 0.052$).
Conclusion
Low ADC within enhancing tumor and the immediately adjacent nonenhancing tumor may help predict survival in patients with glioblastoma. The threshold value preliminarily identified is approximately 1.2×10^{-3} mm^2 s^{-1}. These findings suggest a more sophisticated method of characterizing the spatial variations of MR diffusion parameters may be helpful in predicting clinical outcomes.

Perfusion Imaging Genomic Mapping Uncovers Potential Genomic Targets Involved in Angiogenesis and Invasion

Colen, R. R.·Abrol, T.·Zinn, P. O.
M. D. Anderson Cancer Center
Houston, TX.

Purpose
To create an imaging genomic map, linking MR imaging traits with gene- and miRNA expression profiles, in patients with GBM to determine genomic correlates of a MR perfusion radiophenotype to possibly find new genomic targets for GBM treatment. Increases in angiogenesis demonstrate increases on MRI perfusion relative cerebral blood volume (rCBV) maps. Increases in angiogenesis are seen in patients with highly aggressive and hypervascular tumors. Here, we present the first study examining in a quantitative way perfusion imaging genomics in GBM to determine novel and targetable angiogenic biomarkers in GBM.
Materials & Methods
We identified 30 GBM patients from The Cancer Genome Atlas (TCGA) who had both genetic- expression profiles and neuroimaging. All morphologic image analyses were done using slicer 3.6 (slicer.org) and functional analysis using NordicIce, and reviewed in consensus by two neuroradiologists. Quantitative perfusion parameters where obtain using the region of interest (ROI) method. Regions of interest were placed in the previously segmented regions of contrast enhancement, necrosis, and nonenhancing perilesional FLAIR hyperintensity - the latter reflecting a mixture of edema/tumor infiltration. Biostatistics analysis was performed for gene and miRNA sets whereas the median CBV values of each of the segmented regions were taken as the cutoff to define high and low groups. These groups then were analyzed by Comparative Marker Selection (Broad Inst.). Among the whole gene set the most upregulated mRNAs/miRNAs, were analyzed with ingenuity pathway analysis (IPA).
Results
Ingenuity pathway analysis identified molecular networks, as well as canonical and functional pathways highly associated with cancer, angiogenesis, and invasion in those patients with high tumor rCBV.
Conclusion
The perfusion radiophenotype identified genes and miRNAs and corresponding molecular networks that were highly associated with angiogenesis and invasion. By these means we were able to identify possible key genes and miRNAs involved in the latter regulation. The uncovered genes and miRNAs represent new insight into tumors with high perfusion seen on MRI and the underlying molecular mechanisms in GBM for growth and treatment response.

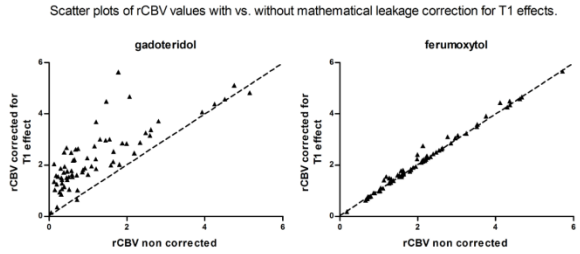
Small- and High-Molecular-Weight Contrast Agents for MR Perfusion Imaging in Cerebral Neoplasms

Varallyay, C. G.[1]·Nesbit, E.[1]·Fu, R.[1]·Gahramanov, S.[1]·Muldoon, L. L.[1]·Li, X.[1]·Rooney, W.[1]·Neuwelt, E. A.[1,2]
[1]Oregon Health Sciences University, Portland, OR,
[2]Department of Veterans Affairs Medical Center, Portland, OR.

Purpose
Using ferumoxytol, a high-molecular-weight iron oxide contrast agent for perfusion MR imaging of brain neoplasms has potential benefits. Being a blood pool agent, theoretically no leakage correction is needed for relative cerebral blood volume (rCBV) calculation. Also, its high transverse relaxivity helps avoiding pronounced T1 effects on the dynamic susceptibility contrast (DSC) imaging. The purpose of this study was to compare rCBV values obtained using gadoteridol versus ferumoxytol in patients with cerebral neoplasms. Relative CBV was calculated in normal-appearing brain areas and in malignant tumors.
Materials & Methods
We analyzed 96 human brain MRI studies acquired in three similar research protocols between 2008 and 2011. Each of them included DSC perfusion measurements on two consecutive days; first with gadoteridol (0,1 mmol/l), and a day later with ferumoxytol (1 or 2 mg/kg). Dynamic susceptibility contrast scans used gradient-echo echo-planar acquisition with a short echo time (20 ms) to reduce susceptibility artifacts and image distortions. Cerebral blood volume maps were calculated in three different ways for each contrast agent; without leakage correction, with mathematical correction for T1 effects only or for combined T1 and T2 effects. Relative CBV values in the normal-appearing thalamus and putamen, as well as in enhancing tumor and tumor hotspots were obtained and compared between contrast agents and leakage correction methods using linear mixed effects model. Results are presented as mean (standard deviation).
Results
Leakage correction for T1 effects substantially increased the mean rCBV values obtained with gadoteridol in enhancing tumors from 1.36 (1.39) to 2.46 (1.41), and in tumor hot spots from 1.99 (1.33) to 3.41 (1.46), $P<0.0001$, but resulted in minimal change in values obtained with ferumoxytol [2.11 (1.22) to 2.18 (1.23) and 3.4 (1.29) to 3.47 (1.29) respectively]. Furthermore, normal-appearing brain assessed with gadoteridol also was affected by leakage correction for T1 effects, most prominently in the putamen, where rCBV increased from 1.28 (0.26) to 1.53 (0.28), $P<0.0001$. Additional correction for T2 effects resulted in a less prominent decrease of T1 corrected rCBV in the tumor and the thalamus, similarly for either contrast agent.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Conclusion
While leakage correction for T1 effects is necessary when assessing rCBV of tumors using gadoteridol, no T1 correction is necessary for ferumoxytol. Correcting for T2 effects is less important in acquisitions with shorter echo times. Mathematical leakage correction can alter rCBV measurement in the normal brain regions and tumors, which is not necessarily attributed to contrast agent leakage.

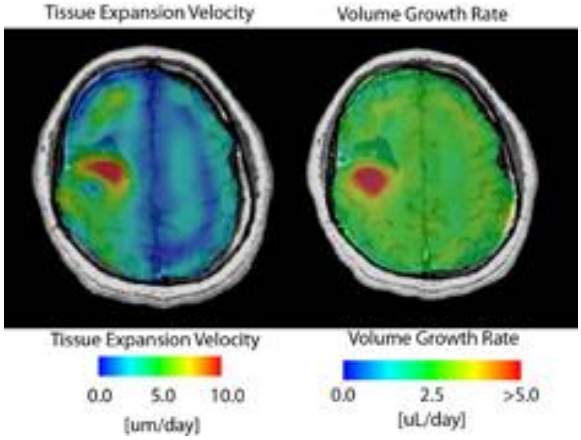
Los Angeles, CA.

Purpose
Brain tumor growth characteristics are estimated traditionally by volumetry; however, a new technique was developed recently for examining subtle changes in the structure of the brain over time in patients with neurodegenerative diseases called “deformation field morphometry” (DFM). Deformation field morphometry mapping involves quantification of the nonlinear (elastic) deformation fields resulting from serial image registration. In the current study we explored DFM mapping as a method for quantifying “tissue expansion velocity” and “volume growth rate” in patients with low grade diffuse gliomas (LGGs) and recurrent glioblastoma (GBM).
Materials & Methods
Deformation field morphometry maps were constructed for both tissue expansion velocity (v) and volume growth rate (ρ) using the deformation field information extracted from nonlinear (elastic) registration of serial 3D MR images (pre or postcontrast T1-weighted or T2-weighted) in the same patient over time. The FMRIB nonlinear registration tool (FNIRT) was used for nonlinear registration. The deformation warp field vector $U(t) = Ux + Uy + Uz$ for each voxel denotes the local displacement direction and magnitude of the tissue at time t during a patient’s clinical course, taken with respect to another scan date (usually the most recent). The “tissue expansion velocity”, v, was calculated as: $v = ||U(t)||/dt \cong ||U(t)||/\Delta t$, where Δt is the time between scans and $||U(t)||$ is the deformation warp field vector magnitude for each image voxel. The “volume growth rate”, ρ, was estimated from the rate of change in the Jacobian determinant, or $\rho = [\det(J(t))-1]/dt \cong [\det(J(t)-1]/\Delta t$, where again Δt is the time between sequential scans.
Results
In patients with suspected tumor progression (GBM) or malignant transformation (LGGs, Figure 1), DFM maps of expansion velocity and growth rate were able to isolate and quantify loci of proliferative tumor. Positron emission tomography scans confirmed spatial specificity in many cases. Regions of elevated expansion velocity appeared slightly outside of FLAIR abnormal regions, suggesting these maps may be useful for localizing infiltrating tumor. Vector fields from DFM data appeared to define the directionality of tumor spread across the brain. Subtle mass effect from slow growing tumor was easily quantified using expansion velocity and growth rate estimates. Changes in tissue expansion velocity and volume growth rates also can be used to quantify localized response to various therapies.



Conclusion
Deformation field morphometry-derived estimates of tumor expansion velocity and volume growth rate are a novel clinical tool for noninvasive quantification of tumor growth dynamics.

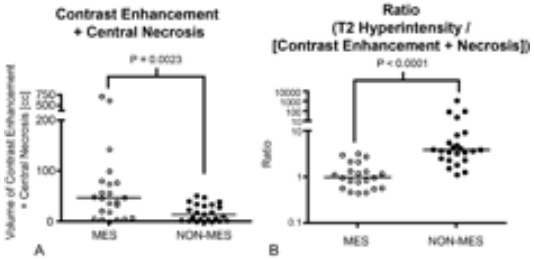
Identifying the Mesenchymal Molecular Subtype of Glioblastoma Using Quantitative Volumetric Analysis of Anatomical MR Images

Naeini, K. M.[1]·Pope, W. B.[1]·Cloughesy, T. F.[1]·Harris, R. J.[1,1]·Lai, A.[1]·Eskin, A.[1]·Chowdhury, R.[1]·Phillips, H. S.[2]·Behbahanian, Y.[1]·Nghiemphu, P. L.[1]·Ellingson, B. M.[1]
[1]David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA, [2]Genentech, Inc., San Francisco, CA.

Purpose
To explore the relationship between radiographic imaging features and glioblastoma (GBM) molecular subtypes, specifically identifying radiologic biomarkers for identifying the mesenchymal (MES) phenotype from non-MES GBMs.
Materials & Methods
A total of 47 patients with histologically confirmed de novo GBM, molecular data, and presurgical, postcontrast T1-weighted and T2-weighted/T2-weighted FLAIR images available were enrolled in this study. The volume of contrast enhancement, central necrosis, and T2 hyperintensity were measured. The ratio of [FLAIR/(enhancement+necrosis)] was calculated. Gene expression subclassification was performed according to standard protocols and subtypes. Subtype names were chosen based on the expression of signature genes: proneural (PN), proliferative (PROLIF) and MES.
Results
A statistically significant difference was observed between the different GBM subtypes when examining the combined volume of contrast enhancement and central necrosis. Specifically, the MES phenotypes, having a median volume of 47cc, had a significantly higher volume of contrast enhancement and necrosis compared with the PN and PROLIF subtypes, which each had a median volume around 2.7cc. The volume ratio of T2/FLAIR hyperintensity to the combined volume of contrast enhancement and central necrosis was statistically different between the different GBM phenotypes. Specifically, the MES phenotype had a statistically lower ratio than both the PN and PROLIF phenotypes. This difference also was confirmed when the PN and PROLIF phenotypes were pooled into a single non-MES group. This ratio was a very strong predictor of the MES phenotype, showing a sensitivity of 83% and a specificity of 87% using a cutoff of 2.3.



Conclusion
The ratio of T2/FLAIR volume to contrast-enhancing and necrotic volume is more effective than any of the other factors in stratifying between MES and non-MES subtypes. This study suggests that the volume ratio can be used as a biomarker for GBM subtype, and by extension, survival.

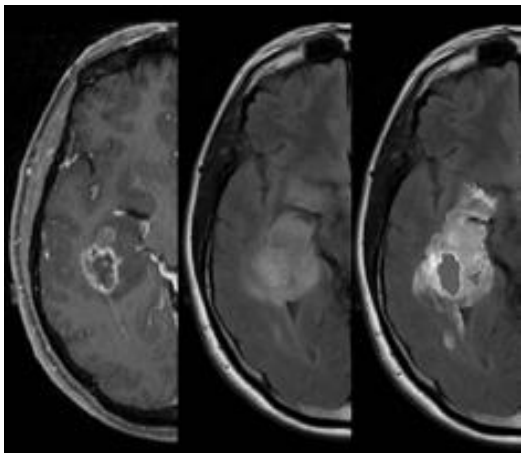
Multiparametric Imaging Model to Accurately Predict Extent of Invasion of High-Grade Gliomas

Durst, C.·Raghavan, P.·Tustison, N.·Patrie, J.·Cupino, A.·Xin, W.·Wintermark, M.
University of Virginia
Charlottesville, VA.

Purpose
Despite advances in the surgical and oncologic approach to high-grade gliomas, the prognosis remains poor. Some hypothesize that a more complete initial surgical resection might improve outcome. The exact extent of high-grade gliomas is difficult to define on MRI. Postcontrast T1-weighted images underestimate and T2-weighted images overestimate the true tumor extent. Prior studies have evaluated the role of diffusion-weighted imaging (DWI), diffusion tensor imaging (DTI), magnetic resonance spectroscopy (MRS) and perfusion-weighted imaging (PWI), in the prediction of extent of local invasion. Although these studies have shown improved accuracy compared to conventional MRI, each has its limitations. This study combines the advantages from multiple conventional and advanced imaging techniques in an effort to provide the neurosurgeon and neuro-oncologist with a multiparametric imaging model that can reliably differentiate tumor margins from surrounding edema.
Materials & Methods
Ten patients with preliminary imaging findings suggestive of a high-grade glioma were enrolled in a prospective study. Each patient underwent a MRI using precontrast T1, T2, FLAIR, gradient echo, DWI, DTI, arterial spin labeling (ASL), and postcontrast T1 and PWI. Each patient then underwent stereotactic biopsies at prespecified points along the biopsy tract. The biopsy sites were coregistered to the imaging sequences so that imaging values could be ascribed to each biopsy site. The imaging values were analyzed against the measured cell density of each biopsy sample as the gold standard. From these data, a statistical multiparametric predictive model was developed using principle component analysis to predict the cell density associated with an infiltrative tumor.
Results
The major components of the model included the mean diffusivity, fractional anisotropy numerator and denominator, contrast transfer coefficient (Ktrans), mean transfer time, and time to peak. A multivariate generalized estimating equation analysis demonstrates an intercept near 0, a slope of approximately 45 degrees, and a

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

coefficient of determination of 0.56. A subject specific model of goodness of fit shows that most patients' data are distributed along the curve. A probability plot of the residuals versus the expected order statistics yields a Filliben correlation of 0.976.



Conclusion

Our proposed multivariate imaging model can predict cell density of the tumor and surrounding tissue, providing the neuroradiologist, neurosurgeon, and neuro-oncologist with valuable information regarding the extent of infiltrative high-grade gliomas. Further validation studies are required to assess whether this would facilitate surgical and radiation planning, improving patients' outcome.

Neurosurgical Resection of Malignant Gliomas Guided by 5-Aminolevulinic Acid Reduces Post-Op Residual Tumor Volume

Holder, C. A.[1]·Hadjipanayis, C. G.[1]·Cordova, J. S.[1]·Hwang, S. N.[2]·Gutman, D. A.[1]·Schreibmann, E.[1]·Danish, H.[1]·Shu, H. G.[1]·Olson, J. J.[1]·Shim, H.[1]
[1]Emory University School of Medicine, Atlanta, GA, [2]St. Jude Children's Research Hospital, Memphis, TN.

Purpose

Malignant gliomas (WHO grade III and IV) are infiltrative primary brain neoplasms with high morbidity and mortality. Surgery remains first line therapy. Completeness of resection and minimization of tumor burden is recognized as a prognostic factor in survival. A significant survival advantage has been seen with as little as 78% resection, and stepwise improvement in survival was evident; however, defining the margins of malignant gliomas at surgery is very difficult due to their infiltrative nature. The purpose of this study was to evaluate the utility of 5-aminolevulinic acid (5-ALA) as an intra-operative fluorescent detection agent by quantitative volumetric measurement of enhancing tumors before and after surgery, in order to determine whether the use of 5-ALA during surgical resection reduces postoperative residual enhancing tumor volume.

Materials & Methods

Malignant glioma cells express biosynthetic pathways that produce protoporphorin IX (PpIX) from 5-ALA. Oral administration of 5-ALA (20 mg/kg) leads to selective accumulation of PpIX in tumor cells. Following excitation with blue light (λ = 400 nm) emitted from a special filter attachment on the operative microscope, the PpIX, which has accumulated selectively in malignant cells, emits a red-violet light of 635 nm. The neurosurgeon then is able to resect the red-violet tumor tissue. Patients with suspected malignant gliomas were enrolled into this IRB-approved study and administered 5-ALA orally four hours prior to surgery. At the time of this abstract, tumor resection has been performed in 18 patients administered 5-ALA or placebo, followed by high-resolution postoperative MRI at 48 hours (including T1-weighted images pre and postgadolinium). Eighteen control patients with matching tumor location and size also were selected. To assess quantitatively the 5-ALA-guided surgery, an FDA 510k-approved software package (Velocity AI) which allows the display, annotation, volume-rendering, registration, and fusion of multimodality medical images was used. The software allows the coregistration of multimodality image datasets; placement of regions-of-interest (ROIs); and calculation, display, and report of relative differences in voxel intensities, radiation dose distributions, or other values within those regions. To estimate the tumor volume before surgery, coarse ROIs were drawn around the tumor and the software was used to semi-automatically segment volumes of hyperintensity (enhancing tumor), as well as hypointensity within the rim of hyperintensity (central necrosis). To estimate the residual tumor postsurgery, subtracted images were produced by subtracting coregistered, postresection, pre and postgadolinium T1-weighted images, correcting for postoperative blood accumulation.

Results

The average tumor resection without 5-ALA-guidance was 81.1%, leaving 18.9% residual tumor (standard error = 4.4). That of 5-ALA-guidance was 91.4%, leaving 8.6% residual tumor (standard error = 1.5). Two-tailed, two sample T-test $p = 0.03269$.

Conclusion

Use of oral 5-ALA for guidance of surgical resection of malignant gliomas reduces the postoperative residual enhancing tumor volume, as determined by semi-automated 3D tumor volume measurements. This improvement is important, since it is believed to be necessary to resect greater than 90% of a malignant glioma in order to make a meaningful difference in patient survival. Thus, the use of 5-ALA for surgical guidance may significantly improve patient outcomes.

Correlation of Morphologic and Physiologic Phenotype of the Nonenhancing Component of Glioblastoma with Patient Survival and Genomic Expression: A TCGA Glioma Phenotype Research Group Project

Jain, R.[1]·Poisson, L.[1]·Khalil, K.[1]·Scarpace, L.[1]·Hwang, S. N.[2]·Gutman, D.[2]·Wintermark, M.[3]·Colen, R. R.[4]·Kirby, J.[5]·Freymann, J.[5]·Rubin, D.[6]·Jaffe, C.[7]·Mikkelsen, T.[1]·Flanders, A.[8]
[1]Henry Ford Health System, Detroit, MI, [2]Emory University, Atlanta, GA, [3]University of Virginia, Charlottesville, VA, [4]Brigham & Womens Hospital, Boston, MA, [5]TCIA/TCGA, St. Louis, MO, [6]Stanford University, Stanford, CA, [7]Boston University, Boston, MA, [8]Thomas Jefferson University Hospital, Philadelphia, PA.

Purpose
Traditionally the focus of treatment planning, response assessment and patient prognosis has been based on evaluation of contrast-enhancing component (contrast-enhancing lesion, CEL) in GBMs. However, non-enhancing component (Non-enhancing lesion, NEL) of GBM also contains important information about tumor and its surrounding environment which is indicative of tumor invasiveness and aggressiveness. The purpose of this study was to correlate morphologic (MRI features) and physiologic phenotype (rCBV) of the NEL in patients with GBM, as well as key genomic markers with patient survival.
Materials & Methods
Forty-five patients had DSC T2* MR perfusion data, and a detailed assessment of the various morphologic features of NEL (percentage NEL, proportion of edema, definition of margins of NEL, T1/FLAIR ratio, deep white matter involvement, NEL crossing the midline) available from The Cancer Imaging Archive (TCIA). Relative cerebral blood volume (rCBVNEL), a physiologic measure of the NEL also was measured. Mutation and copy number variation in the key oncogneic genes EGFR, PDGFRA, PTEN and TP53 were used to stratify patient groups. Correlation of the phenotypic and the genotypic expression of GBM with overall and progression-free survival were done.
Results
We observed that worsening overall survival (log-rank p=0.0145) and progression-free survival (log-rank p=0.0223) are each associated with increasing rCBVNEL. Also associated with increased risk of death or progression in our study were the following morphologic features: Minimal (<5%) edema (OS p=0.0424; PF, p=0.0296) and NEL crossing the midline (OS, p=0.012; PF, p=0.055). The level of rCBVNEL was increased on average in tumors with poorly defined NEL margins compared to those with well defined margins (two-sample t-test p=0.0317). Using a survival regression tree that allowed selection of predictors from the dichotomized rCBVNEL measure and various morphologic features listed in the methods above we found that the overall survival can be well described using the rCBVNEL measure with the high group further divided by the T1/FLAIR ratio (log-rank p=0.0228) with mixed and infiltrative descriptions having worse survival. Interestingly, the T1/FLAIR ratio is not significantly predictive of overall survival when used alone (p=0.288). Remarkably, this split shows a difference in median survival of over one year between the lowest (median 0.50 years, 95%CI: 0.37 - inf) and highest (median: 1.62 years, 95% CI: 1.14 - 2.27) groups. We also noticed that rCBVNEL remains a prognostic indicator within various patient groups which were stratified based on genomic expression, especially within the wild-type EGFR group (log-rank p=0.0085) compared to the altered group (log-rank p=0.6400).
Conclusion
Morphologic features of NEL and genomic alterations of the tumor provide important prognostic information, yet the additional information gained from the hemodynamic parameter of NEL (rCBVNEL) seems to make it a very important prognostic biomarker in patients with GBM. This analysis also raises the question if surgical resection for GBMs should extend beyond the CEL margins for better patient prognosis and also to have a better understanding of tumor biology, which in future may guide therapy decisions based on combined results of morphologic and physiologic phenotypic expression of the tumor as well as tumor genomics.

Simulation of Hemodynamic Parameters in Cerebral Aneurysms and on Virtual Flow Diverter Devices Using a Dedicated Computational Fluid Dynamics Prototype System: First Experiences

Karmonik, C.[1]·Chintalapani, G.[2]·Rangel-Castilla, L.[1]·Redel, T.[2]·Diaz, O.[1]·Klucznik, R.[1]·Zhang, Y. J.[1]·Grossman, R. G.[1]
[1]The Methodist Hospital Neurological Institute, Houston, TX, [2]Siemens AX, Forchheim, GERMANY.

Purpose
To demonstrate the enhanced value in using a dedicated computational fluid dynamics (CFD) prototype system for assessing flow, wall shear stress and pressures in cerebral

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

aneurysms and on virtual flow diverter devices with comparison to phase contrast magnetic resonance imaging (pcMRI).

Materials & Methods

Hemodynamic parameters including streamlines, velocities and wall shear stress were calculated in 18 cerebral aneurysms with a dedicated CFD prototype system (Siemens AX) using 3D digital subtraction angiographic (DSA) data. Simulation results were compared to CFD results obtained with a commercial solver (Fluent, Ansys, Inc) and with phase contrast magnetic resonance (pcMRI) measurements in a subset of six aneurysms. In a subset of nine aneurysms, virtual flow diverters were placed into the calculated velocity field and pressures on these devices were determined. In one case, post-treatment MRI measurements and fluoroscopic images were available for direct comparison to pressures onto the flow diverter/wall calculated with CFD.

Results

The user-optimized interface for preprocessing the 3D DSA allows the creation of computational meshes on average in less than 15 minutes. Simulation time for two cardiac cycles was in the order of several hours, steady state simulation needed less than 30 minutes. Results from the CFD prototype compared favorably with results from the commercial solver and with the pcMRI measurements (Figure 1). Calculation of forces on the virtual flow diverter revealed focal maxima of pressures. Comparison with post-treatment treatment images in one case showed correlation of focal pressure zone with remnant inflow jet into the aneurysm.

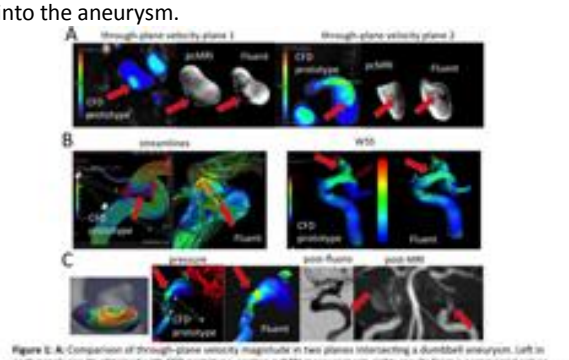

Figure 1: A: Comparison of through-plane velocity magnitude in two planes intersecting a dumbbell aneurysm. Left in each panel: results obtained with CFD prototype, center: pcMRI measurement, right: results from a commercial solver. Common features are marked by red arrows. B: Streamlines and wall shear stress (WSS). Left in each panel: results from CFD prototype, right: results from a commercial solver. C: On left, calculated forces on virtual flow diverter placed into a cerebral aneurysm (red: focal region of high pressure) are illustrated. Center: Pressure on aneurysm wall (coinciding with location of flow diverter). Red arrows indicate focal region of high pressure. Right: Post-treatment fluoroscopic image and post-MRI. Arrows indicate remnant inflow jet into aneurysm originating at approximately same position as location of focal pressure region visualized with CFD.

Conclusion

The use of a dedicated system facilitates CFD simulations and analysis of results. Enhanced value is demonstrated for the evaluation of pressures on virtual flow diverters.

Predicting Outcomes Based on Imaging in Aneurysmal Subarachnoid Hemorrhage

Robinson, C. L.·Hurtado Rua, S.·Gupta, A.·Sanelli, P. C.
Weill Cornell Medical College
New York, NY.

Purpose

Delayed cerebral ischemia (DCI) is a serious complication of aneurysmal subarachnoid hemorrhage (SAH) leading to disability and death. Currently, several imaging modalities are used in clinical practice to detect DCI. At times, there is not good agreement amongst imaging exams for determining DCI, leading to variability in diagnosis and management decisions. Our aim was to evaluate the predictive abilities for clinical outcomes using CT perfusion (CTP) and transcranial doppler sonography (TCD) in symptomatic and asymptomatic patients.

Materials & Methods

A retrospective study of consecutive SAH patients enrolled in an IRB-approved clinical trial was performed. Inclusion criteria were patients with SAH who had CTP and TCD performed. Symptomatic patients were determined by clinical assessment for focal neurologic deficits (such as aphasia, hemiparesis, hemiplegia, etc). The CTP studies were evaluated by two neuroradiologists blinded to all other data to determine perfusion deficits, defined as focal areas of reduced cerebral blood flow and/or elevated mean transit time. Transcranial doppler sonography findings supporting vasospasm were determined by the clinical reports. Clinical outcomes were obtained from medical record review for patients who recovered without neurologic deficits (mRs = 0-2), disability (mRs = 3-5) and death (mRs = 6). A multinomial logistic regression model was developed and fitted to determine the prediction probabilities with 95% confidence intervals (CI) for each outcome based on the imaging findings for both symptomatic and asymptomatic patients.

Results

A total of 97 patients were included in the statistical analysis; 73% (71/97) were female and 27% (26/97) were male. The mean age is 50.5 years (range 28-80 years). The predictive probabilities (95% CI) of the CTP and TCD data in symptomatic and asymptomatic patients are displayed in Table 1. Symptomatic patients with CTP deficits demonstrate statistically significant lower recovery and higher disability and death compared to patients without CTP deficits. Additionally, asymptomatic patients with CTP deficits also demonstrate statistically significant lower recovery and higher disability and death compared to patients without CTP deficits. However, symptomatic patients with TCD deficits do not have significantly different outcomes compared to patients without TCD deficits. Similar findings also are seen in asymptomatic patients.

Table 1: Prediction probabilities and 95% CI

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

	CTP		TCD	
	Deficit	NO deficit	Deficit	NO deficit
Symptomatic:				
Recovery	51% (47-55%)	79% (75-82%)	59% (55-63%)	53% (49-57%)
Disability	39% (35-43%)	16% (14-19%)	32% (28-35%)	38% (34-42%)
Death	10% (8-13%)	5% (3-7%)	9% (7-11%)	9% (7-11%)
Asymptomatic:				
Recovery	77% (74-81%)	92% (90-94%)	90% (88-93%)	87% (85-90%)
Disability	19% (16-22%)	6% (4-8%)	8% (6-10%)	11% (8-13%)
Death	4% (2-5%)	1% (0.5-2%)	2% (1-3%)	2% (1-3%)

Conclusion

CT perfusion provides predictive information for outcomes in both symptomatic and asymptomatic patients. However, TCD as a predictor for clinical outcomes of recovery, disability, and death does not offer much information in symptomatic or asymptomatic patients. Thus, CTP may be helpful for guiding patient management and treatment decisions in the clinical setting.

Cerebral Aneurysm Wall Permeability: A New Marker for Detecting Rupture Risk

Vakil, P.[1]·Ansari, S. A.[1]·Schnell, S.[1]·Wasliewski, M.[1]·Batjer, H.[2]·Bendok, B. R.[1]·Eddleman, C. S.[3]·Markl, M.[1]·Carroll, T. J.[1]
[1]Northwestern University, Chicago, IL, [2]Northwestern University, Dallas, TX, [3]University of Texas Southwestern, Dallas, TX.

Purpose

Cerebral aneurysms pose a significant risk to the public with incidence estimates of up to 6%. Aneurysms larger than 10 mm generally are considered dangerous; however, many aneurysms smaller than 10 mm are known to rupture, highlighting the need for more quantifiable, and noninvasive metrics that may distinguish progressing aneurysms from stable ones. We studied aneurysm wall permeability to intravascular contrast agent using dynamic contrast-enhanced (DCE) MRI as a new metric for assessing rupture risk.

Materials & Methods

With IRB approval, we used a standard DCE MRI protocol to measure contrast agent leakage through the aneurysm wall in 12 patients with angiographically confirmed saccular cerebral aneurysms . Using Tofts's contrast leakage model we quantified the contrast agent leakage rate (k_{trans}) and the leakage space volume (v_l), and compared these parameters against aneurysm size and aspect ratio, well established morphologic markers of rupture risk. We incorporated a vascular term given by the arterial input function (AIF) into Toft's model such that $C(t) = vAIF(t) + (1-v)c_{Tofts}(t)$ where v is the proportion of voxel volume containing vascular signal ($v \leq 1$) and c_{Tofts} is Tofts's classic model given by $C_{Tofts}(t) = Dk_{trans}*sum\{a_i[exp(-m_3t)-exp(-m_it)]/[m_i-m_3],i=1,2\}$ with dose D, $m_3= k_{trans}/v_l$, $m_1= 0.144\ min^{-1}$ and $m_2= 0.0111\ min^{-1}$. Regions of interest were drawn in the CSF adjacent to the aneurysm wall to calculate mean k_{trans} and v_l for each patient. Aneurysm morphology was assessed using CT angiography.

Results

Twelve patients (8W,4M; mean age = 67.5 years ± 10.2; range, 56-76 years) were recruited. The mean contrast leakage rate, k_{trans}, through the aneurysm wall was significantly larger compared to healthy parent vessels ($0.20 \pm 0.17\ min^{-1}$ vs $0.04 \pm 0.03\ min^{1}$, p = 0.0030 student *t*-test). Similarly the leakage volume, v_l, adjacent to the aneurysm was significantly larger compared to the healthy parent (46 ± 28% vs. 12 ± 11%, p<0.001). Figure 1 shows k_{trans} parametric map superimposed on the same slice of a T1-weighted contrast-enhanced anatomical image of a 56-year-old woman with a 1.4 cm aneurysm on the left internal carotid artery. Furthermore, we found that both k_{trans} (R = 0.597,p = 0.040) and v_l (R = 0.712,p = 0.0093) correlated strongly with aneurysm size, indicating that wall permeability modeling may be a useful metric for clinicians in assessing aneurysm rupture risk.

Conclusion

Our preliminary studies in patients with unruptured cerebral aneurysms indicate that DCE MRI kinetic modeling of aneurysm leakage provides quantitative metrics which correlate with classical rupture risk criteria.

Comparison of Two Patient Groups from the Same Geographic Population: Incidental Brain Aneurysms and Patients with Subarachnoid Hemorrhage. What Annual Rate of Hemorrhage Does the Population Prevalence and Observed Number of Ruptures Support?

Miller, T. S.
Montefiore Medical Center
Bronx, NY.

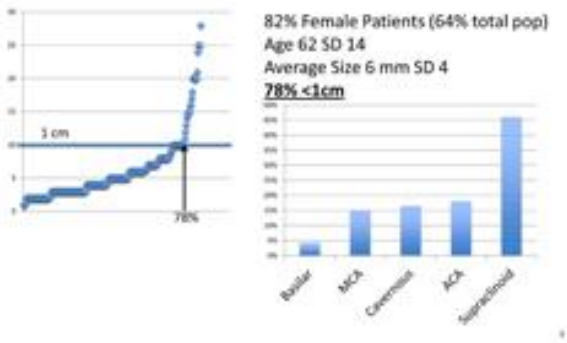
Purpose
To compare the incidence and size of ruptured and incidental unruptured aneurysms in a single urban population at a single center. Some unruptured cerebral aneurysms are more likely to rupture than others and should be treated when discovered. Appropriate management of patients with small (< 1 cm) unruptured cerebral aneurysms is debatable. Prospective studies indicate a rupture rate near zero for a given small aneurysm, while retrospective series demonstrate that most observed ruptured aneurysms are small. Does the population prevalence of small aneurysms support the expected rupture rate of <1% per year?
Materials & Methods
Charts, reports from CT scans, MRI/MRA exams, and angiograms for patients with both a diagnosis of subarachnoid hemorrhage and incidentally detected cerebral aneurysms at a single center between January 2006 and December 2011 were reviewed. Demographics, aneurysm size and location were recorded.
Results
For subarachnoid hemorrhage 370 consecutive patients were included. For incidental aneurysms 20,000 reports were reviewed. Sixty-four percent were female, mean combined age was 51 years (Range 10-91, SD 14). The ruptured cohort included 279 patients with (75%) ruptured cerebral aneurysms. The unruptured cohort included 13,000 unique patients with 800 aneurysms. The mean age of patients with aneurysms was 52 (SD 14.5, Range 17-91). The average size of the aneurysms was 6.08 mm (SD 3.2), 92% were < 10 mm.

270 Ruptured Aneurysms patients w/ Bronx Zip: **92%<10mm**

Average Size	5.68 mm
Median	5.78 mm

Location	Number	Size mm	%
Acomm	77	5.34	29%
Pcomm	56	6.22	21%
ICA	45	7.37	17%
MCA	45	6.38	17%
ACA	5	5	2%
Ant Choridal	12	5.08	4%
Basilar	10	7.33	4%
PICA	10	4.75	4%
Pericalossal	9	6.33	3%
PCA	1	3	0.4%
Total	270		

Results: 800 Aneurysms



Conclusion
In a single population, 85% of incidental aneurysms were < 8 mm in size. Seventy-eight percent of aneurysmal SAH were due to aneurysms <=7 mm, and 90% < 10 mm. The population consists of 1 million adults. A prevalence rate of 6% (double expected) was identified. The population prevalence supports the observed rate of subarachnoid hemorrhage in the same population.

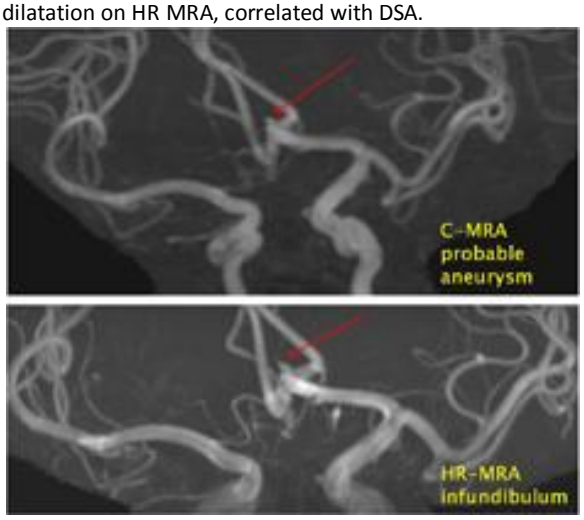
Comparison of the Evaluation of Cerebral Aneurysm of High-Resolution Time-of-Flight MR Angiography at 3.0T and Conventional MR Angiography. Correlation with Standard Digital Subtraction Angiography: A Study of 50 Aneurysms

Lee, A.·Sohn, C.·Yoon, T.·Han, M.·Jung, S.·Yoo, I.·Kim, S.
Seoul National University Hospital
Seoul, KOREA, REPUBLIC OF.

Purpose
1. To evaluate accuracy of 3T HR MRA in detecting aneurysm compared with conventional MRA (C MRA) 2. To prove potential diagnostic advantage of HR MRA using correlation with DSA.
Materials & Methods
Thirty-seven patients with 50 possible aneurysms on C MRA were underwent 3T HR MRA and DSA. The protocols of HR MRA were following: TR 29.0, TE 4.6, matrix 512x512, FOV 20cm, and thickness 0.5mm with 8-channel head coil. Two blinded neuroradiologists reviewed C MRA and HR MRA in the detection of aneurysms, independently. For each possible aneurysm, readers recorded the location and their level of confidence with a 5 point scale [pseudolesion (A), definite infundibulum (B), suspicious infundibulum (C), suspicious aneurysm (D), and definite aneurysm (E)]. VR DSA were obtained and used as the standard of reference. The accuracy was calculated in addition to the sensitivity and specificity of HR MRA compared to C MRA. In particular, cases with advantage of

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

detection on HR MRA were evaluated in detail.
Results
Among 50 possible aneurysms in 37 patients on C MRA, DSA revealed 38 aneurysms in 26 patients and no aneurysm or ID in 12 cases in 11 patients. Multiple aneurysms were 24 cases in 11 patients. On HR MRA, two reviewers exactly detected each 42, 40 cases, superior to C MRA (39, 38 cases). On the lesion-based evaluation, accuracy, sensitivity, and specificity of were 90.5%, 92.5, and 85.3% on HR MRA and 72.1%, 85.5%, and 50.3% on C MRA, respectively. Each three and five suspicious aneurysm on C MRA were recategorized as definite aneurysm on HR MRA. Each eight and 10 suspicious aneurysmal lesion on C MRA, revealed as infundibular dilatation on HR MRA, correlated with DSA.



Conclusion
High-resolution MRA had a high accuracy, sensitivity and specificity for the detection of intracranial aneurysms, comparing C MRA. In equivocal aneurysm on C MRA, HR MRA can be a useful tool and replace DSA.

Evaluation and Optimization of Cerebral CT Angiography Using Model-Based Iterative Reconstruction for Evaluation of Treated Aneurysms: A Phantom Study

Perez, F. A.·Ramos, M.·McCallum, S.·Mengesha, B.·Mossa-Basha, M.·Fink, K. R.·Anzai, Y.·Andre, J.
University of Washington
Seattle, WA.

Purpose
Radiation dose is of particular concern in patients where frequent surveillance CT examinations are performed, including those with treated cerebral aneurysms who undergo routine follow-up CT angiograms. Advancements in CT technology, such as new reconstruction algorithms, are designed to reduce radiation dose while maintaining diagnostic accuracy. Moreover, innovative CT reconstruction algorithms may be helpful to reduce artifacts such as metal from aneurysm clips and coils thereby improving diagnostic accuracy while potentially reducing radiation dose. A phantom CTA study was performed to evaluate the performance of and optimize scanning parameters for a new clinically available model-based iterative reconstruction algorithm, Veo (trademarked; GE Healthcare, Milwaukee, WI), using simulated aneurysms treated with medical grade metallic coils or clips.
Materials & Methods
An in-house phantom was constructed consisting of a human cadaver skull containing agar and catheter tubing filled with 3.5 mg iodine/ml Omni350 contrast and arranged in a configuration to simulate aneurysms treated with coils or clips. Multiple CT scans of the phantom were acquired on a GE Discovery CT750HD scanner with varying mA, kV, pitch, and rotation speed. Each scan subsequently was reconstructed using both traditional filtered back projection and model-based iterative reconstruction (Veo). Three board-certified, fellowship-trained, neuroradiology faculty scored image quality, blinded to CTA technique, using Likert-type items based on coil/clip artifact, aneurysm visualization, confidence in measuring residual aneurysm, quality of artery lumen visualization, and overall diagnostic quality. Differences were evaluated with multifactorial ANOVA using R Statistical Programming Language.
Results
Model-based iterative reconstruction was associated with increased aneurysm clip/coil artifact, decreased confidence in measuring residual aneurysm, and decreased visualization of the artery lumen compared to filtered back projection reconstruction ($p < 0.05$) of CTA data acquired at the same radiation doses.
Conclusion
Reducing radiation exposure in patients undergoing repeat head CTA for routine surveillance of treated aneurysms is an important goal. The use of model-based iterative reconstruction algorithms for the evaluation of treated aneurysms requires additional optimization to achieve diagnostic quality similar to standard filtered back projection reconstruction at a fixed radiation dose.

Reangiography after Perimesencephalic Subarachnoid Hemorrhage

Ringelstein, A.·Mueller, O.·Moenninghoff, C.·Timchenko, O.·Sure, U.·Forsting, M.·Schlamann, M.
University Hospital Essen
Essen, GERMANY.

Purpose
This study aimed to determine the yield of DSA for the

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

detection of causative vascular lesions in patients with perimesencephalic SAH and negative initial noninvasive and invasive neurovascular examinations (CTA, DSA and MRA).
Materials & Methods
We examined the yield of repetitive DSA for the detection of causative vascular lesions in 750 patients presenting to our institution with SAH and 30 of them with a perimesencephalic pattern of the subarachnoidal blood and negative initial noninvasive and invasive neurovascular examinations during a 10-year period.
Results
Repetitive DSA demonstrated a causative vascular lesion in one patient (3.3 %). In all other patients no causative vascular lesion was found.
Conclusion
Repetitive DSA shows a bleeding source after initially negative imaging diagnostics in some rare cases. Such finding has a therapeutic and prognostic impact. Usually, aneurysms in the posterior circulation are diagnosed and bear a higher rebleeding risk. Therefore, we believe that a repetitive DSA should be recommended in patients with perimesencephalic SAH, even under consideration of the risk of a second invasive diagnostic angiography itself.

Prediction of Outcome of Brain Arteriovenous Malformations following Stereotactic Radiosurgery Based on the Angiographic Characteristics at Presentation

Tang, Y.·Fleetwood, I.·Shankar, J.
QEII Health Science Centre
Halifax, NS, CANADA.

Purpose
Stereotactic radiosurgery is the mainstay of treatment for brain arteriovenous malformations (BAVMs). Still, the outcome of radiosurgery is not consistent and some BAVMs do not respond. The purpose of our study was to determine if we can predict the outcome of stereotactic radiosurgery in BAVMs based on their angiographic characteristics at presentation.
Materials & Methods
A retrospective review of all patients who underwent stereotactic radiosurgery for BAVMs at our institution between 1999 and 2009 was carried out. Patients with catheter angiograms prior to radiosurgery and at least three years following radiosurgery were included. Various angiographic characteristics of the BAVMs were studied. Patients' outcomes were classified as achieving complete obliteration, incomplete response, or no change of their BAVMs on the 3-year follow-up angiogram. The association between the angiographic characteristics of the BAVMs at presentation and their outcome following radiosurgery was analyzed using binomial logistic regression.
Results
A total of 75 BAVMs were treated with radiosurgery during this time period. Only 46 of these fulfilled our inclusion criteria. These BAVMs were followed for a median of 38 months (mean 49 months). Twenty-eight (61%) of the BAVMs that were analyzed achieved complete angiographic obliteration at three years following radiosurgery, 16 (35%) had partial response, and two (4%) were unchanged. The location of the BAVM ($p = 0.006$), size of the feeding artery ($p = 0.047$), presence of a deep draining vein ($p = 0.029$), and pseudophlebitic pattern ($p = 0.019$) showed significant correlation with incomplete response. Pial vein less than 3 cm ($p = 0.059$) and venous ectasia ($p = 0.082$) showed a trend towards correlation with incomplete response, but failed to reach statistical significance.
Conclusion
The initial angiographic characteristics of BAVMs may predict the outcome following stereotactic radiotherapy. Deeper draining vein, certain locations, and venous congestion may predict incomplete response to radiotherapy.

Absolute Hemodynamic Quantification in Cerebral Arteriovenous Malformations Using 4D Flow MR Imaging: A Preliminary Study

Honarmand, A. R.[1]·Wu, C.[2]·Entezari, P.[1]·Vakil, P.[2]·Patel, B.[1]·Bendok, B.[1]·Batjer, H.[3]·Carroll, T.[2]·Markl, M.[2]·Ansari, S. A.[1]
[1]Northwestern University Feinberg School of Medicine, Chicago, IL, [2]Northwestern University, Chicago, IL, [3]University of Texas Southwestern, Dallas, TX.

Purpose
Hemodynamic characterization of arteriovenous malformations (AVMs) may have implications for risk stratification. Gross visualization and quantification of intracranial AVM flow dynamics have been investigated using various methods including computational flow dynamics and 4D flow MRI. In this study, we aimed to selectively quantify arterial feeder hemodynamics in a cohort of cerebral AVMs of different Spetzler-Martin grades (SMG) using 4D flow MRI.
Materials & Methods
Following IRB approval, eight patients with documented intracranial AVMs were selected for baseline 4D flow MRI at 1.5T or 3T MR systems (Siemens, Germany) for a prospective study. Flow quantification was performed using ECG gated three-directional velocity encoding with full 3D coverage of the AVM nidus, feeding and draining vessels, and contralateral equivalent normal arteries. 4D flow MRI was acquired in an axial oblique 3D volume using flip angle of 15°, VENC: 100 cm/s, spatial resolution = $(1.2\text{-}1.6)^3 mm^3$, and temporal resolution: 44 ms. Data analysis

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

included 3D visualization of the velocity data and flow quantification using time integrated 3D pathlines positioned orthogonal to the vessel by a commercially available software (Ensight, CEI, Inc. Apex, NC). Peak velocity (m/s), net flow (ml/cycle), forward flow (ml/cycle), retrograde flow (ml/cycle), and regurgitation (%) were quantified retrospectively and compared at two levels: arterial AVM feeders and normal contralateral equivalent arteries.

Results

Eight patients (5M/3F with mean age 23.9 ± 18) with AVMs ranging from SMG 1 (1 patient), SMG 2 (5 patients), SMG 3 (1 patient), SMG 4 (1 patient) were selected for analysis. Peak velocity and net flow of AVM arterial feeders were quantified as the following: 0.35 m/s, 0.7 ml/cycle; 0.62 ± 0.16 m/s, 3.9 ± 2.4 ml/cycle (mean ± SD); 1.25 m/s, 4.05 ml/cycle; 1.84 m/s, 6.11 ml/cycle; in AVM SMGs 1, 2, 3, and 4 respectively. Normal contralateral equivalent artery peak velocity and net flow were measured as the following: 0.23 m/s, 0.31 ml/cycle; 0.52 ± 0.26 m/s, 3.54 ± 2.48 ml/cycle (mean ± SD); 0.57 m/s, 3.22 ml/cycle; 0.72 m/s, 4.42 ml/cycle in AVM SMGs 1, 2, 3, and 4 respectively. No retrograde flow or regurgitation was noted in either arterial feeders or normal contralateral equivalent arteries.

Conclusion

Quantified hemodynamic parameters of peak velocity and net flow were higher in all AVM feeders compared with normal contralateral equivalent controls. Additionally, increasing peak velocity and net flow correlated with higher SMG grading that may be secondary to larger and high flow lesions. Our preliminary results demonstrate the feasibility and sensitivity of 4D flow MRI in quantitative monitoring of hemodynamic parameters of cerebral AVMs. These findings may have implications in novel characterization schemes for risk stratification based on quantitative flow analysis.

Diagnosis and Followup of Intracranial Dural Arteriovenous Fistulae Using Contrast-Enhanced Time-Resolved MR Angiography

Boddu, S.·Saindane, A. M.·Dehkharghani, S.·Tong, F.·Dion, J.
Emory University School of Medicine
Atlanta, GA.

Purpose

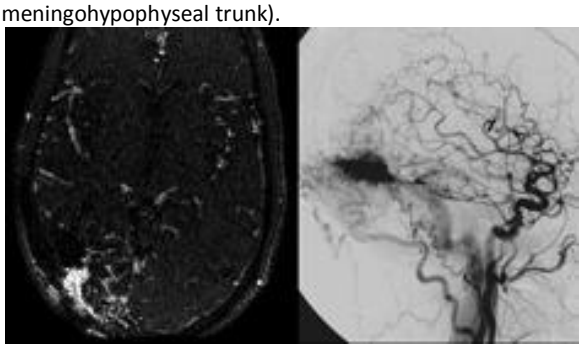
Digital subtraction angiography (DSA) remains the gold standard for diagnosis and followup of intracranial dural arteriovenous fistulae(dAVF). Recent improvements in MRA have shown utility for evaluation of intracranial dAVF. We hypothesize that multiphasic contrast-enhanced time-resolved MRA (CE-TR-MRA) with high spatial and temporal resolution will provide a reliable and effective noninvasive method for diagnosis and followup of dAVF.

Materials & Methods

Twenty-five consecutive patients [18 male, median age 64 years (38-84 years)]with known or suspected intracranial dAVFs over a 24-month period were reviewed. Each patient underwent both MRA and DSA with a median lag of 0 days(0-144 days). MR angiography was performed on a 1.5T GE unit using both 3D-TOF-MRA and CE-TR-MRA using time-resolved imaging of contrast kinetics(TRICKS) with intravenous administration of a standard dose gadolinium-based contrast agent. Ten dynamic phases with submillimeter in-plane resolution and four-second temporal resolution were obtained. MR angiography and DSA studies were reviewed for presence or absence of dAVF, laterality, site, arterial feeders, venous drainage, and venous sinus occlusion. Confidence in the MRA findings also was evaluated. Concordance between the techniques evaluated with DSA as the reference standard.

Results

The 25 patients harbored 29 dAVFs(one patient had three fistulae and two patients had two fistulae each). Sixteen of 25 patients were for initial diagnosis or followup of untreated dAVFs. On both CE-TR-MRA and DSA: 2/16 had no dAVF, 1/16 had spontaneous closure of a previously known Borden type 1 dAVF, 12/16 had Borden Type 1 dAVF and 1/16 with Borden type 3. All patients with untreated dAVF had conclusive reports on CE-TR-MRA except 1/16 with artifact from prior craniotomy, where DSA was recommended to confirm absence of dAVF. Nine of 25 patients had followup after treatment(Borden type 1 (n=2), Borden type 2 (n=4) and Borden type 3(n=3). Eight of 10 dAVFs remained occluded and one had recurrence of treated Borden type 3 fistula demonstrated on both CE-TR-MRA and DSA. Contrast-enhanced TR-MRA for all post-treatment follow-up patients was deemed conclusive. Contrast-enhanced TR-MRA was concordant with DSA for Borden type in the evaluation of both untreated dAVF and followup of treated dAVF in all cases. Both 3D-TOF-MRA and CE-TR-MRA were limited in detection of smaller arterial feeders, specifically of ICA(e.g., meningohypophyseal trunk).



Conclusion

Contrast-enhanced TR-MRA is a reliable noninvasive technique for the diagnosis and followup of intracranial dAVF with excellent correlation with DSA. We recommend

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

CE-TR-MRA as a first line investigation for diagnosis and to guide followup.

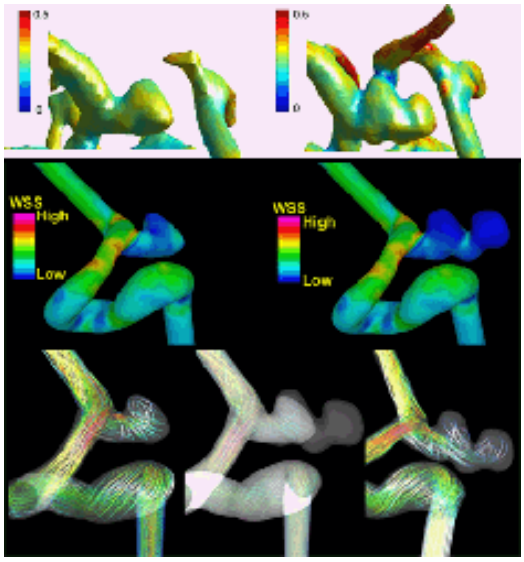
Longitudinally-Followed, Unruptured Aneurysms Exhibit Morphologic and Hemodynamic Changes in Progression towards Rupture

Chien, A.·Vinuela, F.
David Geffen School of Medicine at the University of California Los Angeles
Los Angeles, CA.

Purpose
Due to limited information about aneurysm natural history and the mechanisms underlying aneurysm rupture, choosing the appropriate management strategy for an unruptured aneurysm is challenging. Research based on aneurysm morphology and hemodynamics has found that certain aneurysm shapes and flow properties may relate to aneurysm rupture. With this study, we address whether morphology and blood flow change as an aneurysm progresses towards rupture. Hypothesis: The morphologic and hemodynamic properties of an unruptured aneurysm change in the progression towards rupture.
Materials & Methods
We conducted a retrospective study using unruptured aneurysms diagnosed in our center but not treated. Aneurysms with 3D images recorded at least one year prior to rupture and at the date of rupture were selected. Three aneurysms with initial size 11.6, 7.7, and 6.7 mm located at the posterior communicating arteries were analyzed. For each aneurysm, patient-specific hemodynamic analysis was performed to simulate the flow pattern, and 3D morphologic analysis was used to examine evidence of geometrical changes between unruptured and ruptured states.
Results
All of the aneurysms increased in size (averaging 1.9 mm) and surface area (averaging 32.6%). The figure shows a representative result of a 6.7 mm aneurysm in the unruptured state (left) and rupture two years later at 11 mm (right). Distinct changes in curvature (top), wall shear stress (middle) and flow pattern (bottom) were observed. The center bottom figure presents the original flow superimposed on the ruptured aneurysm shape, showing a prominent change in morphology at the impingement area.



Conclusion
Changes in shape and flow properties were found between unruptured and ruptured states. Through morphologic analysis, we found such changes were not limited to blebs and included the aneurysm body, suggesting certain changes in shape and flow might progressively increase aneurysms rupture risk.

Diffusion Tensor Imaging Predicts Functional Impairment in Mild to Moderate Cervical Spondylotic Myelopathy

Ellingson, B. M.[1]·Holly, L. T.[1]·Grinstead, J.[2]·Salamon, N.[1]
[1]David Geffen School of Medicine at the University of California Los Angeles, Los Angeles, CA, [2]Siemens Healthcare, Portland, OR.

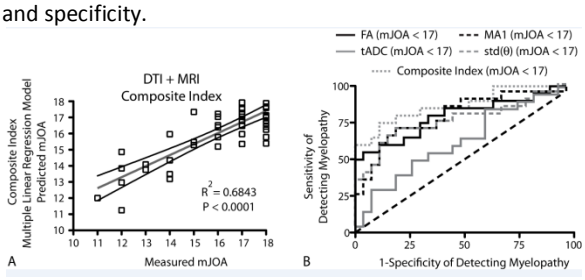
Purpose
The purpose of the current study was to implement DTI as a biomarker for microstructural integrity and functional impairment in patients with cervical spondylosis with or without myelopathy.
Materials & Methods
All patients in this study signed institutional review board-

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

approved informed consent. Forty-eight patients with cervical spondylosis with or without myelomalacia underwent 3T MRI of the cervical spinal cord. A zoomed-EPI technique and custom 2D spatially selective RF excitation pulse were used for DTI measurements of the spinal cord. Fractional anisotropy (FA), mean diffusivity (MD), transverse and longitudinal apparent diffusion coefficient (tADC and lADC), measured longitudinal anisotropy (MA1 = lADC-MD), and the standard deviation of primary eigenvector orientation were evaluated at the site of compression.

Results

Average FA, tADC, MA1, and the standard deviation of primary eigenvector orientation at the spinal level of highest compression were correlated linearly with modified Japanese Orthopedic Association (mJOA) score ($P<0.01$). A combined index consisting of anterior-posterior spinal cord diameter, FA, tADC, MA1, standard deviation of primary eigenvector orientation, and the presence of T2 hyperintensity within the spinal cord accurately predicted functional impairment in mild-to-moderate CSM ($R2=0.6843$, $P<0.0001$). Receiver-operator characteristic (ROC) analysis suggested FA, MA1, and the composite index could identify stenosis patients with mild to moderate symptoms with a relatively high sensitivity and specificity.



Conclusion

Results support the use of DTI as an imaging biomarker for predicting functional impairment in patients with cervical spondylosis. Additionally, a composite index consisting of standard MRI features combined with DTI anisotropy, diffusivity, and directional information can be used to more accurately predict neurologic impairment in patients with mild to moderate CSM and may potentially provide a means for selection of favorable surgical candidates.

Optimized T1-MPRAGE Sequence for Better Visualization of Spinal Cord Multiple Sclerosis Lesions at 3T

Nair, G.[1]·Absinta, M.[1,2]·Reich, D. S.[1,3]
[1]National Institutes of Health, Bethesda, MD, [2]San Raffaele Scientific Institute, Vita-Salute San Raffaele University, Milan, ITALY, [3]Johns Hopkins University, Baltimore, MD.

Purpose

Cord lesions are highly prevalent in multiple sclerosis (MS), and their visualization can help both in diagnosis and patient followup. However, the sensitivity of MRI to spinal cord lesions remains poor, primarily due to suboptimal contrast between lesions and normal-appearing cord. Here, we propose an optimized 3D magnetization prepared rapid gradient-echo (MPRAGE) sequence for improved detection of MS lesions in the cord at 3T.

Materials & Methods

Images were acquired using fast spin echo (T2 FSE), short-tau inversion recovery (STIR), T1-GRE (for T1 mapping), and MPRAGE (T1-MPRAGE) in the sagittal plane, and T2*-weighted scans in the axial plane, on 39 MS patients (Age: 50 ± 12 years; disease duration 14 ± 11 years, EDSS range 1-7) and seven healthy volunteers (Age: 44 ± 7 yeara). Two observers qualitatively evaluated the images for lesion conspicuity. Lesions seen between the C1 and C4 segments in 10 randomly selected MS patients were further evaluated quantitatively for contrast-to-noise ratio between lesion and normal--appearing cord, and for lesion burden.

Results

Spinal cord lesions were more conspicuous on the optimized T1-MPRAGE sequence than any other sequence tested (Figures). In a more detailed analysis of 10 cases, the lesions were almost three times more conspicuous ($p<<0.001$), and the total lesion volume was two times greater ($p<0.05$, $n=10$), in the T1-MPRAGE sequence compared to the standard STIR sequence. Correlation of clinical disability (EDSS) with lesion load from each sequence also demonstrated the importance of the improved lesion conspicuity with T1-MPRAGE.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

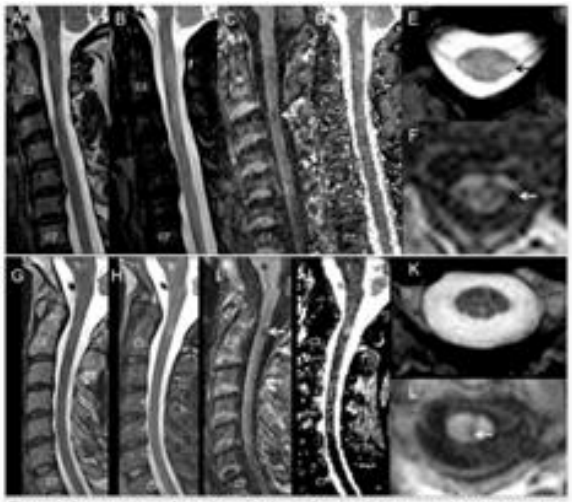

Figure 1: A comparison of imaging techniques for visualizing cervical cord lesions in a 45 y.o. woman (A through F) and a 43 y.o. man (G – L), both with relapsing-remitting MS. T1-weighted MPRAGE (C and I) performed better than routine clinical T2-weighted fast spin echo (A and G), short-TI inversion recovery (STIR, B and H), and multi-echo recombined gradient echo (MERGE, E and K) for visualizing lesions. Quantitative T1-maps of the cervical cord (D and J), generated using a multiple flip angle gradient echo sequence, showed the lesions as hyperintense. The lesions were also visible on axially reformatted T1-MPRAGE images (F and L).

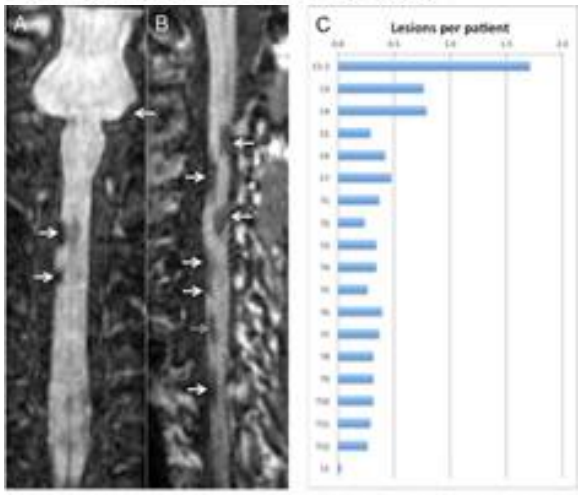

Figure 2: Coronal (A) and curved-reformatted (B) images from the T1-weighted MPRAGE sequence in the cervical cord of two patients, showing lesions mainly on the surface of the cord (white arrows) and a lesion that appears to be completely within the cord (grey arrow). (C) Rate of occurrence of lesions per spinal cord segment as read by the raters using all scans acquired in the MS population studied herein (39 MS patients, Age: 50 ± 12 y; disease duration 14 ± 11 y, EDSS range 1-7).

Conclusion

The optimized T1-MPRAGE sequence described here improves the reliability of lesion visualization and estimation of lesion burden, especially when used in conjunction with other well established clinical sequences.

Predictive Value of Nerve Root Sleeve Diverticula and Cerebrospinal Fluid Leak on Postmyelographic CT for the Development of Postmyelographic Headache

Alhilali, L. M.·Thomas, A.·Piper, S.·Fakhran, S.
University of Pittsburgh Medical Center
Pittsburgh, PA.

Purpose

To determine if evidence of nerve root sleeve diverticula or CSF leakage on postmyelogram CT is useful in predicting subsequent headache in patients undergoing myelography.

Materials & Methods

Three hundred fifty-eight lumbar and 195 cervical myelograms were performed consecutively by one operator (SP), via a lumbar approach, with a 22-gauge spinal needle and identical postmyelography care (three hours of bed rest with head of bed less than 30 degrees, encouragement of oral intake of fluids). Postmyelogram CT studies were reviewed retrospectively at each disk level bilaterally for evidence of either nerve root sleeve diverticula or CSF leak using the following scoring system: (1) nerve root sleeve diverticulum not extending beyond the lateral vertebral body margin, (2) nerve root sleeve diverticulum extending beyond the lateral vertebral body margin, (3) leak of contrast into the periradicular soft tissues, (4) epidural collection of contrast material. Two scores were obtained for each level (left and right) and the total score of either the lumbar or cervical spine was calculated for each patient. Patients were excluded who had evidence during the procedure of epidural or mixed injection of contrast. Results on CT myelogram were correlated with findings on telephone followup performed for postmyelogram symptoms two days after the procedure as well as any subsequent clinical followup.

Results

Inter-rater reliability for scoring nerve root sleeve diverticula and CSF leaks was substantial (Fleiss Kappa = 0.85, 95% confidence interval 0.74-0.96). Headaches were reported by 15 (4.2%) and 10 (5.1%) patients who underwent lumbar and cervical myelograms, respectively. No significant difference was found in the concentration of intrathecal contrast material used between patients with and without headaches who had undergone either lumbar ($p = 0.14$) or cervical ($p = 0.91$) myelography. Total scores were significantly higher for patients with headaches who had undergone lumbar ($p<0.0001$) and cervical ($p<0.0001$) myelography compared to patients without headaches that had undergone the same procedure. Patients with headaches were significantly younger than those without headaches ($p = 0.003$ and $p = 0.0002$ for lumbar and cervical myelography patients, respectively) and the group of patients with headaches had a significantly greater proportion of females ($p = 0.03$ and $p = 0.02$ for lumbar and cervical myelography patients, respectively). Furthermore, using multiple regression analysis, an

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

epidural collection of contrast material was found to be independently correlated with postmyelography headache (p =0.03) in the lumbar spine.
Conclusion
In patients undergoing myelography, a lumbar epidural collection of contrast is associated with postmyelographic headache. Furthermore, patients with postmyelographic headaches are more likely to have nerve root sleeve diverticula and extrathecal contrast extravasation than patients without headache.

KEYWORDS: Myelography, CSF leak

Fluoroscopic-Guided Lumbar Puncture: Fluoro Time and Implications of Body-Mass Index: A Baseline Study

Boddu, S. R.·Fountain, A. J.·Saindane, A. M.·Applegate, K.·Corey, A. S.
Emory University Hospital
Atlanta, GA.

Purpose
Fluoroscopic-guided lumbar puncture is an alternative to the bedside lumbar puncture in challenging patients. This is a less traumatic procedure, which decreases the false positive results, thus preventing the unnecessary subsequent investigations. There are no published guidelines for the acceptable range of fluoroscopic time for lumbar puncture. The study is aimed to obtain baseline fluoroscopic time ranges for lumbar puncture and their variability based on body-mass index (BMI). We also tested the hypothesis that fluoroscopic time of lumbar puncture increase with increasing BMI.
Materials & Methods
Retrospective review of all patients who underwent fluoroscopic-guided lumbar puncture at four hospitals over a one-year period (July 2011 - June 2012) was performed. Procedure logbooks and electronic medical records were accessed for variables such as patient demographics, clinical indication, BMI, and fluoroscopic time. Based on the federal obesity guidelines issued by National Heart Lung and Blood Institute patients were categorized as normal (18.5 - 24.9), over weight (25 - 29.9) , obese (30 - 39.9) or as extremely obese (≥ 40). Subgroups based on the clinical indication included: infection, inflammation, neoplasm, cognitive decline, hemorrhage, idiopathic intracranial hypertension (IIH) and miscellaneous. Logarithmic conversion of fluoroscopic times was performed to render normal distribution to the data. Fluoroscopic times were calculated for each subgroup and chi-square analysis was performed.
Results
Three hundred fifteen (mean age 47.6 years, range18-92, 35% male) fluoroscopic-guided lumbar procedures were performed. Twenty-two patients were excluded due to insufficient data. The mean BMI was higher in female patients (33.8 kg/ m; range: 21.6 - 69.4) than males (30.2 kg/m2; range: 19 - 51.8). Fourteen neuroradiologists and 25 residents/fellows participated. Mean fluoroscopic time for lumbar puncture in our study population was 1.18 minutes (standard deviation: 0.94). The details of each subgroup fluoroscopic times were summarized in Table 1. When the patient population was categorized by clinical indication for the study, we found that the IIH subgroup had the maximum mean BMI of 40.2; (range: 24-55.8) and corresponding maximum mean fluoroscopic time of 1.34 minutes (range: 0.2 - 6.2). The fluoroscopic times are significantly higher among the obese (P = 0.002) and extremely obese (P = 0.0001) in comparison to patients with normal BMI.

Table:1

S.No	BMI	Mean	Median	Standard Error of Mean	95% CI
1	18.5 - 24.9	1.012	0.7	0.14	±0.260.75 - 1.27
2	25 - 29.9	1.075	0.7	0.10	±0.210.87 - 1.28
3	30 - 39.9	1.195	0.7	0.10	±0.21.0 - 1.39
4	≥ 40	1.374	1.1	0.11	±0.221.16 - 1.59

Conclusion
In our study population, the fluoroscopic time for lumbar puncture increases with the increase in patient body-mass index (BMI). Idiopathic intracranial hypertension (IIH) is the single clinical indication with highest fluoroscopic procedure time, presumably related to the maximum mean BMI of this subgroup. This study contributes to literature by providing the baseline fluoroscopic times for lumbar puncture based on body-mass index (BMI) and clinical indication. We suggest use of this data as an initial benchmark in the evaluation of individual and department performance as monitored at our institution.

Determination of Optimal Contrast Concentration for CT-Guided Spine Procedures

Abbott, M. F.·Abbott, D.·Hoang, J. K.·Kranz, P. G.
Duke University
Durham, NC.

Purpose
Contrast frequently is used in CT-guided procedures to ensure proper needle placement. Once injected, however, undiluted contrast often obscures the needle tip, making subsequent needle repositioning more difficult. As a result, several authors have advocated the use of dilute contrast during various CT-guided procedures, including spine interventional procedures. To our knowledge, the optimal contrast dilution has not been established. The purpose of this investigation is to establish the optimal contrast dilution for CT-guided spine procedures.
Materials & Methods
We assessed optimal contrast concentration using both in vitro and in vivo methods, based on various dilutions of commercially available contrast containing 200 mg/mL iodine (Isovue-M 200) with preservative-free sterile saline. First, a phantom containing a 22-gauge needle surrounded by various contrast dilutions from 33 to 200 mg/mL iodine was imaged, and images were scored for needle visibility. Based on these results, a prospective study was performed in which patients presenting for CT-guided interlaminar or transforaminal epidural steroid injections were randomized to one of four contrast concentrations: 66, 100, 133, or 150 mg/mL iodine. Images from the procedure were scored for needle visibility and tissue contrast using a 5-point scale by a blinded neuroradiologist. Generalized estimating equations were utilized to assess the effect of contrast concentration on visibility.
Results
In the phantom study, contrast concentrations of 150 mg/mL or higher unacceptably obscured the needle. In the in vivo study, 42 patients who received a total of 60 injections were enrolled. There was a strong association between contrast concentration and needle visibility ($p = 0.0002$). Of the four concentrations, 100 mg/mL was optimal for allowing needle visualization and providing sufficient tissue contrast, with no instances of unacceptably dilute or concentrated contrast. A concentration of 66 mg/mL resulted in 3/17 cases of insufficient tissue contrast, while 133 and 150 mg/mL resulted in 11/13 and 7/14 cases respectively where the needle was unacceptably obscured by contrast. There was a statistically significant improvement in needle visibility at 100 mg/mL compared with 133 mg/mL ($p = 0.0012$).

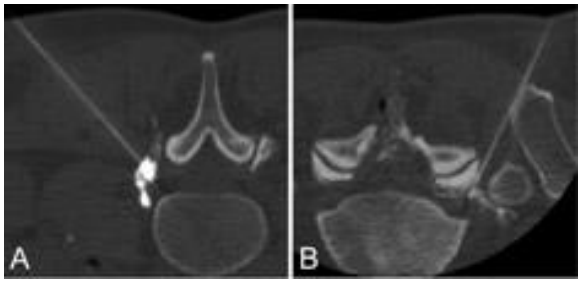

Figure. Effect of contrast concentration on needle visibility. A, Undiluted contrast (200 mg/mL iodine) obscures the needle tip, hindering repositioning. B, Dilute contrast (100 mg/mL iodine) allows visualization of the needle tip while providing acceptable tissue contrast.
Conclusion
For CT-guided spine procedures requiring contrast, the optimal contrast concentration is 100 mg/mL iodine. Use of dilute contrast in such procedures improves needle visibility.

Incorporating Spinal Pain Management Procedures into Neuroradiology Fellowship

Delfyett, W. T.[1]·Wo, S.[2]·Agarwal, V.[1]
[1]University of Pittsburgh Medical College/Presbyterian-Shadyside, Pittsburgh, PA, [2]University of Pittsburgh School of Medicine, Pittsburgh, PA.

Purpose
The performance of spinal pain management procedures (SPMPs) crosses several specialties. Local referral patterns and competition may all contribute to the spinal pain management patient volumes that neuroradiologists may encounter. Data suggests increasing utilization of multiple modalities the treatment of back pain. At our institution a dedicated neuroradiology spinal pain management service has experienced increases in annual patient encounters of 12-23% annually over the past three years, an increase in volume which parallels volume increases previously reported. The purpose of this study is to assess the methods by which neuroradiology fellowship training programs provide the ACGME required instruction in the performance of spinal pain management procedures in light of increasing patient volumes and competition from other specialties.
Materials & Methods
An IRB approved survey using Survey Monkey was distributed twice to all physicians designated as neuroradiology fellowship directors by the ASNR approximately eight weeks apart. The types of spinal pain management procedures performed as part of neuroradiology fellowship as well as volumes of these procedures were queried along with the manner in which these procedures are incorporated into fellowship

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

training. Information regarding which other specialties perform these SPMPs also was requested.
Results
Of 100 surveys 44% response rate was achieved. Among responders; 49% incorporate SPMPs as part of an interventional rotation, 33% incorporate SPMPs as part of a diagnostic rotation, 18% have dedicated spinal intervention services/fellow rotations, 21% have fellows rotate on other services within or external to radiology, 9% provide experience in an elective manner and 9% report no incorporation into fellowship. The volumes of these procedures which the fellows perform was reported between 0-10 cases; for cervical epidural injections 90%, cervical nerve root blocks 84%, lumbar epidural injections 50%, lumbar nerve root blocks 47%, and disk aspirations/intradiscal procedures 67%. Competing services were reported to be; Anesthesia/Pain medicine 90%, Physical Medicine and Rehabilitation medicine 37%, Orthopedics 12%, Neurosurgery 5%, and Neurology 3%. As part of postgraduate surveys, performance of individual spinal pain management procedures were reported as practice needs by 15-35% of graduates according to fellowship directors with the highest reported need for lumbar epidural steroid injections, 35%.
Conclusion
Among responding fellowship directors, the manner in which SPMPs are incorporated into fellowship was found to be heterogeneous, likely related to center specific considerations. Up to 9% report no incorporation of SPMIs into fellowship training despite ACGME requirement. Considering increasing patient volumes and increasing interest in conservative therapies for back pain, neuroradiology fellowship training experience in SPMP remains important to clinical practice as was found on postgraduate surveys. Neuroradiology fellowship program requirements do not specify numerical minima for SPMPs, but the numbers of cases reported are in range of the ACGME specified procedural minima defined for fellowship programs in pain medicine, a source of primary competition. Although center specific considerations often dictate how these procedures are incorporated into fellowship training, a variety of methods may be used, and potential target procedural minima likely can be achieved in the vast majority of neuroradiology fellowship training experiences.

Spinal Cord Stimulators in Outpatient Interventional Neuroradiology Practice

Georgy, M.[1]·Padwal, J.[2]·Georgy, B.[3]
[1]Canyon Crest Academy, San Diego, CA, [2]University of California San Diego, San Diego, CA, [3]San Diego Imaging, University of California San Diego, San Diego, CA.

Purpose
Spinal cord stimulation is a known modality for treatment of chronic back and neck pain. Traditionally, spine surgeons and pain physicians perform those procedures. We are reporting our experience in performing neuromodulation procedures in an out-patient interventional radiology practice.
Materials & Methods
Retrospective analysis of medical records of all trial and permanent implantation patients over a period of four years was performed after obtaining IRB approval. Forty-five patients (32 males and 13 females with median age of 47 years) were included in the study. Primary diagnoses were: 23 cases of failed back or neck surgery syndrome, 12 cases with spinal stenosis, four cases of axial pain, three cases with reflux sympathetic dystrophy, one case of peripheral vascular disease, one case of phantom limb and one case of postconcussion syndrome.
Results
Thirty-four trials were performed in outpatient clinic while 11 trials were performed in hospital outpatient's settings. Trial periods were 3-7 days. Twenty-seven patients (60%) who reported 50% or more pain relief underwent a permanent implantation. An interventional neuroradiologist performed 17 implantations, while spine surgeons performed 10 implantations. Twenty-three implants were epidural (19 lumbar and 4 cervical) while four cases were subcutaneous. During follow-up period, three patients had infections (13%) and required removal of the device and two cases (8%) reported lead migration.
Conclusion
Neuromodulation procedures can be performed safely in an outpatient interventional radiology setting. Complication rates and trial to implant ratio are similar to published data.

Targeted Radiofrequency Ablation of Malignant Spine Lesions before Cement Augmentation Using Novel Bipolar Navigational Device

Georgy, B.
San Diego Imaging, University of California San Diego
San Diego, CA.

Purpose
Report early clinical experience of targeted radiofrequency ablation (t-RFA) followed by cement augmentation in malignant lesions of the spine using a novel bipolar RF ablation system, purpose built for minimally invasive procedures in the axial skeleton.
Materials & Methods
Twenty-five spinal lesions in 15 patients with different malignant etiologies were included after IRB approval. The STAR Tumor Ablation System includes a robust, articulating, navigational osteotome, containing an extensible electrode. The device is bipolar and contains two thermocouples (TC) positioned at 10 and 20 mm from center of the ablation zone to permit real-time monitoring of the ablation zone. Radiofrequency-warmed cement augmentation via the same guiding cannula was performed after lesion ablation.
Results
All procedures were performed safely with no complications or thermal injury. Ablation time ranged from 1.5-6 minutes. Maximum recorded temperature was 65°C at the distal TC and 50°C at the proximal TC (10 and 20 mm from the center of the ablation zone, respectively). Thermocouples on the electrode were used to confirm re-establishment of core temperature prior to cement augmentation. Postprocedure CT showed no significant cement leakage. Average VAS scores dropped from seven preprocedure to 4.7 postprocedure. Average ODQ scores improved from 25.8 to 18 postprocedure. Decreased tumor volume and decreased metabolic activity was confirmed by MRI and PET scan, respectively.
Conclusion
Targeted RF ablation followed by RF-warmed high viscosity cement augmentation was performed successfully in this series of malignant spinal lesions. Improvement in pain and functional status was noted in all patients. The STAR Tumor Ablation System permitted minimally invasive access to all lesions, regardless of location. Proximal and distal TCs allowed accurate monitoring of the temperature inside the vertebral body to avoid complications of nearby vital structures. Targeted delivery of high viscosity cement following ablation via the same guiding cannula provided vertebral stability.

Balloon Kyphoplasty and Radiofrequency Kyphoplasty in Treatment of Patients with Osteoporotic Compression Fractures

Bornemann, R.·Jansen, T. R.·Otten, L. A.·Kabir, K.·Wirtz, D. C.·Pflugmacher, R.
Universitätsklinikum Bonn
Bonn, GERMANY.

Purpose
Since the 1990s, balloon kyphoplasty has been proven as an effective method of treating patients with painful vertebral compression fractures (VCF). However, due to the low viscosity of the PMMA cement uncontrollable cement leakage with corresponding risks often is the focus of discussions on this procedure. The radiofrequency kyphoplasty (RFK) is an innovative procedure available since 2009, for which an ultrahigh viscosity cement is used. It also offers the advantage of over 30 minutes' constant processing time. For the statistical comparison of the two methods clinical and radiologic data of two larger patient groups were evaluated.
Materials & Methods
As part of the surgical treatment of patients with conservative therapy-resistant osteoporotic vertebral fractures a prospective study of RFK was performed between 2009 and September 2010. From the clinical aspect, measurement parameters for efficacy and safety were the course of pain intensity using the VAS (0 to 100 mm) and the ODI (0-100%). For the radiologic outcome the increase in the middle and anterior parts of the treated vertebra and also the reduction of kyphosis after surgery and after 6, 12 and 24 months were evaluated. Furthermore, the extent of cement extrusion and the duration of operation time were compared. There were two groups of patients chosen with the same indication, and with the same average VAS prior to treatment. For the BKP the Kyphon ® technology was used. For the BKP group the same parameters like in the first group were evaluated (matched pairs). To compare the data statistically parametric and nonparametric tests were applied.
Results
For the radiofrequency kyphoplasty group (RFK) 101 patients were recruited, and for the balloon kyphoplasty group (BKP) 101 appropriate patients were selected. In 47% of the RFK patients and in 45% of the BKP patients more than one vertebral body were treated (thoracic or lumbar).Prior to treatment 85 mm on the VAS were calculated in both groups. The decrease in VAS values was (RFK versus BKP) immediately after surgery, 56 mm versus 55 mm ($p = 0.02$), and after 6, 12 and 24 months ($p<0.001$). In both groups improvements in the Oswestry scores were registered after 6, 12 and 24 months without a statistically significant difference. In both groups, the middle part of the vertebral bodies was increased by an average of 3 mm. Radiofrequency yielded a decrease in the average kyphosis angle of 4.6, the BKP resulted in

about 3.9 degrees. Concerning cement leakage a key difference in favor of the radiofrequency kyphoplasty was detected (5.9% versus 26.7%; p <0.0001). For RFK a significant shorter duration of operation time was calculated (28 versus 49 min; p<0.001).
Conclusion
The RFK has proven to be a clinically very effective procedure that does somewhat better than BKP in long-lasting pain relief. No differences could be detected regarding improvement of functioning and the mean restoration of mid- and anterior-vertebral height. As the safety aspect is concerned the RFK offers the advantage of a statistically significant lower proportion of cement extrusion.

Multiple Myeloma: Radiofrequency Kyphoplasty versus Conservative Care in the Treatment of Osteolytic Vertebral Fractures

Bornemann, R.·Jansen, T. R.·Kabir, K.·Wirtz, D. C.·Pflugmacher, R.
Universitätsklinikum Bonn
Bonn, GERMANY.

Purpose
Radiofrequency kyphoplasty (RFK) provides a minimally invasive procedure to treat vertebral compression fractures (VCF) due to osteoporosis, trauma or tumor. Painful osteolytic vertebral fractures due to multiple myeloma often are treated conservatively. Patients suffer from pain and immobilization. There is still a controversial discussion how to treat osteolytic vertebral fractures. Conservative care is the default approach, despite lack of evidence. Radiofrequency kyphoplasty uses ultrahigh viscosity cement to stabilize the fracture. The aims of this study were to compare RFK to conservative care and to evaluate two patient groups which were treated with RFK or conservatively. The control group of conservative care results by patients who denied a surgical intervention. All patients were followed for six months. All patients were seen every six weeks.
Materials & Methods
Patients with painful osteolytic vertebral compression fractures due to multiple myeloma were offered surgical treatment by RFK. Patients which agreed were treated within three days, patients who denied were treated conservatively (analgesics, bracing and physiotherapy). They then wereoffered the choice of continuing conservative care or crossing over to radiofrequency kyphoplasty, after six and 12 weeks. All patients, in the RFK or conservative care group, were treated by the oncologist and received chemotherapy when necessary. Clinical success was defined as: 1) VAS pain improvement ≥ 2.0) final VAS pain ≤ 5.0) no functional worsening on ODI. Ninety patients (51 females and 39 males) with 162 osteolytic vertebral fractures were treated with RFK using the StabiliT Vertebral Augmentation System (Dfine Inc, San Jose, CA). Seventy-eight patients could be followed up to six months. Forty-eight patients (29 females and 19 males) with 92 vertebrae initially were treated conservatively. After six weeks 22 out of 48 patients and after 12 weeks 12 out of 48 patients decided to cross over to RFK. Thirty-four out of 48 patients made a crossover to RFK. Forty-four patients could be followed up to six months.
Results
In the RFK group the median pain scores (VAS) (p<0.001) and the ODI (p<0.001) improved significantly from pre- to post-treatment and maintained at three and six months followup. Postoperative, three and six months follow-up RFK stabilized the vertebral height and avoided further kyphotic deformity. After six months 76 out of 78 patients met the criteria for clinical success. In the conservative group only one out of 48 patients after the initial six weeks of conservative care met the criteria for clinical success and median VAS improvement was two. After 12 weeks of conservative care, only three patients met the criteria for clinical success, and median VAS improvement was two. Further the radiologic data showed a significant height loss and increase in kyphotic deformity in comparison to RFK.
Conclusion
For the vast majority of patients, conservative care did not provide meaningful clinical improvement. Nearly all patients who underwent RFK had rapid substantial improvement. Surgery was clearly much more effective than conservative care and should be offered to patients sooner. Further RFK did not interrupt or delay chemotherapy or radiation therapy!

Sacral Radiofrequency Neurolysis for the Management of Sacroiliac Joint-Related Pain: A Comparison of Three Techniques

Ortiz, A.[1]·Golovac, S.[2]
[1]Winthrop University Hospital, Mineola, NY, [2]Space Coast Pain Institute, Merritt Island, FL.

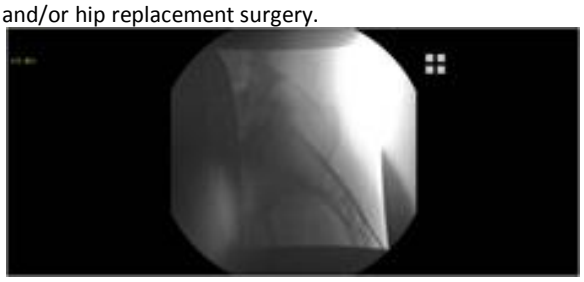
Purpose
To compare the utility, efficacy and safety of three different sacral denervation techniques in the management of sacroiliac joint (SIJ) pain that is refractory to conservative medical management.
Materials & Methods
Forty-seven patients who met eligibility criteria including at least 7/10 sacroiliac joint-related pain, on either over the counter or prescribed analgesic therapy, and with a favorable, but temporary response to image-guided percutaneous sacroiliac joint anesthetic/steroid injections underwent a total of 50 fluoroscopy-guided sacral RF

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

procedures over a 2½-year period. The three types of radiofrequency procedures were cooled RF, bipolar RF and multilesion RF. Patient followup was conducted at three week, three month and one year intervals. The following parameters were recorded: clinical presentation, procedure time, fluoroscopy time, type of anesthesia, complications and pre and postnumeric pain scores and analgesic requirements. The latter was categorized as 0: no analgesics, 1: over the counter analgesics or 2: prescribed analgesics. IRB approval was obtained for this project.

Results

Eight patients, four male and four female, with an average age of 76.5 years underwent cooled RF (average procedure time 2.5 hours and average fluoroscopy time 10 minutes). All patients in this group were followed to one year and experienced complete relief of their SIJ pain. Twenty patients, 15 female and five male, and an average age of 74 years had 28 bipolar RF procedures (five patients had bilateral procedures; average procedure time 1.5 hours and average fluoroscopy time six minutes). All but two experienced significant pain relief by one-year followup. Nineteen patients, 13 female and six male, with an average age of 68.5 years underwent multilesion RF (average procedure time 30 minutes and average fluoroscopy time 1.5 minutes). All patients in this group have been followed to at least three weeks, and are pain free. No major complications were encountered in any patient group; one patient in the multilesion RF group experienced transient neuritis at the treatment site, which responded to conservative management. Thirty-one patients had either prior spine surgical interventions and/or hip replacement surgery.



Conclusion

All sacral RF procedures were effective in providing pain relief with a reasonable safety profile in properly selected patients. The sacral multi-RF procedure, however, was more efficient. Long-term results with the latter technology are still pending.

Gene-Brain-Behavior Relationships in Tuberous Sclerosis Complex: Focus on Radial Migration Lines

van Eeghen, A. M.·Ortiz Teran, L.·Johnson, J.·Pulsifer, M. B.·Thiele, E. A.·Caruso, P.
Massachusetts General Hospital
Boston, MA.

Purpose

The search for neuroradiologic biomarkers in TSC has resulted in varying findings on tubers and white matter (WM) microstructure. Although radial migration lines (RMLs) are the main radiologic WM feature in TSC and are associated with DTI abnormalities, their contribution to the neuroanatomical and neurocognitive phenotype has been understudied. Our aims were to include radial migration lines (RMLs) and normal-appearing WM (NAWM) features in a comprehensive evaluation of the neuroradiologic endophenotype, and to compare macrostructural and microstructural characteristics with genotype and neurodevelopmental outcomes.

Materials & Methods

MR images of 30 patients with TSC, including volumetric thin-section FLAIR imaging and DTI, were evaluated for frequencies of tubers, RMLs, subependymal nodules (SENs), and sub-ependymal giant cell tumors (SGCTs) per hemispheric lobe. Cerebellar lesions were counted. Fractional anisotropy(FA) and apparent diffusion coefficients(ADCs) were measured of the largest tuber, largest RML, and in the NAWM of each hemispheric lobe. Whole brain NAWM DTI indices were compared with 16 control patients. Relationships between neuroanatomical features were explored, and compared with genotype, epilepsy variables, intellectual/developmental quotients, and prospectively collected data on autistic features and global psychologic functioning. Linear regression analysis was performed to identify a predictive neuroanatomical biomarker for intelligence.

Results

A mean of 47 RMLs (range 4-86), 27 tubers (range 1-76) and 10 (range 0-22) SENs were found per patient. Radial migration lines greatly outnumbered tubers, and tubers generally were connected to an RML. Cerebellar lesions were associated with occurrence of SGCTs, and with more

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

severe macrostructural and microstructural features. Lesion frequencies covaried with DTI indices of the largest tuber and RML, but not with NAWM FA or ADC. Normal-appearing WM FA and ADC values of TSC patients were similar to control patients (p=0.26). However, mean FA values of NAWM were significantly associated with the ADC of the largest tuber(p=0.01) and showed a trend towards association with the ADC of the largest RML(p=0.09). All lesion frequencies were significantly associated with level of autistic features, intelligence and age of seizure onset (p<0.05 for all), but NAWM FA and ADC values were not. Of all lesion types, RML frequency showed the strongest associations with intelligence quotients and autistic features (p<0.01). Of the microstructural lesion indices, only RML ADC was significantly associated with intelligence. Linear regression analysis did not yield a unique neuroanatomical biomarker. Distinct genotype-neuroradiologic phenotype associations were observed, with significantly more lesions with more disturbed DTI indices associated with truncating TSC2 mutations compared with patients with TSC1 or TSC2 missense mutations.

Conclusion

Radial migration lines represent the major WM abnormality in TSC and were unvariably, in great frequency, and diffusely present. Normal-appearing WM showed normal DTI outcomes; the association between NAWM FA and lesion ADCs may reflect disrupted axon packing interfering with normal axon guidance mechanisms. Tubers, SENs, RMLs and lesion FA/ADC values covaried strongly together, with genotype and with neurobehavioral outcomes, providing a robust neuroradiologic endophenotype. Until more sophisticated biomarkers such as whole brain DTI are established, SENs may provide a crude but practical biomarker to stratify patients for early intervention or SGCT monitoring.

Normal Developmental Myelination Pattern of Callosal Splenium Commissural Fibers on MR Imaging in Children Three to Six Months of Age

Whitehead, M. T.·Raju, A.·Choudhri, A. F.
University of Tennessee Health Sciences Center/LeBonheur Children's Hospital
Memphis, TN.

Purpose

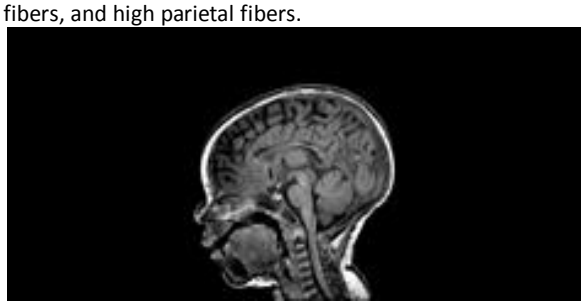
The purpose of this study is to depict the specific developmental callosal splenium MR myelination pattern and distinguish the normal transient mid splenium hypointensity from pathologic splenium lesions.

Materials & Methods

We reviewed 131 consecutive brain MRIs of patients between the ages of three-six months who presented to a single academic children's hospital over a one-year period. Examinations without diffusion tensor images, preterm patients (<38 weeks gestation), patients with severe hydrocephalus, and patients with substantial volume loss were excluded. A total of 50 patients' (ages 3-6 months) MRIs that included sagittal 3D T1-weighted (T1WI) FSPGR (Fast spoiled gradient echo), axial T1 FLAIR, axial T2-weighted (T2WI) fast spin echo, axial T2/FLAIR, and axial diffusion tensor images with 15 encoding directions were reviewed. Regions and degree of callosal splenium, isthmus, and posterior body myelination manifested by T1 and T2 shortening were evaluated. The maximum area of specific regions of T1 prolongation in the developing splenium were measured in the sagittal plane. Tractography was performed with seeds placed over the posterior, mid, and anterior splenium to define the primary origin, destination, and course of traversing commisural fibers.

Results

The splenium signal intensity was significantly different in patients ages three-six months with distinct age-related trends. On T1WI, diffuse hypointense signal was present in nearly all (9/10) three-month-old patients, mixed signal with geographic hypointensity in the mid splenium was present in nearly all (15/16) four-month-old patients, and a mixed mildly heterogenous signal was seen in nearly all six-month-old patients (9/10). Signal intensity was more variable in the five-month-old patients. Tractography revealed three distinct white matter tract populations located in the posterior, mid, and anterior splenium, respectively: medial occipital fibers, medial temporal fibers, and high parietal fibers.



Conclusion

Specific commissural fiber components of the callosal splenium myelinate at different time periods. The transient developmental mid splenium hypointensity on T1WI corresponds to small fiber tracts from associative cortex, principally originating and terminating from the medial temporal lobes. Heterogenous splenium signal alteration in patients ages three-six months is a normal developmental phenomenon that should not be confused with pathologic lesions.

Hipoccampal Malformations in Copy Number Gains of 15q11-q13

Boronat, S.·Thibert, R.·Mehan, W.·Caruso, P.
Massachusetts General Hospital
Boston, MA.

Purpose
Gain of gene dosage of 15q11-q13, either as an interstitial duplication or triplication of the maternal allele or as an isodicentric marker chromosome [idic (15)] has been associated with global developmental delay, autistic spectrum disorder, psychiatric disease, and epilepsy. MR images in these patients have been reported as normal or having nonspecific findings such as a thin corpus callosum. The purpose of this study is to characterize the neuroimaging features of eight patients with this genotype.
Materials & Methods
A retrospective review was performed of the charts of 37 patients affected by isodicentric (15) or interstitial duplication of 15q11-q13. 8 MR inages were available for review: seven patients had an isodicentric (15) and one had an interstitial duplication. The pertinent literature was reviewed.
Results
Seven patients had hippocampal malformations and one patient had mesiotemporal sclerosis. One patient had hypoplasia of the posterior corpus callosum and one had an abnormally thin corpus callosum. One had dilatation of the central ependymal canal from C5 through T1. In the MRI literature, the most frequently reported finding in copy number gain of 15q11-q13 is hypoplasia of the corpus callosum. Although hippocampal malformation has been reported in the neuropathologic literature in copy number gain of 15q11-q13, our study represents the largest series of patients with MRI findings yet to be reported.
Conclusion
Hippocampal malformation is the most frequent finding in neurodevelopmental disorders due to copy number gain at 15q11-q13. This feature may be related to some of the clinical features presented by these patients such as the high incidence of epilepsy and sudden unexpected death.

Prenatal Pattern Analysis and 3D Modeling in Callosal Agenesis

Kasprian, G. J.·Langs, G.·Dittrich, E.·Brugger, P. C.·Prayer, D.
Medical University of Vienna
Vienna, AUSTRIA.

Purpose
To detect and describe abnormalities and differences in cortical folding patterns of fetuses with callosal agenesis (CCA).
Materials & Methods
Three orthogonal T2-weighted sequences (1.5T, slice thickness 4.4 mm, FOV 230 mm, TE = 140 ms) of 21 fetuses with isolated, partial and associated forms of CCA were analyzed retrospectively. 2D pattern analysis consisted of cortical contour delineation (coronal plane) and 2D shape modeling using a multivariate Gaussian model. For 3D modeling, the axial, coronal and sagittal sequences of each subject were reconstructed into an isotropic high-resolution volume. Afterwards, a semi-supervised image processing algorithm is applied to retrieve segmentations of the cortical surfaces for all cases. Based on these segmentations, the symmetry of the 3D shapes was evaluated in terms of shape variation on left and right hemispheres, respectively. Results were compared to 21 age-matched fetuses with normal cerebral development.
Results
Hemispheric asymmetry patterns are less pronounced in the acallosal group of fetuses as demonstrated by 2D pattern analysis. Hemispheric asymmetries were less pronounced in the perisylvian brain regions in CCA cases. 3D modeling readily could visualize the dynamic cortical folding patterns in CCA fetuses and could detect subtle differences in comparison to normal controls.
Conclusion
2D and 3D modeling and pattern analysis are computerized, quantitative methods to detect even subtle differences of atypical cortical folding patterns in fetuses with CCA. In future these tools may be further suitable to differentiate cases of isolated CCA with adverse neurodevelopmental outcome from those with close to normal development.

Monitoring Craniocervical Junction Abnormalities in Osteogenesis Imperfecta Using Plain Radiography and MR Imaging Techniques

Williams, F.·Connolly, D. J. A.
Royal Hallamshire Hospital Sheffield
Sheffield, UNITED KINGDOM.

Purpose
Osteogenesis imperfecta (OI) is an inherited disorder of collagen metabolism with a prevalence of 1 in 10 000-20 000 worldwide. The genetic defect leads to defective bone mineralization and hence weakened and fragile bones unable to withstand normal biomechanical forces. This is of significance at the base of skull and cranio-cervical junction where the weight of the developing brain leads to platybasia-a flattening of the skull base and basilar impression where there is protrusion of the uppermost vertebral structures into the cranium and invagination in which there is lowering of the cranial base. These can lead to serious morbidity and mortality. We aim to study a group of children with OI in order to provide radiologic markers of increasing severity in an effort to predict when intervention is necessary by use of both radiography and MRI which is especially relevant as the children age.
Materials & Methods
Children with OI who were referred to Department of Paediatric Metabolic Bone Disease, Sheffield Children's NHS Foundation Trust and Academic Unit of Child Health, University of Sheffield, United Kingdom were identified by retrospective review of the database. Their demographic and clinical data were collated. All patients underwent genetic testing, serial plain radiography and MR imaging of the skull base and cranio-cervical junction as both initial diagnostic studies and subsequent followup. The MR imaging was reviewed and 2D flow analysis of CSF mechanics at the craniocervical junction was performed in the Academic Department of Radiology, Sheffield.
Results
Thirty-eight patients were identified presenting over a four-year period from 2008-2012. The age range was two years to 23 years. Radiographic analysis was performed on the presentation and follow-up series with respect to the basal angle and the presence or absence of basilar invagination. The majority of patients (34/38) had radiographic evidence of platybasia at diagnosis. In the remaining four cases this subsequently developed on follow-up imaging. Correlation with MRI was made using a modified basal angle measuring technique and evidence was seen of this in 37 patients. Subsequent followup showed progression to varying degrees of invagination in 30 patients. In addition 2D flow analysis of CSF mechanics at the craniocervical junction was obtained in each patient. This demonstrated evidence of significant alteration in CSF flow in 15/38 patients who were patients with the most significant radiologic progression, five of whom had demonstrated evidence of syrinx formation.
Conclusion
Craniocervical abnormalities can be confidently diagnosed on both plain radiography and magnetic resonance imaging and can be used as a guide for future followup of such patients. In addition, the use of CSF flow analysis techniques can be used to monitor and predict eventual brainstem compressive complications and thus be used as a guide for surgical intervention.

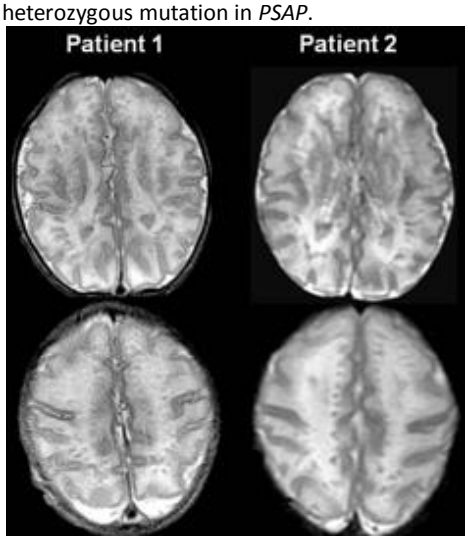
Unique Brain MR Imaging Findings in Two Siblings with Prosaposin Deficiency

Stence, N. V.[1]·Fenton, L. Z.[1]·Lindsay, A.[2]·Lovell, M.[1]·Manchester, D.[1]
[1]Children's Hospital Colorado, Aurora, CO, [2]University of Colorado Denver, Aurora, CO.

Purpose
Prosaposin deficiency (pSap-d) is a rare, neonatal neurovisceral lipid storage disorder described in few case reports. A single report has described brain MRI findings. The prosaposin protein (PSAP) is a product of *PSAP*, a >39 kb gene located on chromosome 10. Prosaposin protein is a lysosomal precursor protein for four sphingolipid activator proteins, the sapopsins, which are indispensible for normal lysosomal catabolism. Prior case reports of pSap-d have described a syndrome of rapid neurologic deterioration and death in the neonatal period. We describe the history and imaging of two siblings with nearly identical unique brain MRI findings who declined precipitously after birth and died in the neonatal period. One was diagnosed with pSap-d at autopsy with genetic testing.
Materials & Methods
A chart review and review of MRI brain imaging findings was conducted in two siblings diagnosed with pSap-d.
Results
Clinical Histories: The first infant was born at 38 weeks gestation and was noted to be hypotonic, jittery, and a poor feeder immediately after birth. A brain MRI was obtained at DOL 9 for onset of seizures. His course deteriorated precipitously and he died at day of life (DOL) 20. His sibling was born at 37 weeks of gestation, and was transferred to the NICU on DOL 2 for poor feeding. Brain MRI was obtained at DOL 3, showing findings similar to her brother. She deteriorated rapidly and died at DOL 53.
Imaging: Brain MRI findings are similar in both siblings. Gray matter intensity nodules were distributed diffusely throughout the periventricular white matter, focally concentrated adjacent to the lateral ventricle atria. Multiple gyri were abnormally enlarged and few in number, with an appearance suggestive of pachygyria. However, the cortex was abnormally thin, and the white matter was diffusely T2 hyperintense (Figure 1). Post mortem: Autopsy was performed in the second infant.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Brain examination revealed heterotopic neurons in the molecular layer of cortex and white matter, simplification of gyral pattern, microcephaly, islands of engorged histiocytes and near complete loss of white matter in the cerebrum. Genetic testing confirmed a compound heterozygous mutation in *PSAP*.



Conclusion

Siblings with pSap-d demonstrated identical unique brain MRI findings of gray matter intensity heterotopic nodules, abnormally enlarged and sparse gyri, cortical thinning, and abnormal white matter hyperintensity. This unique combination of findings could suggest the diagnosis of this rare disorder in the appropriate clinical setting.

Neuroimaging Findings in Twenty-Five Children with Isolated and Associated Hemimegalencephaly

Bosemani, T.[1]·Boltshauser, E.[2]·Staudt, M.[3]·Flores-Sarnat, L.[4]·Buerki, S.[5]·Pieper, T.[3]·Sarnat, H. B.[4]·Wei, X.[4]·Hartman, A. L.[1]·Huisman, T. A. G. M.[1]·Poretti, A.[1]
[1]The Johns Hopkins University School of Medicine, Baltimore, MD, [2]University Children's Hospital, Zurich, SWITZERLAND, [3]Epilepsy Center for Children and Adolescents, Schön Klinik, Vogtareuth, GERMANY, [4]University of Calgary and Alberta Children's Hospital, Calgary, AB, CANADA, [5]University Children's Hospital, Berne, SWITZERLAND.

Purpose

Hemimegalencephaly (HME) is a rare congenital hamartomatous malformation characterized by excessive growth limited to one cerebral hemisphere. Hemimegalencephaly may occur in isolation or be associated with neurocutaneous syndromes. Typical neuroimaging findings in HME include enlargement of the affected cerebral hemisphere with a dysplastic and thickened cortex, abnormal signal intensity and increased volume of the ipsilateral white matter, and enlargement of the lateral ventricle. We aim to evaluate the differences between isolated and associated HME with respect to neuroimaging findings including degree of severity of HME and involvement of cranial nerves and intracranial vessels.

Materials & Methods

MR images of 25 children (13 males and 12 females) with HME were included in this study. At the time of MRI, the median patient age was 0.8 years (range one day to 9.8 years). MR imaging findings were reviewed retrospectively. We used the anatomical grading of severity reported by Flores-Sarnat. Additionally, all MR images were evaluated qualitatively for asymmetry in size of cranial nerves, intracranial vessels, and posterior fossa structures.

Results

Hemimegalencephaly was isolated in 17 children. In eight patients, HME was associated with neurocutaneous syndromes including epidermal nevus syndrome (n = 4), megalencephaly-capillary malformation (n = 2), Klippel-Trenaunay syndrome (n = 1), and hemicorporal hypertorphy (n = 1). The severity of HME was classified as Grade 1 (mild) in 7/25 (28%, four associated), Grade 2 (moderate) in 11/25 (44%, two associated) and Grade 3 (severe) in 7/25 (28%, two associated). We were not able to identify and evaluate all studied structures in each patient. This is reflected in the denominator of the following ratios. The ipsilateral olfactory bulb, trigeminal and optic nerves were enlarged in 4/19 (21%, one associated), 1/18 (6%, one), and 1/25 children (4%, one), respectively. Asymmetric dilatation was observed in the ipsilateral meningeal vessels in 14/25 patients (56%, seven), ipsilateral anterior and middle cerebral arteries in 8/25 (32%, two), ipsilateral internal cerebral vein in 5/24 (21%, two), and ipsilateral posterior cerebral artery in 5/25 (20%, two). Ipsilateral enlargement of the cerebellum and middle cerebellar peduncles was present in 4/25 patients (16%, four and three, respectively). Reduction in size of the ipsilateral cerebral peduncle was found in 6/25 (24%, one).

Conclusion

In children with HME, ipsilateral enlargement of structures other than the involved cerebral parenchyma is present, particularly the olfactory bulb, meningeal vessels, cerebral vessels, hemicerebellum and middle cerebellar peduncles. Ipsilateral enlargement of the trigeminal and optic nerves, meningeal vessels, hemicerebellum and middle cerebellar peduncles were more frequent in children with associated HME compared to the isolated group. However, the associated group tended to be milder in terms of anatomical degree of severity. Reduction in size of the ipsilateral cerebral peduncle was present only in children with Grade 2 or 3 HME and mostly associated with involvement of the temporo-parietal lobe. Reduction in size of the ipsilateral cerebral peduncles seems to be a secondary finding, most likely due to Wallerian degeneration.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Ataxia, Cognitive Impairment, and Ocular Motor Apraxia with Cerebellar Cysts and Dysplasia: A New Form of Dystroglycanopathy?

Poretti, A.[1]·Huisman, T. A. G. M.[1]·Bertini, E.[2]·Boltshauser, E.[3]
[1]The Johns Hopkins Medical School, Baltimore, MD,
[2]Ospedale Pediatrico Bambino Gesù, Rome, ITALY,
[3]University Children's Hospital, Zurich, SWITZERLAND.

Purpose
Cerebellar cysts are a rare finding in pediatric neuroimaging and are rather characteristic for congenital muscular dystrophies (CMD) due to impaired glycosylation of alpha dystroglycan. We aim to evaluate the MRI spectrum, characterize neurologic/ophthalmologic features and cognitive outcome and report genetic analysis in seven children (including three siblings) with an apparently new syndrome characterized by cerebellar cysts.
Materials & Methods
All images were qualitatively evaluated for infra and supratentorial abnormalities. Data about neurologic and ophthalmologic features and outcome were collected from clinical history and follow-up examination. *POMT1*, *POMT2*, *POMGnT1*, *FKRP*, *FKTN*, *LARGE*, and *GPR56* genes were screened in all patients. In three children a SNP 6.0-Array also was performed.
Results
The seven patients included four males and three females. At a mean age of 7.2 years (range 3.5 to 13.5 years), cognitive impairment and ataxia were found in all patients, ocular motor apraxia in six, and severe myopia in three. Qualitative MR evaluation showed cerebellar cysts in the cerebellar hemispheres and vermis in all patients. Additional MR findings included cerebellar dysplasia and an enlarged fourth ventricle in all children, vermian hypoplasia and brain stem morphologic abnormalities in six, and an elongated and squared shape of the fourth ventricle in five. In all patients, no mutations were found in the *POMT1*, *POMT2*, *POMGnT1*, *FKRP*, *FKTN*, *LARGE*, and *GPR56* genes. The SNP array showed no pathogenetic imbalances in all children evaluated.
Conclusion
The seven children share the same clinical and neuroimaging phenotype including cognitive impairment, ataxia, ocular motor apraxia, cerebellar cysts, and cerebellar dysplasia. These are features of dystroglycanopathies. However, weakness, a key feature of CMD, was not a finding. Additionally, no mutations were found within the known dystroglycanopathy genes. Therefore, we suggest that the reported clinical and neuroimaging phenotype may represent a new syndrome related to the dystroglycanopathy spectrum.

Midbrain-Hindbrain Involvement in Septo-Optic Dysplasia

Severino, M.·Allegri, A.·Roviglione, B.·Pistorio, A.·Maghnie, M.·Rossi, A.
Gaslini Children's Hospital
Genova, ITALY.

Purpose
The diagnosis of septo-optic dysplasia (SOD) requires at least two features of the classical triad: (i) optic nerve hypoplasia, (ii) pituitary hormone abnormalities, and (iii) midline brain defects. Midbrain-hindbrain involvement has not been described well, despite mutations of genes (i.e., OTX2 and FGF8) regulating brainstem anteroposterior (AP) patterning in SOD patients. We aimed to describe midbrain-hindbrain involvement in SOD and to identify possible clinical-neuroimaging correlations.
Materials & Methods
We studied 38 SOD patients with MRI (mean age 61 months, 21 males). Patients were categorized subjectively based on the presence (group A, 21 patients) or absence (group B, 17 patients) of visible brainstem anomalies. We then measured height and AP diameter of midbrain, pons, and medulla, AP midbrain/pons diameter (M/P ratio), vermian height, and tegmento-vermian angle, and compared the results with a database of 114 normal age- and gender-matched controls. Differences between groups were evaluated with nonparametric ANOVA test (Kruskal-Wallis) and the results were corrected a-posteriori according to Bonferroni (p_B). Furthermore, patients were subdivided based on the presence of midline anomalies in three subtypes: group I (septal agenesis, 23 patients), group II (abnormal corpus callosum, seven patients), and group III (no midline brain defects, eight patients), and the association between brainstem and midline abnormalities was investigated (Fischer exact test). Finally, we studied the association between brainstem involvement and clinical features (Chi-square and Fisher exact tests).
Results
Septo-optic dysplasia patients with brainstem abnormalities (group A) presented reduced AP pons diameter compared to controls (p_B<0.0001) and to group B (p_B=0.012), and higher M/P ratio compared to controls (p_B<0.0001) and to group B (p_B<0.0001); their AP medulla oblongata diameter (p_B=0.001), height of the pons (p_B=0.00072) and of the vermis (p_B=0.0009) were shorter than controls. Six out of 21 patients with brainstem abnormalities (group A) presented thickening of the quadrigeminal plate with aqueductal stenosis and triventricular hydrocephalus (surgically treated in all patients), and three of them also had agenesis of the epithalamus (i.e., pineal gland, habenular trigone and posterior commissure). There was a statistically significant

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

association between brainstem abnormalities and corpus callosum dysgenesis (p = 0.011) and developmental delay (p = 0.035), respectively.
Conclusion
Midbrain-hindbrain abnormalities are a significant, albeit under-recognized, component of the SOD spectrum. Patients with these abnormalities are more likely to present with developmental delay.

Pituitary Hypoplasia with Absence of Internal Carotid Artery: Report of Two Cases

Nath, J.·Bawa, P.·Neimark, M.
SUNY Health Science Center at Brooklyn
Brooklyn, NY.

Purpose
We report two cases of a rare association of congenital pituitary hypoplasia with absence of left internal carotid artery.
Materials & Methods
A four-year-old Indian American girl with short stature, hypothyroidism and neurodevelopmental delay was evaluated for pituitary hypoplasia. MR imaging of brain and sella revealed absence of anterior pituitary gland with absence of normal flow-void of left internal carotid artery (LICA). MR angiography demonstrated absence of LICA in carotid canal with an anomalous intracavernous communication from right ICA supplying distal cavernous and supraclinoid LICA. A two-year-old boy with multiple congenital anomalies including VSD and single incisor underwent MR imaging of brain and sella. MR imaging demonstrated a small anterior pituitary gland suggestive of pituitary hypoplasia. Normal flow void of LICA was not seen. A prominent flow void was seen arising from cavernous right ICA and continuing as distal LICA supplying left anterior circulation.
Results
Association of congenital pituitary hypoplasia with ICA agenesis and trans-sellar anastomosis, an extremely uncommon anomaly.
Conclusion
The internal carotid artery develops in the 4^{th} embryonic week while the pituitary primordial develops in 3^{rd} to 4^{th} week. Rare association of absence of one internal carotid artery and pituitary hypoplasia suggests a possible relationship of these two anomaly. Only a few case reports of this entity are reported in literature. Absence of internal carotid artery with pituitary hypoplasia may describe a new disease entity.

KEYWORDS: Pituitary gland, Carotid artery, Pituitary hypoplasia

MR Imaging of the Fetal Brain Using a Rapid 3D Steady-State Sequence

Williams, F.[1]·Griffiths, P. D.[1]·Jarvis, D.[2]·McQuillan, H.[2]·Paley, M.[2]·Armitage, P.[2]
[1]Royal Hallamshire Hospital Sheffield, Sheffield, UNITED KINGDOM, [2]University of Sheffield, Sheffield, UNITED KINGDOM.

Purpose
To evaluate the capacity of a rapid T2-weighted 3D sequence to diagnose fetal brain abnormalities by comparing the results with current 2D methods. We also have made assessments of the estimates of energy deposition using those methods.
Materials & Methods
Fifty pregnant women were included in this study under the guidance of the institutional review board. All of their fetuses had suspected brain abnormalities on ante-natal ultrasonography or were at increased risk of a brain malformation based on the results of an earlier pregnancy. All of the fetuses had a routine MR protocol that includes three orthogonal plane single-shot fast spin-echo and 2D steady-state sequences. In addition, a 3D rapid steady-state sequence of the fetal brain was performed (acquisition time approximately 40s) and the standard and 3D sequences were reported independently and the results compared. The SAR predicted by the scanner was recorded in 12 cases in order to estimate the energy deposited by the three sequences.
Results
The 3D rapid steady-state sequences produced diagnostic quality images in 41/50 (82%) of cases. All of the failures were in second trimester fetuses (9/26 - 35% failure rate). There was a discrepancy between the standard report and findings using the 3D sequence in 2/41 of the fetuses with good quality 3D imaging. The predicted SAR deposition of the 3D steady-state sequences was comparable to the single-shot fast spin-echo sequence.
Conclusion
Our initial assessments of a 3D rapid steady-state sequence to image the fetus are encouraging in terms of diagnostic information and acceptable energy deposition values. The high failure rate in second trimester fetuses probably relates to greater mobility of the smaller fetuses and improvements in the 3D sequence are required in terms of reduced acquisition time and higher resolution.

Brain Imaging Controversies: DTI in the Clinic: To Be or Not To Be

O-327

Pro

Roberts, T. P. L.
Children's Hospital of Philadelphia
Philadelphia, PA.

Presentation Summary
Diffusion imaging with MRI (including DTI, HARDI ...) provides at least two valuable technological advances: 1. fiber tracking of white matter pathways and structural connectivity, 2. microstructural characterization of regional white matter. Although, in many cases, "ground truth" interpretation is currently lacking, utility in characterizing pathology is clearly evident and can in many settings be of value in diagnosis, prognosis and treatment planning as well as in the study of processes of development and degeneration, once again placing the radiologist in a critical role at the interface of basic and clinical science, at the junction of technology and medicine.

Presentation Summary
Chronic cerebrospinal venous insufficiency (CCSVI) is a controversial, hypothetical condition recently proposed (Zamboni, et al.) to be an etiological factor in the pathogenesis of multiple sclerosis (MS); specifically, it has been suggested that the neuroimmunologic cascade of events that produces the focal plaques and diffuse neurodegeneration characteristic of MS is somehow triggered or promoted by chronically insufficient venous drainage from the brain and spinal cord. This idea is now the subject of intensive study and debate, not only with respect to its scientific merits but also regarding the ethical questions surrounding unproven therapies for incurable diseases (such as the “Liberation Procedure” for MS) and the roles of government, media, and public discourse in setting priorities for medical research. Chronic cerebrospinal venous insufficiency, dubbed “The Big Idea” by Dr. Zamboni, set off a social-media-fueled firestorm when it was first proposed in 2009 but the notion that MS has a vascular etiology dates back many decades. It has fallen out of favor for many valid reasons, not the least of which is the overwhelming and ever-growing mountain of evidence over the past few decades that MS is primarily an auto-immune disease. The CCSVI hypothesis thus resurrected an old debate between the vascular and immune theorists. The initial studies supporting the CCSVI hypothesis were lacking in proper blinding and control procedures, and yielded what seemed like impossibly perfect results, heightening levels of skepticism and making the debate especially contentious. Since then, other research groups have weighed in with several additional studies, some well blinded and controlled, some not. A recent meta-analysis found even the better studies to be highly inconsistent, yet still concluded that a link between venous abnormalities and MS may indeed exist. In the meantime, even in the absence of definitive proof that CCSVI not only exists as a genuine clinical entity but is causative rather than an epiphenomenon, clinical trials are ongoing to study the safety and effectiveness of venous angioplasty for MS. Most concerning is the fact that many patients are being treated outside of any clinical trial, with a few procedures leading to disastrous complications. The CCSVI debate is highly relevant to neuroradiologists as the diagnosis is based on imaging of the venous system, whether by ultrasound, computed tomography, magnetic resonance, or catheter angiography. Much of the discussion now surrounds not only the entity of CCSVI itself but the relative merits and drawbacks of the various imaging modalities in making this controversial diagnosis. The remarkably wide range of normal variation in venous anatomy and physiology also is central to the debate. This

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

presentation will put the "con" into the CCSVI controversy; the studies to date will be summarized and the presenter will show, by a preponderance of the evidence (as the lawyers like to say), that CCSVI is a proverbial blind alley in the search for an MS cure. Disclaimer: Please note that the presenter was assigned to the "con" side of this debate by the session organizers. He is currently the PI on a carefully blinded CCSVI study funded by the National Multiple Sclerosis Society, which he is conducting with no preconceived expectations; he will let the data speak for themselves when they become available.

Head and Neck Controversies: To Fat-Sat or Not to Fat-Sat: Post Contrast Perineural Tumor

O-339

Pro

Shatzkes, D. R.
Lenox Hill Hospital
New York, NY.

Presentation Summary
The search for perineural tumor spread (PNTS) is one of the most challenging undertakings of the head and neck radiologist. It requires detailed knowledge of anatomy and tumor behavior, and intense scrutiny of imaging studies. Optimizing technique is critical. While all agree that contrast-enhanced MRI is the modality of choice for detecting PNTS, there is some disagreement with regard to the optimal sequences utilized. The controversy revolves around the skull base, and the fact that this area, which includes the foramina that transmit the cranial nerves between the extracranial and intracranial compartments, is composed of bone and air-containing structures, both of which can incite susceptibility artifact. These artifacts may be exaggerated when fat-suppression techniques are applied. On the flip side, high signal fat within skull base marrow, the neural foramina, and in the soft tissues below the skull base may serve to diminish conspicuity of pathologic contrast enhancement within cranial nerves, one of the imaging hallmarks of PNTS. It is my opinion, and one I believe is shared by the majority of my colleagues, that the benefits of fat-suppression, with indisputable advantage along the extracranial course of the cranial nerves, outweigh its costs. This differential has increased since my highly esteemed colleague Dr. Curtin wrote his editorial on the topic in 2004. Though the use of 3T scanners has increased in the interim, improvements in fat-suppression techniques have reduced the prevalence and severity of degradation by susceptibility artifact. Additionally, most protocols utilized in H&N tumor mapping and the search for PNTS include a contrast-enhanced whole brain sequence which provides an opportunity to assess skull base foramina and associated intracranial structures like the cavernous sinuses and Meckel cave in the absence of fat suppression. In summary, the increased conspicuity of the enhancing cranial nerve against suppressed fat of the skull base marrow and adjacent fatty soft tissues is worth the cost of the negligible increase in susceptibility artifact due to fat suppression. Let's see what Dr. Curtin has to say. It's always worth hearing.

Quality in Radiology

Blackmore, C.
Virginia Mason Medical Center
Seattle, WA.

Presentation Summary
Higher quality in radiology is an opportunity to improve care and lower costs. In this presentation, I will discuss the multiple aspects of quality in radiology, both technical and professional, including how quality can be measured at the individual and institutional levels. I also will relate radiology quality to national trends and initiatives, contrasting a quality driven health care market from one driven solely by cost. Finally, I will highlight opportunities for quality improvement projects, and how radiologists can both be involved with and benefit from quality initiatives.

Clinical Trials in INR

Derdeyn, C. P.
Mallinckrodt Institute
St. Louis, MO.

Presentation Summary
The clear challenge facing medicine in general is proving the value of what we do: for us in neuroradiology that means the value of imaging and image-guided intervention in improving patient outcomes. In the past, we have been focused on innovation and bringing new imaging techniques and interventional devices to the clinical arena. This is important and this activity was rewarded under the fee for service model. Accountable care organizations, presently being piloted, will reward the system for the outcome of individual patients. These systems will make decisions regarding individual patient care based on what has been proven to improve outcome. This may be algorithm-based. We know that what we do has enormous impact on patient care and patient outcomes. For much of what we do, however, we lack high-level evidence that this is the case. Clinical trials, and in particular randomized clinical trials, are the coin of the realm for proving efficacy. In this talk, I will focus on why randomized trials are so important, using recent examples of studies in our domain with profound impact. Nonrandomized trials and registries may identify subgroups with better outcomes, but this does not necessarily reflect a benefit from a procedure. The recent endovascular stroke trials are a case in point. There is great interest in comparative effectiveness research as well. How these types of studies might work in the cerebrovascular is not clear, but are important to consider. Finally, we will review areas for future research in stroke and cerebrovascular disease relevant to our field.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

MR Patterns and Translational Research in Two New Entities of Mitochondrial Encephalomyelopathy

Valk, J.
Free University Hospital
Amsterdam, NETHERLANDS.

Jaap Valk, MD, PhD received his education from the State University, Leiden and Stichting Klinisch Hoger Onderwijs Rotterdam. Dr. Valk is curently a neuroradiologist at MRI Centrum, Amsterdam, Rotterdam. He is credited with more than 15 books on neuroradiological, psychiatrical and radiological subjects and has published more than 200 scientific articles in leading journals. Dr. Valk has had postgraduate courses and given invited lectures at many conferences. He is a member of 15 (Dutch, European, American and other International) Scientific Organizations. Dr. Valk was Knighted by the Queen of the Netherlands, June 2006: Knight in the order of the Dutch Lion (Ridder in de Orde van de Nederlandsew Leeuw).

Presentation Summary
Systematic and computer-assisted MRI Pattern Recognition helped us to detect a number of so far unclassified white matter disorders (Marjo van der Knaap, Jaap Valk: Myelination and Myelin disorders, 3d edition, Springer Verlag, Berlin). This was followed by research into genetics and analysis of disease mechanisms. In this presentation we will focus on two newly described mitochondrial disorders with autosomal recessive inheritance, LBSL (leukoencephalopathy with brain stem and spinal involvement and elevated lactate) and LTBL (leukoencephalopathy with thalamic and brain stem involvement and elevated lactate), of which the mutated genes were identified. Long-term followup showed unexpected phenotypic variation.

RSNA MIRC Teaching Files on Tablets

Flanders, A. E.
Thomas Jefferson University Hospital
Philadelphia, PA.

Presentation Summary
This presentation will provide an overview of the traditional radiology teaching file and the transition to web-based solutions in the now filmless radiology department. The presentation will feature the RSNAs MIRC Teaching File System software which is freely available and provides a feature-rich turnkey solution to anonymize images and author teaching file cases. It uses a patient-centric workflow that automatically organizes cases with multiple exams into a coherent chronological timeline. The software features an easy-to-use basic and advanced authoring template system and an automatic anonymizer for DICOM data as well as burned-in pixel data. It has a powerful data engine which can search for combinations of metadata in large collections and display the most relevant cases in seconds. There are modules for creation of self-study quizzes and a feature for creating conferences through a "shopping-cart" model. Moreover, the software has functionality to share cases locally or to your myRSNA account. Cases can be exported individually to the user desktop as individual images or as a Powerpoint file which can be used directly. The participant will have the opportunity to "kick-the-tires" of the RSNAs public MIRC Teaching File portal which catalogs cases from a number of public libraries worldwide. The participant also will learn about the online MIRC resources which provide easy-to-follow instructions for obtaining and installing the software, setup and configuration as well as authoring and searching. Participants should bring their favorite wireless device to the session (preferably a laptop or a slate) to maximize the experience.

MR Spectroscopy

Brandao, L. A.
Clinica Radiologica Luis Felippe Mattoso
Rio De Janeiro, BRAZIL.

Presentation Summary
The first thing we will discuss in this presentation is what we need to start the service. The answer for that question is motivation! We want to do it. And the reason for that is because we know magnetic resonance spectroscopy (MRS) really makes a difference in many clinical situations! Magnetic resonance spectroscopy (MRS) is a useful technique to further access various intracranial diseases, particularly to specifically determine which major category of disease is manifest by the observed lesion (neoplastic, inflammatory, ischemic⋯). A few disease processes such as Canavan's disease and nonketotic hyperglycemia have distinct MRS profiles that may allow the precise diagnosis. In the case of rim-enhancing lesions, the spectral pattern permits differentiation of pyogenic abscess from tumors by demonstrating the presence of amino acid peak (0.9 ppm) in abscesses. MR spectroscopy not only helps to distinguish infective from noninfective lesions but also may give information on the type of infective agent, which may guide the clinician to initiate appropriate antibiotic therapy, while the pus culture results are awaited. So, when appropriately incorporating MRS into the neuroradiologic evaluation, this technique will produce relevant information to radiologists and clinicians for their understanding of adult and pediatric neurologically based disease processes. Now that we have demonstrated MRS is a powerful technique that can improve our diagnostic capability, in order to implement MRS in our practice, we need be familiar with some technical issues, such as: 1-Magnetic field strengths - since the main objective of proton MRS is to detect weak signals from metabolites, a minimum of 1.5T is advised; 2-Protons (^{1}H) are the most used nuclei for clinical applications of MRS in the human brain; 3-Single voxel and multivoxel MRS- what should be my choice? 4-PRESS x STEAM- which one is better? 5-What is necessary to obtain a diagnostic quality spectra? All of the previously mentioned issues will be addressed. Finally,

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

to implement MRS in our service we also need to be familiar with the main metabolites and their meaning. We need to know spectra is age specific, parameter specific and region specific, which means the metabolites observed in the spectra are related to patient's age, the technique employed in terms of TE and TR and the region where the voxel was placed. Finally, we need to know that some differences will be observed in the spectra obtained in a 1.5T x 3T. Now, we can get started!

O-353 **5:15 PM - 5:30 PM**

fMRI

Shah, G. V.
University of Michigan
Ann Arbor, MI.

Presentation Summary
Mapping of various brain functions before surgery was mainly by structural MRI and surface anatomy. Physiologic tests like WADA could determine laterality of brain for language function, but was deemed invasive, expensive and elaborate. Intraoperative electrocorticography and direct cortical electrical stimulation (DCES) are very precise tests, but utilize much precious OR time, require a large team and can be challenging, especially for language function. Advent of fMRI has allowed detailed mapping of various brain functions and fusing them with structural images result in precise localization. This is an attractive alternative to more invasive and elaborate older tests for brain mapping. Having a clinical fMRI service can add a great value to a clinical radiology service; it can enhance its utility and engender greater confidence in radiologists' ability to help a neurosurgeon. However, the changeover poses challenges for both the radiologist and the neurosurgeon. The challenges include logistical challenges, scheduling challenges and personnel challenges. Technical issues related to conducting the test, postprocessing the test and delivering the test to neurosurgical navigation program should be resolved beforehand. There is a diverse vendor pool for different moving parts and components of the operation, which should be integrated well. Matters related to operational efficiency, physician communication and education also should be resolved in an efficient manner. Addressing and overcoming these challenges while starting a new fMRI service, while imparting excellent fMRI maps can win the trust and confidence of referring physicians and translate in increased efficiency and enhanced work flow.

O-354 **5:30 PM - 5:45 PM**

CT Perfusion

Wintermark, M.
University of Virginia
Charlottesville, VA.

Presentation Summary
I will present a practical approach to implement a new imaging service at an institution, taking perfusion CT as an example.

O-355 **5:45 PM - 6:00 PM**

MR Perfusion

Preece, M. T.
Radiology Imaging Associates
Denver, CO.

Presentation Summary
MR perfusion imaging can be a simple and valuable adjunct in tumor analysis. A pragmatic approach to the interpretation of MR perfusion imaging as it relates to tumor will be presented, particularly geared toward the private practice radiologist. Discussion will include basic perfusion principles as well as several examples from clinical practice.

O-356 **6:00 PM - 6:15 PM**

DTI and Tractography

Chepuri, N. B.
Abbott-Northwestern Hospital
Minneapolis, MN.

Presentation Summary
I will discuss the methods that can be used to successfully implement an advanced MRI algorithm such as DTI into a private radiology practice.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

(37) General Programming: How Does the Brain Think? From Cytoarchitecture to Neurotransmission and Imaging

O-357 **7:30 AM - 8:00 AM**

Cortical Chemoarchitecture

Zilles, K.
Institute of Neuroscience and Medicine
Jülich, GERMANY.

Presentation Summary

Transmitter receptors are key molecules of neurotransmission and connectivity. Their *regionally specific distribution patterns* differ between sensory, motor and multimodal association areas as well as between various areas within each of these major functional groups. The receptor-based regional segregation of the cerebral cortex is further differentiated by the *layer specific distribution patterns* of receptor densities. Thus, mapping of transmitter receptor distributions provides data for understanding the molecular basis of cortical organization and connectivity. Borders of cortical areas and layers can be precisely defined by localized changes of the density of single or multiple receptor types calculated in single cortical layers or averaged over all layers. In most cases, receptorarchitectonic borders are found at precisely the same positions, where borders are also detectable in cytoarchitectonic, axonal tracing or functional neuroimaging studies as well as analysis of fibrearchitecture. This finding underlines the representation of connectional aspects by receptor distribution patterns. Receptorarchitectonics can also reveal hitherto unknown cortical areas (e.g., in the Broca region). Furthermore, distribution patterns of multiple receptors in each single area show a specific balance between the various receptors, i.e. the "receptor fingerprint". The cluster analysis of fingerprints of cortical areas reveals segregated systems belonging to different functional modalities and embedded in a hierarchical organization.

The thalamic input to the primary sensory cortical areas terminates in layer IV and supragranular layers. We hypothesized, that this connectional aspect of is reflected by laminar distribution of receptors in all primary sensory areas. Very high densities of $GABA_A$, muscarinic M2 and α_2 receptors are found in the supragranular layers and particularly layer IV of the primary visual, auditory and somatosensory cortex. The cholinergic nicotinic receptor is nearly exclusively expressed in layer IV of the primary visual, auditory, and somatosensory areas. In sharp contrast to these primary sensory areas, adjoining secondary sensory areas display significantly lower densities of $GABA_A$, muscarinic M2 and α_2 receptors, but markedly higher densities of other receptors. Motor and multimodal cortices have a completely different, but regionally typical laminar distribution pattern.

In conclusion, regional and laminar multiple receptor distribution patterns provide a comprehensive overview of known and novel organizational principles of cortical connectivity.

O-358 **8:00 AM - 8:30 AM**

Specific Brain Circuits, Default Networks and Task Networks

Schmahmann, J. D.
Massachusetts General Hospital and Harvard Medical School
Boston, MA.

Dr. Jeremy D. Schmahmann is Professor of Neurology at Harvard Medical School and Neurologist at the Massachusetts General Hospital where he is Director of the Ataxia Unit, a member of the Cognitive Behavioral Neurology Unit, and Director of the Laboratory for Neuroanatomy and Cerebellar Neurobiology. He received his medical degree with distinction at the University of Cape Town, completed residency in the Neurological Unit of Boston City Hospital, and postdoctoral fellowship in the Department of Anatomy and Neurobiology at Boston University. Dr. Schmahmann's research focuses on anatomical substrates of cognition. He pioneered the role of the cerebellum in intellect and emotion, and received the Norman Geschwind Prize in 2000 from the American Academy of Neurology and the Behavioral Neurology Society, and the American Neurological Association's Distinguished Neurology Teacher Award in 2008. He is a Fellow of the American Academy of Neurology, and the American Neuropsychiatric Association. He has been cited in The Best Doctors in America since 1996. His >175 publications include The Cerebellum and Cognition (Academic Press), MRI Atlas of the Human Cerebellum (Academic Press), Fiber Pathways of the Brain (Oxford University Press), Cerebellar Disorders in Children (Mac Keith Press), and Handbook of the Cerebellum and Cerebellar Disorders (Springer).

Presentation Summary

It is premature to believe that we know precisely how or why humans are endowed with the inner workings of the mind. There is sufficient anatomical, imaging, and clinical evidence available however, to allow for a consideration of the neural basis of the mental operations essential for thought. The constituent elements of the neural basis of

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

thought are the 20 billion neurons of the cerebral cortex arranged in multiple distinct areas and characterized extensively with respect to their morphologic and cellular specialization, the remaining 80 billion or so neurons of the subcortical nuclei and cerebellum, and the white matter paths that link these geographically distant areas into distributed neural circuits. The evidence from anatomical investigations in nonhuman primates of the existence and functional properties of these circuits receives support from functional MRI studies in humans showing activations in interconnected brain areas by task-specific conditions, and from resting-state functional connectivity MRI studies that reveal networks of brain areas active during the apparent brain-idling state and during directed cognitive processes. These functional studies are supported by the identification using diffusion tensor MRI in humans of white matter tracts that link cortical and subcortical areas, producing results in agreement also with analyses of these pathways in nonhuman primates. The question of how the vast, complex, and intricate neural architecture of the brain subserves as elusive a concept as thought is both intriguing and vexing. This lecture will attempt to address this question by considering first what we mean by thought, drawing on the insights of educators and philosophers. Next we will review the general and specific principles of brain organization (Schmahmann and Pandya 2006, 2008) and the nature of cortico-cortical and selected subcortical connections. We will draw on the principles of anatomical organization of the brain to provide an approach to understanding how the nervous system functions to support emotion, as well as trivial, contemplative and reflective thought, and deductive reasoning. Finally, we will discuss selected clinical scenarios that provide empirical evidence in support of these notions.

O-359 **8:30 AM - 9:00 AM**

Different Types of Neurotransmission

Naidich, T. P.
Mount Sinai Medical Center
New York, NY.

Presentation Summary
Thought is the net result of the underlying architecture of the brain cortex (cytoarchitecture) and white matter (myeloarchitecture), the distribution of neurotransmitter receptors within the brain (chemoarchitecture), and the pattern of interconnecting regions that make up the multiple circuits and hubs of the brain (connectivity). This session explores the regional specializations of gray and white matter that are the anatomical underpinnings of thought, extends these to the synaptic, bulk transmission and electrical synchronizations by which regions communicate, and presents our current theories as to how these interact to achieve the task-directed activity, emotional feelings and cognitive accomplishments that are the human mind.

Imaging as Cash Cow or Cooked Goose? Thriving in a New Era of Neuroradiology

Sorensen, A.
Siemens Healthcare
Malvern, PA.

Imaging has had a very strong track record of innovation but also is perceived as being an expensive and often overused family of technologies. What does the future hold for imaging? How will evolving reimbursement models impact the demand for what neuroradiologists do? What are the key steps we as a specialty need to take in order to remain relevant in the years ahead? This presentation will discuss potential answers to these questions based on the evolving framework of medical care in the United States.

Brain - Part I: Brain Tumor: Imaging Pearls

Fatterpekar, G. M.
New York University School of Medicine
New York, NY.

Learning Objectives
Upon completion of this presentation, participants will be able to:
1) Highlight distinguishing features of vasogenic and cytotoxic edema.
2) Discuss important tumor mimics including subacute infarction, vasculitis, inflammatory and demyelinating conditions. Provide the attendee with certain key distinguishing features to help differentiate tumor mimics from tumor.
3) Discuss imaging features to distinguish primary neuroglial neoplasms from metastasis.
4) Discuss imaging features to distinguish low-grade from high-grade neoplasms.
5) Discuss key imaging features that can help the neuroradiologist suggest the pathology of the underlying neoplasm.
6) Discuss tumor recurrence from treatment-induced changes including pseudoprogression and pseudoresponse.

O-369 **11:45 AM - 12:15 PM**

Brain - Part II

Filippi, C. G.
Columbia University College of Physicians and Surgeons
New York City, NY.

Learning Objectives
Upon competion of this presentation, participants will be able to:
1) Describe classic imaging findings and clinical presentations of both common and uncommon demyelinating diseases of the brain.
2) Explore the role of MR imaging in disease management in demyelinating disease and the utility of advanced neuroimaging techniques in framing differential diagnoses.
Presentation Summary
This session will present cases of demyelinating disease of the central nervous system beginning with a classic case of multiple sclerosis (MS) in which discussion will focus on reviewing the most recent revised McDonald Criteria in 2010 as well as considering newer MR techniques to address cortical lesion detection. Current issues in therapy and the use of MR in patient management are going to be highlighted. Additionally, more challenging cases of multiple sclerosis will be shown including tumefactive MS lesions and Marburg variant or malignant multiple sclerosis. In these cases, there will be emphasis on the use or potential shortcomings of advanced imaging techniques that may help in shaping the differential diagnosis. Complications of new therapies for MS including progressive multifocal leukoencephalopathy (PML) and immune reconstitution inflammatory syndrome (IRIS) associated with cessation of therapy following PML development will be featured. In the classic differential of multiple sclerosis, there are other considerations. Additional cases that are grouped in MS traditionally include Lyme and acute disseminated encephalomyelitis (ADEM), and there will be a discussion on current thinking in ADEM. Neuromyelitis optica (NMO), long considered a variant of MS, will be featured as a case because NMO is being recast currently as a distinct entity with its own unique diagnostic criteria. Lastly, a final case of Susac syndrome will be shown as it is commonly misdiagnosed as MS or ADEM, and its classic clinical features and imaging findings will be demonstrated.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

O-370 **1:15 PM - 1:45 PM**

Evaluation of the Patient with a Thyroid Mass: Best Practices

Aiken, A. H.
Emory University Hospital
Atlanta, GA.

Presentation Summary
The evaluation of thyroid nodules and masses is a broad, complex and controversial topic. This presentation aims to look at the current evidence for three of the most common clinical scenarios: 1. Incidental thyroid nodule on CT or MRI: When to recommend ultrasound or biopsy? 2. Palpable thyroid mass: What is the best test? 3. Preoperative evaluation of a thyroid mass with cancer diagnosis: What is the best test? Thyroid nodules are extremely common, with approximately 50% at autopsy. Most of these nodules are less than a centimeter. Thyroid cancer also is common, but not nearly as common as thyroid nodules, with approximately 2-5% at autopsy. Thyroid cancer incidence is on the rise without a significant change in mortality rate. There is some evidence that a rising incidence of subcentimeter papillary thyroid cancer results from increased detection on CT. There are no current guidelines for the management of these extremely common incidental thyroid nodules. This presentation will review the current literature and suggest some practical guidelines to help radiologists decide how to report these nodules. The combination of size criteria and clinical risk factors such as age is the best approach to date. The common practice of using a 10 mm size threshold alone to recommend ultrasound (US) is arbitrary and results in excessive work-up of these incidental nodules, cost and patient anxiety. Current evidence suggests that a stratification approach, incorporating aggressive imaging findings, age younger than 35-40 years, and a15 mm cutoff for triaging work-up, may reduce this excess work-up of benign ITNs while capturing the same proportion of thyroid malignancies. Ultrasound is the study of choice for the evaluation of an intrathyroidal mass or nodule. CT has no signs that help to differentiate malignant from benign thyroid nodules and is therefore not the study of choice. The Society of Radiologists in Ultrasound (SRU) has developed ultrasound criteria to determine high- risk nodules and prompt fine needle aspiration (FNA) for diagnosis. The SRU recommends FNA for the following US characteristics: 1. >1 cm & microcalcification. 2. > 1.5 cm solid or coarse calcifications. 3. > 2 cm mixed solid & cystic components. 4. Nodule w/ substantial growth. 5. Nodule w/ abnormal cervical lymph nodes. The American Thyroid association (ATA) guidelines also currently recommend ultrasound as the preoperative study of choice for evaluation of uncomplicated thyroid cancer. However, cross-sectional imaging should be recommended for cases with: 1. Aggressive pathology. 2. Clinical signs of extra-thyroidal extension: vocal cord palsy, fixed mass, dysphagia, respiratory symptoms, etc. 3. Lateral compartment lymphadenopathy by palpation or ultrasound. Many thyroid cancer experts also would consider cross-sectional imaging for ultrasound or palpable central compartment lymphadenopathy.

O-371 **1:45 PM - 2:15 PM**

Imaging Evaluation of CSF Leak: What Study to Order

Hudgins, P. A.
Emory University School of Medicine
Atlanta, GA.

Presentation Summary
Evidence-Based Practice: integration of individual clinical expertise, patient values, and the best research evidence into the decision-making process for patient care. For diagnosis of CSF leak EB research is lacking for virtually every modality we currently use! Therefore, discussion of imaging modalities that follows is based on individual clinical experience/expertise. Our approach was developed by consensus between ENT and Neurological Surgical Departments and Head and Neck Radiology Section. **Cerebrospinal fluid (CSF) leak** is defined as extradural CSF extending through a dural and arachnoid defect, into the paranasal sinus cavities, nasopharynx, mastoid air cells or middle ear cavity. Intraspinal CSF leak can occur either through a tear in a nerve root sleeve or directly through meninges, and clinical presentation is usually a low pressure headache syndrome . Only CSF leaks above the foramen magnum will be discussed. **Rhinorrhea:** CSF leak into the nasal cavity or paranasal sinuses. **Otorrhea:** CSF leak into mastoids or middle ear cavity. **Clinical presentation** is variable, but common symptoms are oto or rhinorrhea and patient often complains of a salty taste or nasal drip that does not respond to nasal vasoconstrictors. Chronic mastoid or middle ear opacification unresponsive to tympanostomy tubes, is presenting complaint when the leak is in the tegmen tympani or mastoideum. If the leak is high volume, daily low pressure headaches may occur, worse at the end of the day. Prior to modern imaging techniques and improved recognition of the syndrome, meningitis was common, but current rates are probably lower than 10%. However, meningitis is a dreaded complication with dramatic neurologic sequelae. **Etiology for CSF leak** is

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

either congenital or acquired. **Congenital leaks** usually are due to a meningocele or meningoencephalocele and generally manifest early in life. Inner ear anomalies may be associated with peri or endolymph leaking into the middle ear, often mixed with CSF. **Acquired leaks** are much more common. Postoperative and post-traumatic leaks account for > 60% of all leaks. Spontaneous leaks are increasing in frequency, especially in the United States where average BMI is rising. **Diagnosis** can be straightforward, or difficult and complicated. It is critical that the presence of a leak be proven prior to imaging, and the first step should be to collect 1-2 ccs to check for ***B_2*-transferrin or Beta-trace protein, specific to CSF,** for immunoelectrophoresis protein assay. **Imaging should not be used to diagnose a CSF leak, but to find the source of the leak. PICO: Problem/Intervention/Comparison/Outcome PICO:** Known CSF leak/Diagnostic test/ 1) nuclear medicine cisternogram vs 2) high-resolution CT versus 3) CT-cisternogram versus 4) MRI brain versus 5) MR-cisternogram versus 6) intrathecal gadolinium cisternogram. **Nuclear medicine - cisternogram.** Rarely necessary, only in questionable cases. Limitations: patient must be actively leaking, lacks anatomical detail. **High-resolution computed tomographic (CT) scan of skull base**, including cribriform plate, ethmoid sinus roof, all walls of sphenoid sinus, mastoid complex, region of geniculate ganglion and middle ear complexes. Include tympanic cavity even if rhinorrhea and not otorrhea is described. Technique is critical, must be thin-section, no patient motion, bone algorithm. Reformations in all planes, even oblique, to assess for skull base bony defect. Careful review on work-station, as skull base defect may be small. Standard sagittal and coronal reformations may not be best plane to display defect. **Imaging findings:** Bone defect, fluid in dependent portion of sinus, or mucosal thickening at level of defect from CSF beneath intact mucoperiosteum. Bi-dimensional measurement of defect, precise description of location help plan repair. Active leak at time of study NOT required. **CT-cisternogram.** Only required if > 1 bone defect present on noncontrast CT, or if confirmation is requested by surgeon. Pt must be actively leaking or leak can be exacerbated by Trendelenburg position or other maneuver on day of study. Start with non-contrast high-resolution CT. LP - 5-7 ccs intrathecal contrast, placement confirmed at fluoroscopy. Perform provocative maneuvers to see leak. Repeat CT, prone coronal, within one hour of LP, so contrast will pool in dependent portion of sinus, mastoid or middle ear, or nasal cavity. Prone position may exacerbate leak by increasing intracranial pressure. For difficult or small leaks, repeat high-resolution CT, supine, after prone study so that reformations can be performed. Review soft tissue algorithm to assess for meningocele. **MRI brain and cisternogram.** Should not be primary diagnostic modality. Always obtain MR to see if soft tissue in sinus is from intra-cranial compartment, ie, meningocele, or meningoencephalocele. Encephalocele or meningocele usually associated with encephalomalacia at site. Dural enhancement with contrast MR is not uncommon and does not always mean meningitis is present. **Intrathecal gadolinium.** Promising early results with this technique suggest high sensitivity for detecting skull base and spinal leaks. Pre-LP do T1 and T2 imaging through skull base in three planes. 0.5 ml intrathecal gadolinium. Repeat scans with T1 fat saturation techniques after LP. Scans can be obtained up to 24 hours after LP to enable detecting low volume leaks.

O-372 **2:15 PM - 2:45 PM**

Imaging of Hyperparathyroidism: An Era of Modalities and Multiple Phases

Hoang, J. K.
Duke University Medical Center
Durham, NC.

Presentation Summary
1. The role of parathyroid imaging is to accurately localize the parathyroid adenoma in eutopic and ectopic locations, and to detect multiglandular disease. The traditional modalities for parathyroid imaging are cervical ultrasound and nuclear scintigraphy. 4D CT has advantages common to both ultrasound and scintigraphy and is useful as a second-line investigation. 2. The 4D CT protocol is comprised of multiple phases (typically two to four phases) and reformatted images in three planes. 3. Characteristic enhancement pattern for a parathyroid adenoma on 4D CT is peak enhancement on an arterial phase, washout of contrast from the arterial to delayed phase and low attenuation on the noncontrast images. The morphologic imaging findings are central low attenuation change, lobulated margins, and a feeding artery or enlarged draining vein. 4. Interpretation of parathyroid imaging is challenging because of ectopic lesions, multiglandular disease, and lesion mimics such as thyroid nodules and lymph nodes. The radiologist's ability to detect a parathyroid lesion on 4D-CT and differentiate it from mimics can be increased with appreciation of the typical enhancement characteristics and morphologic features.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

(41) Special Session: Human Papillomavirus and Head and Neck Cancer

O-373 **1:15 PM - 1:35 PM**

The Epidemic of HPV-Associated Oropharyngeal Cancer

Sturgis, E. M.
The University of Texas M.D. Anderson Cancer Center
Houston, TX.

Dr. Sturgis joined the faculty of the Department of Head & Neck Surgery as assistant professor with a joint appointment in Epidemiology at The University of Texas M.D. Anderson Cancer Center in 2000. He completed a Master of Public Health in 2004 and was promoted to associate professor with tenure in 2005 and full professor with tenure in 2010. His principal research interests are human papillomavirus and molecular epidemiology of carcinomas of the head and neck region. His work has generated numerous interviews with the lay press, including mention in U.S.News and World Report, the New York Times, and the Wall Street Journal. Additionally, he has explored these trends and potential genetic risk factors for HPV-associated cancers in additional publications. His principal clinical interests are sarcomas of the head and neck region and differentiated thyroid cancer. He has over 190 peer-reviewed publications and over 40 invited reviews/book chapters. He has been/is principal investigator on a NIH R03, an American Thyroid Association grant, a Fanconi Anemia Research Fund grant and project leader on a NIH U01 grant, as well as co-investigator on 3 NIH R01 and 2 NIH SPORE grants, co-mentor on a NIH K07 and recipient of three career development awards.

Presentation Summary
This presentation will review the epidemiology of the epidemic of human papillomavirus (HPV)-associated oropharyngeal cancer. This discussion will cover the basics of HPV oncogenesis as well as the behaviors associated with this disease. The typical clinical presentation of HPV-associated oropharyngeal cancer will be reviewed. Much of this presentation will cover the dramatic demographic shifts and public health impact of the rising incidence in oropharyngeal cancer in the U.S.

O-374 **1:35 PM - 1:55 PM**

Imaging of HPV-Related Oropharyngeal Cancer

Ginsberg, L. E.
M.D. Anderson Cancer Center
Houston, TX.

Presentation Summary
HPV-associated oropharyngeal squamous cell carcinoma is an increasingly recognized and distinct clinic-pathologic entity. This presentation will review the MD Anderson experience of imaging findings associated with this malignancy, to include characteristics that may distinguish the HPV +ive vs. HPV –ive primary malignancy, the issue of cystic nodal metastases typical of this diagnosis and the associated problem of misdiagnosis, and finally, the imaging spectrum of atypical nodal patterns and distant metastatic sites that are increasingly being observed with HPV-associated oropharyngeal cancer.

O-375 **1:55 PM - 2:15 PM**

Treatment Implications of HPV-Associated Oropharyngeal Malignancy

Rosenthal, D. I.
The University of Texas M.D. Anderson
Houston, TX.

Presentation Summary
There is an epidemic of oropharynx cancer and a shift in demographics from tobacco-related to HPV-related.
The standard AJCC staging system based on TNM categories is no longer predictive of prognosis in the HPV era.
I will discuss treatment selection including RT, chemotherapy, and surgery. New techniques including endoscopic surgery and proton therapy will be discussed.
Since patients with HPV+ oropharynx cancers have a better prognosis than tobacco-related cancers, current clinical trials focusing on treatment de-intensification to reduce toxicities and promote better functionality will be discussed.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

O-376 **1:15 PM - 1:40 PM**

The Future of Spinal Imaging: Is There Still Room for Plain Films?

Van Goethem, J. W.
Antwerp University Hospital
Antwerp (Edegem), BELGIUM.

Presentation Summary

A plethora of imaging techniques is available to visualize the spine. The most recent techniques, especially magnetic resonance imaging (MRI), allow in detail visualization of spinal structures and have been able to depict spinal pathology in detail and accurately. Awareness of the possible harmful effects of ionizing radiation used in diagnostic spinal imaging have further weakened the position of plain film spinal imaging as an imaging modality. One might wonder if there is still room for plain film spinal imaging in 2013. In this presentation I will emphasize situations where plain films still have a key role in spinal imaging. Using new technical developments radiation levels can be kept to a minimum. Careful use of plain films for well defined indications is still very valuable in the diagnostic work up of several disease entities. Moreover, plain films are still the only imaging method, besides niche techniques, allowing to image the patient standing with optional flexion/extension films. I will show imaging algorithms that will allow radiologists to determine exactly for what indications plain film spine imaging should be used today.

O-377 **1:40 PM - 2:00 PM**

Advanced Imaging: The Next 50 Years

Thurnher, M. M.
Medical University Vienna
Vienna, AUSTRIA.

Presentation Summary

Findings on conventional MRI in spinal cord diseases are not specific to the severity of cord damage and are unable to discriminate potentially reversible edema and/or ischemia from irreversible changes. Despite significant expansion of imaging capabilities, the spinal cord has continued to pose great challenges. The introduction of high-field MRI has substantially altered spinal cord imaging. *DTI metrics* and *fiber tracking (FT)* allow more accurate characterization of intrinsic integrity of tissues including cellular density and architecture. After initial technical problems, good solutions that have overcome some of the initial challenges have helped to incorporate DWI and DTI into everyday clinical MR routine. *Perfusion MR imaging (PWI)* may provide a significant advantage in the diagnosis of neoplastic or infectious processes in the spine. *Ultrafast MRI* has been shown to drastically decrease scan time. Today, we're just at the beginning of "Sci-Fi spinal imaging". It is more than a prophecy that the next generation imaging techniques will provide an excellent set of biomarkers for understanding diseases of the spinal cord.

O-378 **2:00 PM - 2:20 PM**

Novel Imaging of Disks

Hackney, D. B.
Beth Israel Deaconess Medical Center
Boston, MA.

David Hackney is Chief of Neuroradiology at Beth Israel Deaconess Medical Center and Professor of Radiology and Assistant Dean for Faculty Development at Harvard Medical School. He has served HMS in numerous capacities including co-chairing the Faculty Development Working Group for the Medical Education Reform process, and chairing the Faculty Diversity Committee. Dr. Hackney has published over 170 original manuscripts, as well as editorials, reviews and chapters, and hundreds of abstracts. His academic work has focused on spine and spinal cord imaging, with particular interest in MR imaging of spinal cord injury. ***He has served on numerous NIH federal advisory boards including the Trauma Task Force, the Medical Imaging Study Section (MEDI-regular member) for the Center for Scientific Review, the Training Grant and Career Development Committee (NST-regular member) for NINDS, and special emphasis panels for the NCI. He also has served as a member of the federal Food and Drug Administration, Radiological Devices Panel, Medical Devices Advisory Committee, for which he is now a Consultant. He was also a member of Veteran's Administration State of the Art Conference on Traumatic Brain injury.*** *He is a Past President of the American Society of Neuroradiology, and a fellow of the American College of Radiology and the International Society of Magnetic Resonance in Medicine. He consistently appears on lay "Best Doctors" lists. Dr. Hackney's primary research interest concerns MR imaging of spinal cord injury.*

Presentation Summary

Many years of study of the intervertebral disk, and advances in MR imaging in the last few decades, have shed considerable light on the complex degenerative process. It is clear that the changes in the composition of the disk are closely related to the stresses to which it is subjected and its nutrition. The disk loses its constituent

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

glyclosaminoglycans (GAG), loses water, and collagen and macromolecular degradation products accumulate in this nearly avascular tissue. All of the above alter the MR characteristics of the disk in reproducible ways. This means that we now have the ability to predict the macromolecular composition of the disk by employing a combination of MR methods. Even more exciting, there has been substantial progress in understanding the mechanical function of the disk, how it is changed by degeneration, and how degeneration progresses. With the ability to interrogate not only composition, but also structure, we can begin to predict degradation of disk function with MR. This opens the possibility of individualized treatment, better prediction of disease progression in the absence of treatment, and the response to therapy. Among the methods we will consider are approaches to estimating the content of water and GAG, integrity of the annulus fibrosus, mechanical stiffness and damping coefficient of the disk, and responses to loading. We will discuss T2, T1 and proton density maps, along with sodium imaging, magnetization transfer, chemical exchange saturation transfer (CEST), and diffusion methods.

O-379 **2:20 PM - 2:45 PM**

Ultra High Field and Novel MR Imaging in the Human CNS

Atkinson, I. C.
University of Illinois at Chicago
Chicago, IL.

Presentation Summary
The major challenge of healthcare today is the containment of costs without compromise of quality of care and hopefully with improved patient outcome. Imaging has been blamed as one of the cost drivers. This economic perspective requiring “more for less” may appear at odds with the introduction of new MR technologies, such as ultra-high field 7.0 and 9.4T MR scanners, hyperpolarization and quantitative metabolic MR imaging. However, this is only if these new technologies address the same clinical questions. A less pessimistic strategy is to address more pertinent clinical questions beyond those available from proton MR imaging. Metabolic MR imaging based on 23-sodium, 17-oxygen, 13-carbon, 31-phosphorus and 39-potassium have been demonstrated in the human and clinical applications are being evaluated. Quantification of signals into bioscales rather than image contrast allows numerical modeling that can provide valuable insight into disease processes not possible with anatomical imaging. Quantitative sodium imaging that provides direct measurement of tissue viability and cell density at clinically useful spatial resolution in less than 10 minutes will be demonstrated as a prototypical bioscale in the clinical setting of brain tumor management. But how will cost be managed? Technologies that can assess treatment responses in near real-time (i.e., during treatment) address the question of whether the therapy is appropriate. Patients who do not respond can be triaged into more effective therapies. Costs of ineffective and often expensive treatments thereby can be avoided early and the patient does not suffer untoward consequences of inappropriate therapy needlessly. Decisions as to treatment protocols no longer have to be based on population studies where survival is the clinical outcome measure but rather true personalized medical care can be delivered. Costs of such new technology are covered by the redistribution of costs from ineffective treatments and improved patient outcome. These new quantitative metabolic MR imaging methodologies will be described in relation to clinically relevant diseases of the central nervous system where better information can facilitate more effective medical management. Replacement of existing less effective procedures may be expected to make these new technologies cost neutral.

Diffusion-Weighted MRI “Claw Sign” in Differentiation of Infectious from Degenerative Disease – ASSR Mentor Award Winner

Patel, K.·Poplawski, M.·Pawha, P.·Naidich, T.·Tanenbaum, L. N.
The Mount Sinai Medical Center
New York, NY.

Purpose
Modic signal changes, a common observation in MR imaging, are signal intensity findings in vertebral body marrow adjacent to the endplates of degenerative disks. Type II and III patterns are easy to recognize and indicative of chronic degenerative disease. Type I Modic change is more likely to be clinically symptomatic and characterized by decreased signal on T1WI and increased signal on T2WI that can be difficult to differentiate from and often suggestive of vertebral osteomyelitis and diskitis (1). Of late, diffusion-weighted MR imaging (DWI) has been shown to be a useful tool in imaging of osseous and epidural spinal lesions, including spinal infection (2). In this retrospective observational study of patients who were referred for spinal MRI, we characterize and correlate the MRI appearance of spinal levels in patients with Modic I signal changes, and in patients with confirmed spinal infection, with particular attention to the presence or absence of the DWI “claw sign”.
Materials & Methods
Seventy-four patients with Modic I type endplate abnormalities were selected and classified into three groups: clinically confirmed diskitis/osteomyelitis (n=21), degenerative Modic I change (n=33), and suggestive of infection but clinically disproved (n=20). Each abnormal spinal level was evaluated in terms of MR endplate and disc signal changes, enhancement, and appearance on DWI (b value of 500s/mm2). The presence of diffusion “claw sign” was scored on a scale of 1=definite,

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

2=probable, 3=questionable, 4=absent (diffuse DWI signal).
Results
Type I changes in the absence of infection invariably correlated with a characteristic DWI "claw sign" of high diffusion signal at the boundary of the proliferative marrow process and the normal marrow, while patients with type I Modic signal and confirmed spondylodiskitis exhibited significant absence of the "claw sign" on DWI (average "claw" score of 1.21±0.07 vs. 3.67±0.17, p<0.01). Similarly, the group in which infection was initially suggested, but subsequently discounted, had an average score of 1.45±0.13. Suggestion of infection seemed to be related to the presence of high T2 signal in the disk space, which in this study had a high sensitivity, but low specificity for infection. On the other hand, absence of the "claw sign" (combined score 3 and 4) had a high sensitivity (90%), specificity (98%) and predictive values for infection.
Conclusion
DWI offers powerful characterization information in patients with Type I Modic MR signal changes and assists in the differentiation of degenerative disease from spondylodiskitis of the spine.

Performance Measures and PQI

Seidenwurm, D. J.
Radiological Associates
Sacramento, CA.

Presentation Summary
Performance measures are employed to improve patient care, especially in areas where gaps in care are documented in the literature. Performance measures in neuroradiology attempt to specify quality care in a manner that is reproducible among various practice sites, actionable by the measured physician, and, most importantly, relevant to the practice of neuroradiology and not excessively burdensome to report. Performance measures are based on high quality evidence as distilled in multispecialty guidelines, and tested in clinical settings prior to introduction. Performance measures are retired when all sites achieve a high level of performance, a uniform threshold is reached and remains stable, or if new evidence or clinical priorities change the ratio of benefit to cost in quality improvement.

O-381 **1:40 PM - 2:05 PM**

Accountable Care Organizations

Beauchamp, N. J.
University of Washington
Seattle, WA.

Norman J. Beauchamp Jr, MD, MHS, is Professor and Chairman of the Department of Radiology at the University of Washington. He holds degrees from Michigan State University (BS in Biology, MD) and The Johns Hopkins School of Public Health (MHS). He is also a Professor of Neurological Surgery and Industrial Engineering at the University of Washington. Dr. Beauchamp completed his radiology residency, neuroradiology fellowship and neurointerventional training at The Johns Hopkins Medical Institution. He joined the faculty at Johns Hopkins in 1996. While at Johns Hopkins, he served as Vice Chairman for Clinical Operations and Interim Chairman. In 2002, he assumed the role of Chairman of the Department of Radiology at the University of Washington. During his tenure, he also has served as President of the UW Physician Practice. Dr. Beauchamp's area of research emphasis has been in developing and applying MRI-based

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

advanced imaging techniques to extend the treatment window in acute stroke as well as using imaging to identify risk predictors of stroke and dementia. He was the recipient of the American Society of Neuroradiology Basic Science Fellowship Award and the American Roentgen Ray Society Scholarship. He is the Director of the Epidemiologic Studies Image Analysis Center in the Department of Radiology at the UW. The center has been primarily funded by the NIH National Heart, Lung and Brain Institute and at present is involved in the analysis of three multicenter cohort studies enrolling over 6000 individuals. He has served as a grant reviewer for the NIH, the RSNA R and E Foundation, and currently is on the grant selection Committee for the Walter H. Coulter Foundation Translational Research Partnership Awards in Bioengineering at the University of Washington. He has served as the Chair of the Radiology Research Alliance and as Chair of the Coalition for Bioimaging Research. His efforts as an educator have been lecturing in his area of research focus, participating in Radiology Society educational efforts, and in developing future leaders in Radiology. Pursuant to this, he recently co-edited the book, Radiology Business Practice, How to Succeed. He served on the Editorial Board for the journal Radiology. He has served as Chair of the American Roentgen Ray Society Education/CME Committee. Dr. Beauchamp is currently serving on the Board of Directors of the Society of Chairs of Academic Radiology Departments, The Executive Council of the American Roentgen Ray Society and previously was on the Board of the Association of University Radiologists. He is the incoming President of the American Roentgen Ray Society and President-elect of the Society of Chairs of Academic Radiology Departments.

Presentation Summary
The role of the neuroradiologist in an accountable care organization requires a greater focus on partnership, leadership and integration of care. In this presentation, we will emphasize essential tactics to ensure success in our new health care environment.

Infratentorial Tumors

Poussaint, T.
Boston Children's Hospital
Boston, MA.

Presentation Summary
Brain tumors are the most common solid pediatric tumors and are the leading cause of death in children from solid tumors. The estimated incidence of all childhood primary brain and central nervous system (CNS) tumors is 5.1 cases per 100,000 person-years. Approximately 4,300 new cases of childhood primary nonmalignant and malignant brain and central nervous system tumors will be diagnosed in the United States in 2013.(CBTRUS). Supratentorial tumors are most common in the first 2-3 years of life and infratentorial tumors are most common from age 4-10 years. In children older than 10 years, supratentorial and infratentorial are of equal frequency. When infratentorial tumors involve the posterior fossa they may present with the clinical symptoms of ataxia, dysmetria, headache, nausea, vomiting, neck pain or extraocular muscle impairment. If the tumor involves the brainstem, children may present with extraocular muscle impairment, facial paresis, swallowing problems, hemiparesis, quadriparesis, ataxia or dysmetria. The common posterior fossa tumors of childhood include medulloblastoma, cerebellar astrocytoma, brainstem glioma, and ependymoma. Less frequently diagnosed posterior fossa tumors in children are atypical teratoid/rhabdoid (ATRT) tumors, hemangioblastoma, dermoid-epidermoid tumors, acoustic schwannomas, meningioma, enteric cysts, teratoma and skull base tumors. Improvements in imaging, especially MR, has resulted in improved detection and treatment planning. The understanding of the known molecular genetics, histopathologic and imaging features of some of these tumors, including medulloblastoma, will be reviewed.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

O-385 **1:40 PM - 2:00 PM**

Supratentorial Tumors

Koral, K.
University of Texas Southwestern Medical Center at Dallas
Dallas, TX.

Presentation Summary
Approximately one-half of the pediatric brain tumors are supratentorial. The histopathology of pediatric supratentorial tumors are more varied compared to the cerebellar and brainstem tumors. In addition to the density/signal characteristics of the tumor, the age of the patient and location of the tumor are equally important parameters in forming a relatively short differential diagnosis. It is helpful to categorize the supratentorial tumors into i) Cerebral hemispheric tumors, ii) Sellar/ Suprasellar tumors, iii) Pineal region tumors while generating a differential diagnosis. Astrocytomas are the most common tumors of the supratentorial compartment, pilocytic astrocytomas (WHO grade 1) comprising the majority of them. The supratentorial pilocytic astrocytomas tend to be in the optic-hypothalamic region and are associated with neurofibromatosis type I. Intense enhancement of the solid component and cyst formation are features observed in more than one-half of the pilocytic astrocytomas. Facilitated diffusion is encountered almost universally in pilocytic astrocytomas and may be a valuable adjunct in diagnosis. Other less common astrocytomas include WHO grade 2 tumors such as pleomorphic xanthoastrocytoma and pilomyxoid astroctyoma. Anaplastic astrocytoma (WHO grade 3) is seen uncommonly in children. Gangiogliomas (usually WHO grade 1) is a peripheral tumor of the supratentorial compartment, such as desmoplastic infantile gangliogliomas (DIG) and dysembroplastic neuroepithelial tumors (DNET). Embryonal tumors (e.g., primitive neuroectodermal tumor, atypical teratoid/ rhabdoid tumor) generally show restricted diffusion. Craniopharyngioma is typically associated with cysts and calcifications of the sellar and suprasellar region in children. Germinoma and Langerhans cell histiocytosis of the suprasellar region generally present with diabetes insipidus and nonvisualization of T1 shortening of neurohypophysis. Pineal region tumors include germ cell tumors (e.g., germinoma) and pineal parenchymal tumors (e.g., pineoblastoma).

O-386 **2:00 PM - 2:20 PM**

Effects of Treatment

Rollins, N. K.
Childrens Medical Center
Dallas, TX.

Presentation Summary
In comparison to adults, pediatric brain tumors are rare. However, nearly 20% of pediatric solid tumors arise in the brain. Pediatric brain tumors differ from those seen in adults with respect to location and histologic type. Intracranial metastases from extracranial malignancies and CNS lymphoma are rare in children while the high-grade glial tumors of the cerebral hemisphere seen in adults are uncommon in children in whom infratentorial tumors of embryonal (e.g., PNET, medulloblastoma, etc.) and neuroepithelial tumors predominate. Neurotoxicity associated with pediatric brain tumors may result from the neurosurgical intervention, hydrocephalus, chemotherapy, and/or radiotherapy as many pediatric CNS tumors require radiation therapy for control. Conformational radiation therapy limits exposure of normal regional brain while maintaining or improving local tumor and potentially limiting the toxic effects of radiation on normal brain. As in adults, high-dose conformational radiation therapy may be associated with frank radiation-necrosis that simulates recurrent tumor, although radiation necrosis in uncommon in children. Medulloblastoma/PNET and atypical rhabdoid tumors (ATRT) are associated with occult leptomeningeal disease and tumor recurrence after chemotherapy. Whole brain irradiation with a boost to the tumor bed is needed either once the patient has reached three years of age or earlier if tumor progresses during chemotherapy. Radiation necrosis is a focal process within the tumor bed while radiation neurotoxicity is a global process. Radiation necrosis may present with seizures, altered mental status, neurologic dysfunction similar to that at initial presentation with the tumor, and signs of increased ICP. Diffuse radiation neurotoxicity may be acute, early delayed, or late onset and delayed. Acute neurotoxicity occurs one-six weeks after irradiation and presents with an acute encephalopathy. Early delayed changes occur one-four months after radiotherapy. Affected patients may be sleepy, encephalopathic, and show signs of increased ICP. Acute and early delayed complications are steroid responsive. Late delayed neurotoxicity occurs months to years after treatment and is associated with cognitive decline, personality changes, and gait disturbances and does not improve with steroid therapy. Radiotherapy is particularly deleterious to infants and children under three years of age. Younger age at time of treatment, larger port size, higher dose, and larger number of treatments contribute to the well known cognitive, endocrine and neurologic sequel; the most devastating long-term deficits are neurocognitive. Acute neurotoxicity and significant late treatment effects in long-term survivors of pediatric brain tumors are a substantial burden for patients, their families, and society and a major goal of pediatric cancer therapy is to maintain or improve cure rates while decreasing neurotoxicity. Discussion of neurotoxicity resulting from treatment of childhood cancer is incomplete without considering childhood acute lymphoblastic leukemia (ALL), one of the most common malignancies of childhood and more common than brain tumors. ALL is treated with methotrexate (MTX); a cell cycle-specific agent that inhibits the enzyme dihydrofolate reductase, preventing the conversion of folic acid to

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

tetrahydrofolic acid and inhibiting cell replication. Both high-dose intravenous MTX and intrathecal MTX are associated with demyelination, white matter necrosis, loss of oligodendroglia, axonal swelling, microcystic encephalomalacia, and atrophy relatively selective for the deep cerebral white matter. MTX also causes a relative excess of homocysteine, a byproduct of the folate deficiency, which may be responsible for small vessel vasculopathy. L-asparaginase is thought to deprive leukemic cells of the essential amino acid L-asparagine thereby disrupting cell replication. Additional neurotoxic effects of L-asparaginase result from chemotherapy-induced transient protein S deficiency and coagulopathy, leading to intracranial venous and/or arterial thrombosis and hemorrhage; usually intraparenchymal. Potential host factors responsible for heightened sensitivity to MTX and L-asparaginase toxicity include age, sex, race, associated syndromic condition, and pharmacogenetics. Primary chromosomal abnormalities of leukemic cells are known to be associated with different prognoses and genetic polymorphisms encoding for drug-metabolizing enzymes, transporters, and receptors may account for variable sensitivity to toxic side effects. Multi-agent chemotherapy in combination with 1800-2400 Gy cranial irradiation prevents overt CNS relapse at the price of significant neurotoxicity. Cranial irradiation has been replaced with intensive intrathecal and systemic chemotherapy, with low CNS relapse rates. Indications for CNS radiation include CNS disease at presentation, CNS relapse, and unacceptable MTX neurotoxicity.

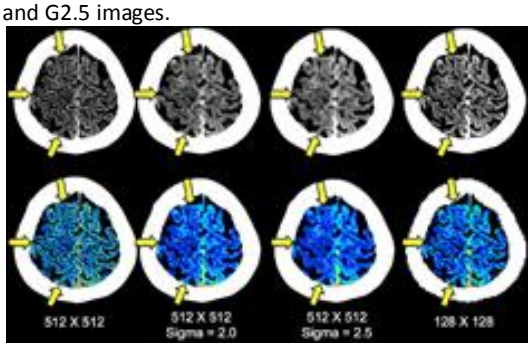
Gaussian Filter versus Downsizing with Antialiasing: Which One is Better to Improve Contrast-to-Noise Ratio of Early Ischemic Change on Noncontrast CT?

Kim, E. Y.[1]·Ahn, S. S.[2]·Shin, N. Y.[2]·Carneiro, F.[1]
[1]The University Hospital, Cincinnati, OH, [2]Severance Hospital, Seoul, KOREA, REPUBLIC OF.

Purpose
It has been documented that early ischemic changes on admission noncontrast CT (NCCT) quantified using ASPECTS to predict outcomes after intra-arterial therapy. However, it has been reported that interobserver reliability of ASPECTS is limited. The low-contrast resolution of NCCT is inherently lower than MRI due to its higher noise. Gaussian filter or downsizing with antialiasing can reduce noise, resulting in improvement of contrast-to-noise ratio (CNR), which may ultimately improve interobserver reliability. However, there has been no comparison study between the two methods. The purpose of this study was to compare the CNRs of normal-appearing gray matter (cortex/basal ganglia; NAGM), normal-appearing white matter (NAWM), and early ischemic change in the cortex and/or basal ganglia among the original images, Gaussian-filtered images, and 128×128-downsized images.
Materials & Methods
We enrolled 30 patients who underwent 5 mm sequential NCCT of the head, demonstrating occlusion in the ICA, M1, and/or M2 on CTA, within six hours of symptom onset. The original 512×512 matrix NCCT DICOM images were processed with Gaussian filter of sigma 2.0 (G2) and 2.5 (G2.5) and downsized with antialiasing to 128×128 matrix images. Regions of interest were drawn in the NAGM, NAWM, and the cortex/basal ganglia showing early ischemic changes in all image sets. The CNR was calculated using the standard deviation of the normal-appearing gray/white matter. Repeated measures ANOVA were conducted for statistical analysis.
Results
The mean CNR between the NAGM and NAWM was 2.12 ± 0.46 in original images, 6.38 ± 1.44 in G2 images, 7.66 ± 2.41 in G2.5 images, and 4.12 ± 0.94 in downsized images (P<0.0001). There were significant differences among the four image sets in post hoc analysis (P<0.0001). The mean CNR between the NAGM and contralateral cortex/basal ganglia showing early ischemic changes was 0.73 ± 0.41 in original images, 1.81 ± 0.95 in G2 images, 2.05 ± 1.09 in G2.5 images, and 0.98 ± 0.59 in downsized images (P<0.0001). There were significant differences among the four image sets in post hoc analysis except for between G2 and G2.5 images.



Conclusion
The Gaussian-filtered or downsized NCTT images demonstrate significantly improved CNRs between the NAGM and NAWM, and NAGM and contralateral cortex/basal ganglia with early ischemic changes, which may help improve interobserver reliability of ASPECTS. Gaussian filter is better than downsizing with antialiasing in terms of improvement of CNR.

Effect of CT Perfusion Deconvolution Algorithms on Estimation of Penumbra and Ischemic Core in Middle Cerebral Artery Stroke

Nicholson, A.·Hwang, S.·Dehkharghani, S.
Emory Healthcare
Atlanta, GA.

Purpose
Qualitative cerebral blood flow (CBF) maps and quantitative relative cerebral blood flow (rCBV) measurements are used to predict final infarct volume in acute stroke patients. Phantom and clinical studies have shown significant differences in perfusion metrics such as rCBF, when computed with different deconvolution algorithms. In particular, singular value decomposition methods of deconvolution (often used in clinical perfusion analysis software) are known to have varying sensitivities to benign arrival-time delay, which can result in the overestimation of hypoperfused tissue. Our aim is to determine if a correlation exists between CBV abnormality and final infarct core on follow-up MRI and to investigate the degree to which this correlation is affected by the use of different deconvolution algorithms.
Materials & Methods
After institutional review board approval, a consecutive series of acute stroke patients with middle cerebral artery occlusion (MCAO) were characterized retrospectively. Patients were selected who received CTA and CTP of the head in the setting of their acute presentation, per our standard clinical protocol. From these patients we selected those who had a follow-up brain MRI within 28 days of presentation. Seventeen patients met these criteria (mean age 63.5 years, 40% male, mean NIHSS 17.7). Subjects were characterized by the duration of stroke-like symptoms, lateralization of clinical findings, and NIH stroke scale. CT perfusion data were analyzed with freely available independent software (Perfusion Mismatch Analyzer: http://asist.umin.jp/index-e.htm). Three separate perfusion datasets were obtained for each patient: using standard (sSVD), delay-insensitive block-circulant SVD (bSVD), and delay-corrected (dSVD) deconvolution algorithms. User-generated ROIs were placed on the CBF maps generated by each of these techniques. Lesion volumes as well as mean Tmax values (by bSVD technique) were computed for each ROI. Manual ROIs also were placed on the MRI images (DWI for MRIs obtained 0-7 days after presentation and FLAIR for MRIs obtained 7-28 days after presentation). Repeated measure analysis of variance was performed to identify significant differences among the different methods of perfusion computation.
Results
Correlation (R2) values between the volume of CBV abnormality and that of the DWI abnormality were 0.7243 for sSVD, 0.7605 for dSVD, and 0.8948 for bSVD. Average rTmax values in the region of CBF abnormality were 272.7% for sSVD, 163.6% for dSVD, and 351.3% for bSVD.
Conclusion
Correlation between volume of CBV abnormality and final infarct volume was highest with bSVD and lowest with sSVD. This is supportive of the concept that delay-sensitive sSVD will overestimate hypoperfusion secondary to benign arrival-time delay, whereas delay-insensitive bSVD values are more reflective of true tissue perfusion. Relative values of Tmax were higher in bSVD than in the other deconvolution algorithms as a result of the inclusion of less benign oligemia in lesion selections. For future studies we plan to coregister the MR images with the perfusion maps to directly measure perfusion parameters in the area of infarct core, as well as incorporate threshold-generated ROIs in the measurement of abnormal rCBF volumes.

KEYWORDS: Brain perfusion, Deconvolution

O-389 **3:31 PM - 3:39 PM**

Degree of Anterior Insula Infarction at Admission Is the Strongest Predictor of Infarct Growth in Endovascular-Treated Stroke Patients without Recanalization

Morais, L. M. T.·Kamalian, S.·Borgie, R. C.·Payabvash, S.·Franceschi, A. M.·Schaefer, P. W.·Yoo, A. J.·Lev, M. H.
Massachusetts General Hospital
Boston, MA.

Purpose
Admission core infarct volumes greater than 70 ml on diffusion-weighted-imaging (DWI) are an established marker for poor stroke outcome. Previous pilot studies also have suggested a strong correlation between stroke severity and degree of insula infarction. We hypothesized that percent insula infarction is associated more strongly with poor tissue outcome in proximal occlusive-stroke patients treated with intra-arterial therapy (IAT) than is admission DWI lesion volume.
Materials & Methods
We identified 74 consecutive IAT patients who presented with acute middle cerebral artery (MCA) occlusion. Two experienced neuroradiologists rated the admission DWI scans according to percent anterior and posterior insula infarction using a 4-point scale (normal, <50%, >50%, 100%). Admission DWI and follow-up MRI core infarct volumes were segmented independently, and infarct growth determined. Following IAT, patients were stratified into good (TICI 2/3) versus poor (TICI 0/1) recanalization groups. Univariate (spearman rank correlation) and multivariate regression analyses were performed to determine the relationship between admission imaging and clinical variables, and final infarct volume/growth in each of the revascularization groups.
Results
There were 23/74 (31%) patients with no/poor revascularization (TICI 0/1) and 51/74 (69%) with good/excellent revascularization (TICI 2/3). For the poor recanalization group, percent anterior insula infarct was

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

the *only* predictor of infarct growth for both the uni- and multivariate analyses (spearman rho = 0.43, p = 0.04). Predictors of final infarct volume in this group included age, anterior/posterior/total insula percent infarct, and admission DWI lesion volume (all p<0.05). For the good recanalization group, admission NIHSS score was the *only* predictor of infarct growth for both the uni- and multivariate analyses (spearman rho = 0.34, p = 0.02). Predictors of final infarct volume in this group included anterior/posterior/total insula percent infarct, and admission DWI lesion volume (all p<0.05). Overall, there were 26/74 (35%) with anterior insula infarct >50% and 48/74 (65%) without. These dichotomized anterior insular infarct groups were matched for mean admission NIHSS score and time-to-imaging (p = 0.3 and 0.4, respectively), however mean final infarct volume and infarct growth were lower in the <50% anterior insula infarct group (78+/-55 ml versus 166+/-104 ml, p<0.0001 for volume, and 66+/-81 ml versus 114+/-95 ml, p<0.03 for growth).

Conclusion

In this highly selected endovascular-treated cohort, percent anterior insula infarction at admission was the *only* independent predictor of infarct growth in patients without significant revascularization. We speculate that anterior insula infarction may be a stronger surrogate for overall stroke severity than is DWI lesion volume, because the unique vascular supply of this location reflects the combined effects of not only the degree of superior division MCA occlusion, but also of the quality of collateral flow from both the anterior and inferior MCA divisions (as well as that of other pial collateral sources). Future studies with CT or MR perfusion imaging will determine if radiographic penumbral flow markers (not available for our current study) more strongly correlate with infarct growth than does the “clinical penumbra” (i.e., NIHSS score) in IAT patients *with* significant recanalization.

Pseudo-Continuous Arterial Spin Labeling Perfusion in Acute Ischemic Syndrome: A Feasibility Study

Nael, K.[1]·Meshksar, A.[1]·Khan, R.[1]·Carmody, R.[1]·Salamon, N.[2]
[1]University of Arizona Medical Center, Tucson, AZ,
[2]University of California Los Angeles, Los Angeles, CA.

Purpose

To evaluate the feasibility of a modified arterial spin-labeled (ASL) perfusion in patients with acute ischemic syndrome (AIS) and to compare the results with dynamic susceptibility contrast (DSC) perfusion.

Materials & Methods

Forty-five patients (28M, age: 38-90 years old) with AIS who underwent both ASL and DSC perfusion imaging were evaluated retrospectively. For ASL we used a pseudo-continuous (PCASL) pulse sequence with optimized image readout using a 3D GRASE (gradient and spin echo) and background suppression. A total of 30 pairs of tag and control images was obtained in four minutes using a two-second post-labeling delay and a labeling pulse duration of 1.5 seconds. Arterial spin-labeled cerebral blood flow (CBF) and DSC time-to-peak (TTP) and CBF maps were evaluated for image quality, presence and type of perfusion abnormality. In addition diffusion-perfusion mismatch was evaluated on each modality and patients were categorized into two categories of perfusion-diffusion mismatch using a modified version of Diffusion and Perfusion Imaging Evaluation for Understanding Stroke Evolution (DEFUSE) criteria: 1) Mismatch: perfusion abnormality volume > 1.5 (150%) of DWI lesion volume; 2) Matched: perfusion abnormality volume < 1.5 (150%) of DWI lesion volume. Wilcoxon test was used to evaluate the differences in image quality scores and Kappa test for interobserver and intermodality agreement.

Results

Dynamic susceptibility contrast and ASL studies were rated of diagnostic image quality in 96% and 94% of patients respectively with interobserver agreement of k = 0.81 for DSC and 0.72 for ASL. The image quality of ASL, although diagnostic, was rated significantly lower than for DSC (p = 0.005). There was no significant difference between the image quality of studies acquired at 3T versus 1.5T for DSC (p = 0.3) or ASL (p = 0.1). In all (30/45) patients who had DWI positive lesion, both DSC and ASL showed a type of perfusion abnormality without disagreement. Among 15 patients without DWI lesion, three patients had regional perfusion deficit on both DSC and ASL indicative of true nature of ischemia. The ASL-DWI mismatch classification agreed with TTP-DWI in 27 of 30 cases with $\kappa = 0.71$, 95% CI, 0.52-0.87. The agreement between the ASL-DWI and CBF-DWI was lower with agreement in 23 of 30 cases yielding a $\kappa = 0.46$, 95% CI, 0.23-0.76). In all discrepant cases, the disagreement was due to overestimation of hypoperfused lesion on ASL than on corresponding DSC maps.

Conclusion

The described ASL protocol is feasible in the assessment of perfusion deficit in patients with AIS and can provide an alternative method in evaluation of patients who cannot receive gadolinium. However the ASL technique as currently used still underperforms DSC method with lower image quality and only moderate agreement for mismatch classification mainly due to overestimation of hypoperfusion. Further improvement in ASL methodology such as faster sequence design and arterial transit delay insensitive techniques such as velocity selective ASL is needed before ASL can be incorporated as a major perfusion modality in large clinical scale.

Susceptibility-Weighted Imaging at 3T Is Superior to Time-of-Flight Angiography for the Detection of Peripheral Thrombi in Patients with Acute Stroke

Radbruch, A.[1,2]·Mucke, J.[1]·Schlemmer, H.[2]·Heiland, S.[1]·Bendszus, M.[1]·Rohde, S.[1]
[1]University of Heidelberg, Heidelberg, GERMANY, [2]German Cancer Research Center (DKFZ), Heidelberg, GERMANY.

Purpose
Time-of-flight (TOF) angiography detects occlusion or stenosis of arteries in patients with acute ischemic stroke due to the absence of blood flow in the occluded vessel, depicted as loss of signal. In contrast susceptibility-weighted imaging (SWI) enables intravascular clot imaging in terms of the susceptibility vessel sign (SVS). Susceptibility vessel sign is defined as a hypointensity within the occluded vessel with a greater diameter than the one of the contralateral vessel, which occurs due to the high sensitivity of SWI sequences for blood products. The aim of this study was to compare the diagnostic accuracy of both methods regarding the determination of vessel occlusion in patients with acute stroke.
Materials & Methods
Ninety-four patients who presented clinical symptoms for acute stroke (NIHSS>2) and displayed a region of impaired perfusion on the time to peak perfusion map determined by dynamic susceptibility contrast perfusion images (TE 35, TR 1920, FoV 240, slice thickness 5 mm, 75 dynamic scans, injection of 0.1 mmol/kg DOTAREM with bolus technique after the third frame followed by 20ml of NaCl solution) in the area of the anterior(ACA), middle (M1, M1/M2, M2/M3) or posterior (PCA) cerebral artery were included prior to thrombolytic therapy. For all patients TOF angiography and SWI at 3T were assessed with respect to delineation of SVS on SWI and vessel occlusion or stenosis on TOF angiography.
Results
Eighty-seven of 94 patients displayed a clearly definable SVS on SWI within the affected artery. In 72 patients the SVS could be correlated with occlusion or stenosis observed on the TOF angiography (1 ACA, 36 M1, 13 M1/M2, 12 M2/M3, 10 PCA). No patient displayed occlusion or stenosis on TOF angiography without a correlate on SWI. Fifteen patients displayed SVS on SWI (14 M2, 1 M1) without any sign for occlusion on the TOF angiography(Figure 1). Sensitivity for detection of embolic occlusion within major vessel segments(e.g., M1, ACA and PCA) was 97% for SWI and 96% for TOF angiography. In contrast sensitivity for detection of embolic occlusion within M2/M3 was 84% for SWI and 39% for TOF angiography.

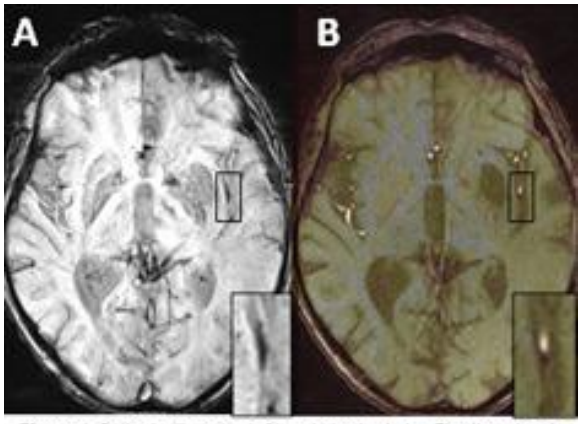

Figure 1. Patient with acute left-hemispheric-stroke. The thrombus in the peripheral segment of the MCA can be visualized clearly on SWI (A). Coregistration of SWI and TOF-angiography (B) highlights the TOF-angiography signal within the SVS.

Conclusion
Susceptibility-weighted imaging and TOF angiography provide equal results for the detection of proximal thrombemboli while SWI is superior for the detection of peripheral clots. Since TOF angiography can provide additional information for stroke identification and classification due to peripheral vessel rarefaction we suggest a combined analysis of TOF angiography and SWI for vascular assessment of ischemic stroke.

KEYWORDS: Thrombus imaging, Susceptibility-weighted imaging

Blood Flow "Oversupply" following EC-IC By-Pass?

Mikulis, D. J.[1]·Al Harbi, M.[1]·Mandell, D. M.[1]·Poublanc, J.[1]·Wong, T.[1]·Crawley, A. P.[1]·Fisher, J. A.[2]
[1]Toronto Western Hospital, Toronto, ON, CANADA, [2]Toronto General Hospital, Toronto, ON, CANADA.

Purpose
The EC-IC by-pass procedure can significantly improve blood flow in the MCA territory secondary to proximal large vessel steno-occlusive disease. In spite of this, no advantage over medical management for treatment of steno-occlusive disease has been observed. EC-IC by-pass however remains a treatment option for medical failures. Flow dynamics before and after EC-IC by-pass has been studied, but, to our knowledge, there are no reports that describe persistent steal physiology despite restoration in blood flow.
Materials & Methods
Ten patients with moyamoya disease who had cerebrovascular reserve (CVR) studies before and after EC-IC by-pass surgery were identified retrospectively in a database of over 600 CVR studies. 3T TOF MRA, phase-contrast by-pass flow assessment (NOVA), and whole brain blood flow mapping using ASL (GE Healthcare, Milwaukee) were performed in 12 by-passed hemispheres.

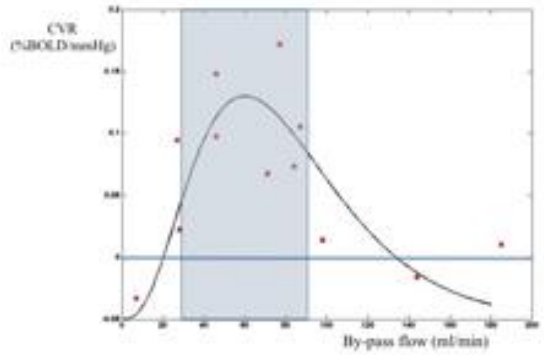
Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Cerebrovascular reserve was obtained using a BOLD MRI EPI sequence during precision control of arterial CO2 to achieve two brief CO2 elevations of 10 mmHg above resting levels. Whole brain CVR maps were generated following linear regression of end-tidal CO2 waveforms with CVR = % BOLD signal/mmHg CO2.

Results

All patients had evidence of steal physiology in the by-pass territory prior to surgery. All by-passes were patent post surgery. Seven by-passes with by-pass flow in the range of 30-90 ml/min showed conversion of steal physiology to positive vascular reactivity. Of the five patients without CVR improvement, two showed by-pass flow of 30 ml/min or less, but two unexpectedly showed the highest by-pass flow in the group (> 90 ml/min - Figure 1). One patient in this latter subgroup showed resting blood flow on ASL that was two std devs. above normal (age-matched).

Figure 1



Conclusion

The data suggest that high by-pass flows may overwhelm the MCA territory such that recovery of vascular reserve fails to occur. This can be associated with elevated resting blood flow reflecting the failure of the reserve mechanism to re-establish blood flow control. The significance of this physiology is uncertain as there have not been adverse events reported in these patients at this time.

High-Resolution MR Imaging in Large Vessel Occlusions

Hui, F. K.[1]·Jones, S. S.[1]·Obusez, E. C.[1]·Zhu, X.[2]·Uchino, K.[1]·Hussain, S.[1]·Lou, X.[3]·Jiang, W.[4]
[1]Cleveland Clinic Foundation, Cleveland, OH, [2]China-Japan Friendship Hospital, Beijing, CHINA, [3]Chinese People's Liberation Army General Hospital, Beijing, CHINA, [4]The Second Artillery General Hospital, Beijing, CHINA.

Purpose

Large vessel occlusions are an important cause of ischemic stroke. Imaging goals center on identifying the site of occlusion, the size of ischemic core and the size of ischemic penumbra. The etiology of the occlusion typically is inferred by history and demographics, or subacutely during investigation for shunt, hypercoagulable state or other causes. Current generation vascular imaging is based primarily on lumenography. Contours of the vessel lumen on lumenography may suggest the presence of atherosclerosis, dissection or thrombus. High-resolution MRI (HRMR) techniques can characterize wall morphology in the presence of an occlusion, which may impact clinical care by better definition of intra-occlusion wall characteristics as well as downstream vasculature normally confounded by the lack of antegrade flow.

Materials & Methods

The High Resolution MRI database of Cleveland Clinic and Beijing Tiantan Hospital were reviewed to identify patients with large vessel occlusions on lumenography, performed with diagnostic quality high-resolution MRI imaging. Clinical data were reviewed for each patient, and images analyzed by experienced neuroradiologists at both institutions. Where possible, conventional angiography/lumenography was reviewed for comparison.

Results

Nine patients with large vessel cerebral artery occlusions were identified in whom high-resolution MRI characteristics were reviewed and categorized. Images were correlated with demographics, risk factors, and the working diagnosis of each case.

Table : Vessel Wall Imaging

Patient	Lumenography	HRMR Findings	Presumed Diagnosis	Excluded
1	Right MCA occlusion	The occlusion site showed thickening wall with enhancement.	Atherosclerosis	Clot, vasculitis, dissection
2	Right MCA occlusion	The occlusion showed the enhanced eccentric plaque without lumen. The proximal or distal sites showed thickening wall and circle enhancement.	Atherosclerosis	Clot, vasculitis, dissection
3	Right MCA occlusion	plaque without lumen. The proximal or distal sites showed eccentric thickening wall.	Atherosclerosis	Clot, vasculitis, dissection
4	Right MCA occlusion	The occlusion showed the enhanced eccentric plaque without lumen. The proximal or distal sites showed thickening wall and circle enhancement.	Atherosclerosis	
5	Occlusion Basilar, no flow in post PICA V4. Flow down Basilar from PCOMs	Focal, irregular enhancement of proximal basilar artery with intermediate signal material without outer vessel narrowing. Shows slow flow (White Snake) in the bilateral post PICA V4, implying patency of the distal vertebral artery.	Atherosclerosisvs focal dissection.	Pure Clot/Vasculitis
6	L M1 occlusion with leptomeningeal collaterals	L M1 narrowing/occlusion with circumferential enhancement	Atherosclerosis/Inflammation	Clot/Dissection
7	R Vertoccluded past C4 with trickle flow from L V4 to narrow Basilar artery	R V4 Filling defect (clot) from C2 horizontal segment to Basilar. Concomitant mid basilar narrowing of both inner and outer diameter with enhancement.	Thrombus filling R V4 segment and proximal basilar artery, with coincident basilar artery atherosclerosis.	
8	L P1 occlusion, L V4 irregular narrowing	L V4 flap, narrowing, enhancement with P1 filling defect in a low flow enhanced area.	Dissection plus clot	Pure Clot /Vasculitis/Atherosclerosis
9	R ICA occlusion with cessation of flow at the cavernous segment	Dissection and subintimal blood is seen at the supraclinoid ICA with wall enhancement of the adjacent ICA proximally and distally. The ICA lumen was smaller than expected.	Dissection	Pure Embolic Event, Atherstenosis

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

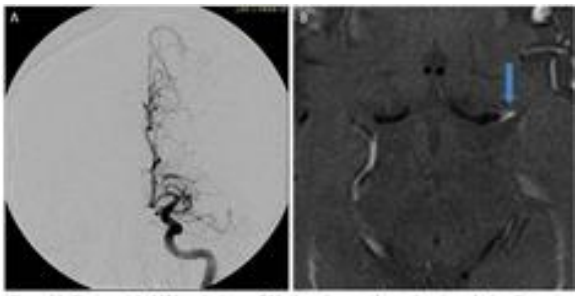

Figure 1A: Shows a right MCA occlusion on DSA, thrombus vs atherosclerotic occlusion. Figure 1B Shows that it is not a thrombus . Concentric wall enhancement and thickening , however, uncertain if atherosclerotic or vasculopathic.

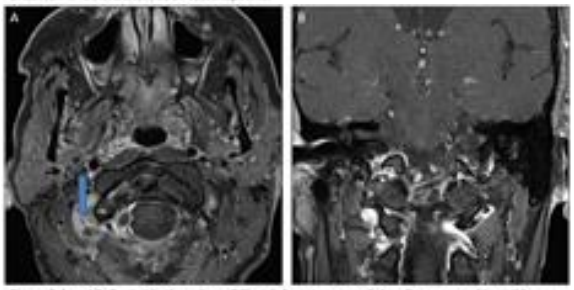

Figure 2 A and B: Probable thrombus : Filling defects in areas of slow flow are starkly visible. Limited experience with these findings makes differential characteristics in post contrast imaging uncertain.

Conclusion
High-resolution MR of vascular occlusions can identify wall characteristics as well as characterize the course and caliber of the vasculature distal to the occluded segment. This information may be useful in determining preferred approaches for endovascular revascularization.

Echo-Planar Fluid Attenuated Inversion Recovery in Patients with Acute Stroke: A Comparative Analysis with Fluid Attenuated Inversion Recovery

Meshksar, A.·Khan, R.·Carmody, R.·Erly, W.·Kubal, W.·Nael, K.
University of Arizona Medical Center
Tucson, AZ.

Purpose
To prospectively evaluate the diagnostic performance of an EPI-FLAIR sequence in evaluation of acute stroke with potential reduction in scan time and compare the result with conventional FLAIR images.
Materials & Methods
Thirty-four consecutive patients (18 F, 16 M, age range: 32-96 years old) with clinical suspicion of acute stroke were evaluated prospectively with an acute stroke protocol which encompassed both conventional FLAIR (subsequently referred to as FLAIR) and EPI-FLAIR imaging. Using an EPI sequence with integration of parallel acquisition (GRAPPA x 2), EPI-FLAIR images were acquired in 50 seconds compared to three minute acquisition time for FLAIR imaging. Image quality was evaluated by two neuroradiologists independently and in different sessions using a 1-4 grading scale. In addition the images were assessed to determine the presence of hyperintensity on FLAIR and EPI-FLAIR images and compared to the DWI abnormality and rated as concordant or discordant. The DWI images were coregistered with FLAIR and EPI-FLAIR images and the signal intensity ratio (SIR) of the lesion to contralateral normal white matter were calculated for both FLAIR and EPI-FLAIR. Interobserver and intermodality agreement and correlation were tested with Kappa and Spearman Rank correlation respectively. The quantitative analysis was performed utilizing a t test.
Results
Except for two studies that were deemed nondiagnostic (one due to motion artifact and the other due to susceptibility artifact related to dental braces), all studies were rated as being of diagnostic quality by both observers and without significant difference in image quality scores ($p = 0.4$). The interobserver agreement for image quality scores was excellent for both FLAIR ($k = 0.85$) and EPI-FLAIR ($k = 0.80$). Twelve patients did not have infarction (DWI lesion). In 22 patients with acute infarction (+DWI lesion), FLAIR and EPI-FLAIR agreed in 19 (86%) with good correlation ($r = 0.94$, 95% confidence interval: 0.89-0.97). In only three patients (14%) EPI-FLAIR was discordant with FLAIR and unable to show hyperintensity detected on both FLAIR and DWI. The mean ± SD of the SIR values on EPI-FLAIR and FLAIR for DWI positive lesions were 1.20 ± 0.1 and 1.27 ± 0.16 respectively ($p = 0.1$) and concordant with a recently published clinical trial. In three discordant cases, despite subjective discrepancy, there was no statistically significant difference between mean SIR values of FLAIR (1.22) and EPI-FLAIR (1.13) ($P = 0.10$).
Conclusion
The described EPI-FLAIR sequence is feasible with acceptable qualitative and quantitative results in comparison to routine FLAIR images for evaluation of patients with acute stroke. EPI-FLAIR can be implemented in acute stroke MR protocol resulting in much needed reduction in scan time for these patients.

CT Perfusion in the Halifax Acute Stroke Imaging Study

Shankar, J. J. S.·Langlands, G.·Phillips, S.
QE II Hospital
Halifax, NS, CANADA.

Purpose
The thrombolytic time window for treatment of acute ischemic stroke (AIS) is based on time and not on the tissue involved. Different time window for different patients have been suggested based on different clinical scenario. So to make a proper judgement regarding

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

thrombolysis in acute stroke we need to evaluate the tissue window. CT perfusion has been a valuable and widely available tool for the assessment of tissue at risk in cases or AIS. But due to limited experience in many centers including ours, we decided to first evaluate the parameters of CT perfusion in relation to follow-up imaging. Our hypothesis was that the final volume of infarcted brain on follow-up imaging will not be smaller than that predicted by the cerebral blood volume (CBV) parameter on CTP imaging performed at the time of AIS.
Materials & Methods
We retrospectively analyzed our prospectively kept acute stroke database. The study was approved by the institutional ethics committee. We analyzed patients admitted to our hospital between April 1st and August 31st, 2012 with symptoms of AIS and had CTP done at their hospital arrival. We calculated the ASPECT score on plain head CT at baseline, lesion on cerebral blood flow, volume, time to peak maps and CT angiogram source images (SI) and volume of final infarct size on follow-up CT or diffusion imaging, whichever was available. The volume was calculated manually on the PACS work station. The lesion volume on different CTP parameters and SI data then were correlated with the final infarct volume. This analysis was done by three observers - a fellowship trained neuroradiologist, a stroke neurologist with more than 20 years experience in the field and a medical student with two weeks training in the analysis of acute stroke imaging including CTP. Paired t test, regression analysis and correlation analysis were done. A p value of <0.05 was considered significant. The interobserver variability also was analyzed.
Results
We had a total of 84 patients with AIS and CTP at admission in this time period. Out of these only 38 patients met all the criteria for final analysis. There was no significant difference between CTP CBV or SI and follow-up MRI/CT lesion volume (P>0.05). Lesion volumes were greater on time to peak (TTP) and cerebral blood flow (CBF) CTP images compared to follow-up MRI/CT (P<0.05). The correlation coefficient (r) between lesion volume on TTP, CBF, CBV or SI to follow-up lesion volume on MRI/CT was 0.41, 0.78, 0.81 and 0.70 respectively (correct to two significant figures). Regression analysis between each imaging parameter's ischemic volume at admission and final infarct volume found that the CBV correlated best with the final infarct volume (R2 = 0.6591).
Conclusion
Results from the Halifax Acute Stroke Imaging Study (HASIS) confirms our hypothesis that admission CTP and SI in suspected AIS patients can predict final infarct volume, where final volume of infarcted brain will not be smaller than that predicted by CTP CBV.

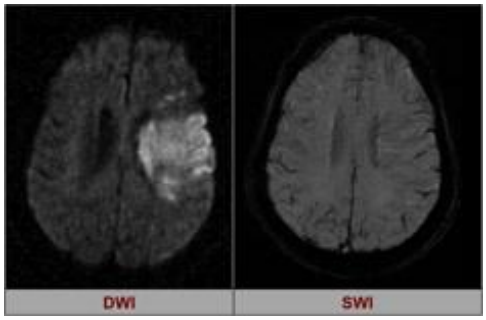
Acute Cerebral Infarction Is Strongly Associated with Increased Prominence of Ipsilateral Deep Medullary Veins on Susceptibility-Weighted Imaging

Salehi, B.·Jacobson, J.·Oyoyo, U.·Kido, D.
Loma Linda University Medical Center
Loma Linda, CA.

Purpose
During ischemia, oxygen dissociates from iron atoms in hemoglobin, forming deoxyhemoglobin, a paramagnetic molecule that acts as a negative contrast agent on susceptibility-weighted imaging (SWI). Accordingly, dramatic changes in oxygen saturation of venous vascularity are reflected on SWI by the blood oxygen level dependent (BOLD) effect. Our purpose is to determine the association between prominence of cerebral deep medullary veins (DMV) in SWI and the presence of recent cerebral infarct.
Materials & Methods
Under an IRB waiver, a cohort of 22 consecutive cases of acute stroke with SWI with brain imaging obtained in the first week after initial symptoms. Controls were 27 normal volunteers with brain MRI using the same 1.5T scanner. Two neuroradiologists reviewed SWI of the all cases and controls; DMV prominence was determined for each cerebral hemisphere using a 7-point ordinal visual scale. Demographic information as well as the length of hospital stays, as an index for clinical outcome, were collected from the medical record. Differences in DMV prominence per hemisphere between stroke patients and controls were assessed using Chi Square and Mann-Whitney tests.
Results
Stroke cases were 21.7 times more likely than normal controls to present with deep medullary vein asymmetry (OR, 95% CI: 2.48, 189.1). Deep medullary veins of the partially infarcted hemisphere were more prominent compared to normal hemisphere, resulting in the asymmetric appearance (Figure). Among the cases, those presenting with asymmetric DMVs were older compared to stroke cases without (median, 62 years versus 56 years); however, this was not statistically significant (Median test, p = 0.67). Male stroke patients were 5.6 times more likely than female stroke patients to present with asymmetric medullary veins (OR, 95% CI: 0.814, 38.5). No correlation between prominence of the deep medullary veins and length of hospital stay was observed.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Conclusion
In the setting of acute cerebral infarct, ispilateral deep medullary veins (DMVs) appear larger and darker on susceptibility-weighted imaging resulting in asymmetric appearance compared to the normal hemisphere. This asymmetric prominence of DMVs likely is mediated by elevated deoxyhemoglobin on the infarcted region.

CT Permeability in Prediction of Hemorrhagic Transformation following Acute Ischemic Stroke

Shankar, J. J. S.·Cobb, A.
QE II Hospital
Halifax, NS, CANADA.

Purpose
The thrombolytic therapy is the mainstay of treatment of acute ischemic stroke (AIS). The hemorrhagic complication is one of the most important complications following treatment of AIS. It will be useful to have a tool which can predict the hemorrhagic complication in these patients at presentation. CT perfusion (CTP) has been a valuable and widely available tool for the assessment of tissue at risk in cases or AIS. The data of CTP can be used to extract information of CT permeability, which has been described by some studies to be useful in predicting the hemorrhagic transformation. Our hypothesis was that the permeability surface area product will be able to predict the hemorrhagic transformation on follow-up scan in patients with AIS.
Materials & Methods
We retrospectively analyzed our prospectively kept acute stroke database. The study was approved by the institutional ethics committee. We analyzed patients admitted to our hospital between April 1st and August 31st, 2012 with symptoms of AIS and had CTP done at their hospital arrival. We calculated the permeability surface area product in addition to the other routine CTP parameters. Paired t test was done to compare the permeability ratio between patients with and without hemorrhagic transformation. A p value of <0.05 was considered significant. Sensitivity, specificity, positive and negative predictive values also were calculated for a certain cut off value.
Results
We had total of 84 patients with AIS and CTP at admission in this time period. Out of these only 38 patients had a follow-up imaging done in our institution. Out of these permeability could be calculated for 14 patients. The relative permeability was calculated as a ratio of permeability on the side of AIS versus that on the contralateral side at the same level. Patients with hemorrhagic transformation on follow-up scan had significantly higher (p = 0.001) relative permeability compared to patients with no hemorrhagic transformation on followup. For a relative permeability cut off of 1.5, the sensitivity, specificity, positive and negative predictive values were 85.7%.
Conclusion
Our study confirms our hypothesis that the permeability surface area product can predict the hemorrhagic transformation on follow=up scans in patients with AIS. This showed high sensitivity, specificity, positive and negative predictive values at relative permeability cut off of 1.5.

Histogram Analysis of Dynamic Susceptibility Contrast Perfusion MR Images in Oligodendroglial Tumors: Correlation between Cerebral Blood Volume, Grade and Angiogenic Subtypes According to 1p19q Status

Kim, B.·Kim, S.·Jung, H.·Kim, H.·Cha, J.·Kim, K.·Jeon, P.·Kim, H.·Byun, H.
Samsung Medical Center
Seoul, KOREA, REPUBLIC OF.

Purpose
Grading of oligodendroglial tumors using MR images have low predictive accuracy given that low-grade tumors exhibit heterogeneous patterns of blood flow in different patients. And degree of oligodendroglial vascularity is associated with loss of heterozygosity (LOH) on 1p/19q. The aim of this study was, first, to analyze histogram of MR perfusion images of oligodendroglial tumors in grading histopathologic subtype and, second, to assess the difference of distribution of relative cerebral blood volume

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

(rCBV) values in subtype of oligodendroglial tumors according to 1p/19q status.
Materials & Methods
Thirty-three patients (20 women, 13 men; mean age, 47.4 years; range, 23 - 75 years) with histologically confirmed oligodendroglial tumors underwent preoperative dynamic susceptibility contrast MR imaging at 3.0T and were analyzed retrospectively. Patients were classified by histopathologic grade (high- and low-grade) and stratified into two cytogenetic groups: 1p or 1p and 19q LOH (Group 1), and 19q LOH only on intact alleles (Group 2). Routine rCBV measurements were obtained from ROIs of the whole tumors. Mann-Whitney tests compared the utility of histogram parameters of rCBV values for histoapathologic grading and identification of cytogenetic subtypes.
Results
Of the 33 patients, 22 was classified to Group 1 (9 low-grade, 13 high-grade) and 11 was identified to Group 2 (five low-grade, six high-grade). High-grade tumors were showing relatively low kurtosis and skewness of rCBV values than low-grade ones, signifying that high-grade ones have a tendency of heterogeneous and predominant distribution of high rCBV values on its rCBV histogram (P = .038 and P = .035, respectively). In each Group 1 and 2, high-grade subtypes also showed relatively low kurtosis and skewness of rCBV values than low-grade subtypes, implying the similar tendency of high rCBV values distribution. In addition, Group 1 showed relatively low kurtosis and skewness of rCBV values than those of Group 2. Mean, mode and maximum value of rCBV, however, showed statistically insignificant difference (P > .05).
Conclusion
The rCBV histogram analysis showed somewhat different distribution of rCBV values between low- and high-grade oligodendroglial tumors despite most overlapping histogram parameter. And our results showed that role of 1p/19q LOH in angiogenesis of tumor vascularity, which have an effect on the difference of rCBV value distribution.

MR Susceptibility-Weighted Contrast-Enhanced Perfusion Imaging and Diffusion Tensor Imaging Patterns in Patients with Progressive/Recurrent Glioblastomas after Bevacizumab Treatment

Liu, X.[1]·Tian, W.[2]·Hussain, A.[2]·Ekholm, S.[1]
[1]University of Rochester School of Medicine & Dentistry, Rochester, NY, [2]University of Rochester Medical Center, Rochester, NY.

Purpose
Bevacizumab is the humanized monoclonal antibody that blocks vascular endothelial growth factor (VEGF) and inhibits angiogenesis, and has been used widely in patients with glioblastomas. However, Bevacizumab-induced MRI changes are still full of conflicting controversies, including advanced imaging techniques of MR dynamic susceptibility-weighted contrast-enhanced MR perfusion imaging (DSC PWI) and diffusion imaging. For example, new restricted diffusion followed by Bevacizumab treatment is thought be a good response in some studies, but other studies thought this was indication of tumor progression. Some studies found that decreased cerebral blood volume (rCBV) is a good therapeutic response after Bevacizumab treatment, in contrast, some researcher thought that elevated blood perfusion responded to antiangiogenic therapy, and subsequently increase survival in such patients. Therefore, the purpose of this study was to evaluate patterns of DSC PWI and diffusion tensor imaging (DTI) in patients with progressive/recurrent glioblastomas after Bevacizumab treatment.
Materials & Methods
Fifty-two cases with pathology or radiologic confirmed progressive/recurrent glioblastomas after Bevacizumab treatment were reviewed. Serial DSC PWI and DTI examinations were performed after Bevacizumab treatment. The maximal rCBV ratios and minimal apparent diffusion coefficient (ADC) value in the examinations when the glioblastomas presenting minimal enhancement after Bevacizumab treatment and recurrence/progression were evaluated.
Results
The mean maximal rCBV ratio of reference in glioblastomas after Bevacizumab treatment was 1.65 ± 0.52; there were 41 patients with the mean maximal rCBV ratio of recurrent/progressive glioblastomas significantly higher, 6.11 ± 4.58, *p* value of paired t test was 0.013. There were 11 patients whose maximal rCBV ratio at recurrence/progression was relatively lower, 1.26 ± 0.29, without significant difference compared to reference, *p* = 0.71. All patients showed new restricted diffusion after Bevacizumab treatment. The mean minimal ADC value of reference was 0.49 ± 0.17, the mean minimal ADC value of 41 and 11 patients at recurrence/progression were 0.63 ± 0.19 and 0.71 ± 0.57 respectively, and there was no significant difference compared to reference, *p* value of 0.22 and 0.09 respectively. Discussion: The recurrent/progressive glioblastomas after Bevacizumab could present two types of perfusion changes, re-increased high rCBV and unchanged low rCBV. In contrast, the minimal ADC alone may have limited value in detecting recurrence/progression after Bevacizumab treatment.
Conclusion
Our preliminary result shows that there were different patterns of MR PWI/DTI changes in recurrent/progressive glioblastomas after Bevacizumab treatment. Combing multiple imaging biomarkers is necessary for imaging interpretation.

Diffusional Kurtosis MR Imaging in the Evaluation of Gliomas

Spampinato, M.·Manzoor, M.·Rumboldt, Z.·Kereshi, B.·Jensen, J.·Helpern, J.·Tabesh, A.
Medical University of South Carolina
Charleston, SC.

Purpose
Our aim was to assess microstructural differences between glioblastoma multiforme (GBM) and non-GBM gliomas, with the hypothesis that diffusional kurtosis metrics will differ between GBM and other gliomas.
Materials & Methods
Eleven treatment-naïve adult subjects with pathology proven gliomas, six GBM (WHO grade IV) and five non-GBM (1 WHO grade I; 1 grade II; 3 grade III), were identified retrospectively. All subjects had undergone a preoperative MRI including a twice-refocused spin-echo echo-planar imaging diffusion sequence (b values = 0, 1000, 2000 s/mm^2 with 30 noncollinear gradient directions for each nonzero b value). A tumor volume-of-interest (VOI) including the entire solid portion of the mass was manually outlined on FLAIR images. A VOI was drawn within the contralateral normal-appearing white matter (NAWM). Average mean kurtosis (MK) and mean diffusivity (MD) values within the tumor were obtained using in-house software and normalized to the contralateral NAWM values. Mann-Whitney test and receiver operating characteristic (ROC) curves were used for statistical analyses.
Results
Mean unnormalized MK was significantly different (p = 0.045) between GBM (mean +/-SD = 0.73 +/- 0.08) and non-GBM (0.60+/-0.10) neoplasms. Mean normalized MK, as well as unnormalized and normalized MD were not statistically significantly different between groups. The area under the ROC curve for MK was 0.75 (95% confidence interval = 0.456-1). A threshold MK value of 0.62 provided a sensitivity of 83.3% and specificity of 67% in the identification of GBM. A threshold MK value of 0.72 had a sensitivity of 50% and a specificity of 83.3% in the identification of GBM.
Conclusion
Greater microstructural complexity of GBM can be detected using diffusion imaging. Diffusional kurtosis imaging has potential applications in the noninvasive assessment of tumor grade.

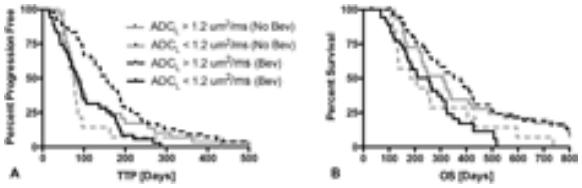
Apparent Diffusion Coefficient Histogram Analysis Is a Predictive, Not Prognostic, Imaging Biomarker for Recurrent Glioblastoma Treated with Bevacizumab

Ellingson, B. M.[1]·Shebjam, S.[2]·Kim, H. J.[1]·Harris, R. J.[1]·Woodworth, D. C.[1]·Pope, W. B.[1]·Lai, A.[1]·Nghiemphu, P. L.[1]·Mason, W. P.[2]·Cloughesy, T. F.[1]
[1]David Geffen School of Medicine at the University of California Los Angeles, Los Angeles, CA, [2]University of Toronto, Toronto, ON, CANADA.

Purpose
Bevacizumab is now the standard of care for treatment of recurrent glioblastoma in the United States. Apparent diffusion coefficient (ADC) histogram analysis has been shown to be a valuable imaging biomarker for predicting the response of recurrent glioblastoma to bevacizumab; however, no studies have compared pretreatment ADC histogram analysis between bevacizumab and a matched cohort of patients that were never exposed to bevacizumab during their treatment history. The purpose of the current study was to determine whether ADC histogram analysis performed prior to treatment in recurrent glioblastoma is a predictive (bevacizumab-specific) or prognostic (treatment independent) biomarker of response to bevacizumab.
Materials & Methods
All patients in this study signed institutional review board-approved informed consent. A total of n = 89 recurrent glioblastoma patients from UCLA treated with bevacizumab and n = 43 recurrent glioblastoma patients from the University of Toronto that were treated with a variety of chemotherapies and never exposed to bevacizumab were included in this retrospective study. In all patients, ADC values within pretreatment contrast-enhancing ROIs were extracted and the resulting histogram was fitted to a mixed model with a double Gaussian distribution. The mean value of ADC in the lower Gaussian curve (ADCL) was used as the primary biomarker of interest. Cox proportional hazards model and Log-rank tests were used for survival analysis.
Results
Cox multivariate regression analysis accounting for the interaction between bevacizumab- and nonbevacizumab-treated patients suggested the ability for ADCL to predict PFS and OS is dependent on treatment (P = 0.045 and P = 0.003, respectively). Cox regression suggested bevacizumab-treated recurrent glioblastoma with pretreatment ADCL>1.2um2/ms had a significantly longer overall survival (OS) compared with bevacizumab-treated patients with ADCL1.2um2/ms (P<0.025). Univariate analysis suggested an ADCL value of 1.2um2/ms stratified short and long-term progression-free (PFS) and OS in bevacizumab-treated patients (Log-rank, P = 0.009 and P = 0.0103, respectively); however, no differences in PFS or OS were observed in the nonbevacizumab-treated cohort (Log-rank, P = 0.0562 and 0.3737, respectively).

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Conclusion
Together, results suggest ADCL extracted from ADC histogram analysis is a predictive, not prognostic, imaging biomarker for stratifying PFS and OS in bevacizumab-treated recurrent glioblastoma.

Elemental Brain Volumes Derived from Cytoarchitectonics and Crossing White Matter Tracts Are an Independent Predictor of Mortality for Glioma with Improved Understanding of Infiltration

Hamilton, J. D.[1]·Kumar, V. A.[1]·Schellingerhout, D.[1]·Shah, K.[1]·Chi, L.[1]·Hunter, J.[2]·Naidich, T. P.[3]·Chavalli, L.[1]·Leeds, N. E.[1]·Prabhu, S.[1]·Kumar, A. J.[1]·Hayman, L. A.[4]
[1]M. D. Anderson Cancer Center, Houston, TX, [2]Texas Children's Hospital, Houston, TX, [3]The Mount Sinai Hospital, New York, NY, [4]Anatom-e Information Systems, Houston, TX.

Purpose
Previous reports have hinted that there are elemental brain volumes (EBV) that guide glioma spread, beyond gyral and sulcal anatomy. We investigate how this can be used to define if the tumor is growing or spreading, and confirm these observations with survival data.
Materials & Methods
Seventy-four patients with diffuse gliomas (Grade II-IV) with pre and postoperative MR imaging and at least two years of followup were reviewed retrospectively from the year 2005. Tumors were determined to be "growth pattern" if they were confined to the archicortex or neocortex and if neocortical were located in a single EBV, defined by architectonics and white matter branching. Extension beyond these regions through the crossing, deep white matter fibers of the corona radiata and sagittal striatum was considered "spread pattern" by a consensus of three-nine neuroradiologists, blinded to survival data. This determination was compared to other previous reported single and multiparameter survival criteria (e.g., age, Karnofsky performance, size, extent of resection, enhancement, tumor grade, etc.) to determine its utility and independence from other criteria. (Please note that the construction of this atlas and its use for specific brain locations are submitted to this meeting as a separate communication).
Results
Determining if a glioma is growth versus spread pattern was an independent predictor of mortality (p = 0.007), regardless of tumor grade or size. Although spread pattern was more likely to be multifocal (p = 0.004), it was a better predictor of mortality than multifocality. As a single criterion these patterns had similar performance to a previously verified multiparameter criteria (VAK criteria) and its addition improved all post-hoc multiparameter modeling.

Coronal and sagittal T1 post-contrast images of a 45 year African American female with a multifocal glioblastoma confined to EBV associated with Brodmann area 6, who survived 24 months after diagnosis (Initial KPS 90).

Conclusion
The survival data provide evidence that this parcellation strategy to define glioma growth patterns is useful. This strategy worked particularly well for common glioma locations such as near the central sulcus and sylvian fissures but may need refinements in less common locations, such as the occipital lobe. Crossing deep white matter tract creating a net-like barrier to spread may explain these observation but other hypothesis such as the localized genomic signature and stem cell migration patterns have yet to be tested.

Longitudinal MR Spectroscopic Imaging in a Cohort of Newly Diagnosed Glioblastoma Patients Receiving Adjuvant Antiangiogenic Therapy

Andronesi, O.[1,2]·Borra, R.[1,2]·Gerstner, E.[1,2]·Marjanska, M.[3]·Batchelor, T.[1,2]·Rosen, B.[1,2]
[1]Massachusetts General Hospital, Boston, MA, [2]Harvard Medical School, Boston, MA, [3]University of Minnesota, Minneapolis, MN.

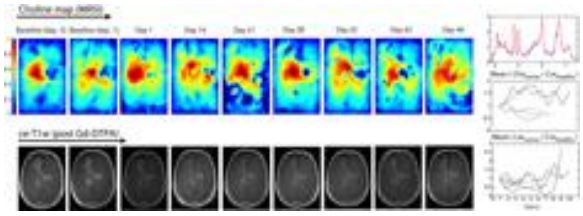
Purpose
The aims of this longitudinal imaging study were to establish: a) if a vascular normalization "window" occurs in newly diagnosed glioblastoma patients treated with a combination of antiangiogenic and standard chemoradiation therapy, b) the metabolic consequences of such normalization, c) the mechanisms of tumor response and relapse.
Materials & Methods
Multimodal MR imaging at 3T has been performed with structural, perfusion, diffusion and spectroscopic imaging. A group of 40 glioblastoma patients treated with cediranib

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

(oral pan-VEGF receptor tyrosine kinase inhibitor) and standard chemoradiation were scanned serially: two baselines (days -5 and -1), weekly during six weeks of chemoradiation, and then monthly until disease progression or patient went off study. MR spectroscopic imaging (MRSI) was acquired with an optimized low power adiabatic sequence using LASER (Localization by Adiabatic SElective Refocusing). Acquisition parameters were repetition time (TR) of 1.5 s, echo time (TE) of 45 ms, single slice, matrix size 16x20, 10 mm in plane resolution, 15 mm slice thickness. Spectral data were interpolated to a matrix of 32x32 and subsequently fitted by LCModel software. Mean concentrations of six metabolites (N-acetyl-aspartate (NAA), total choline (tCho), creatine (Cre), myo-inositol (mIns), lactate (Lac) and lipids (Lip)) were calculated within tumor regions of interest (ROI) and in normally appearing white matter.

Results

Here we include preliminary results on 11 patients. We observed differences in metabolic time courses in tumors measured by MRSI as compared to changes in tumor contrast-enhanced T1-weighted (ce-T1w) images. In some patients with reduction of tumor ce-T1w the levels of tCho increased throughout the course of the treatment. The ratio of mean tumor Cho to mean Cre in the normal-appearing white matter ($tCho_{tumor}$ / $Cre_{healthy}$) seems to identify two subgroups of patients, one group showing 75% increase, while second group a 25% reduction of this ratio. The ratio of mean tumor Lac to mean healthy Cre (Lac_{tumor} / $Cre_{healthy}$) appears to increase towards the end of chemoradiation.



Conclusion

Choline and lactate are metabolic biomarkers that have been associated with tumor proliferation and hypoxia, respectively. Our data suggest that metabolic MRSI provides complementary information to functional and structural MRI that could help in better understanding and predicting response to combined antiangiogenic and chemoradiation therapy in newly diagnosed glioblastoma patients. Further statistical analysis of all patients aiming to correlate metabolic, permeability, perfusion, diffusion and clinical endpoints is undergoing.

Repeatability of MR-Based Vessel Caliber Estimates in Brain Tumor Imaging

Polaskova, P.[1,2]·Emblem, K. E.[3]·Jafari-Khouzani, K.[1,2]·Kalpathy-Cramer, J.[1,2]·Batchelor, T. T.[4]·Gerstner, E. R.[4]·Rosen, B. R.[1,2]·Stufflebeam, S. M.[1,2]
[1]Massachusetts General Hospital, Charlestown, MA, [2]A.A. Martinos Center for Biomedical Imaging, Charlestown, MA, [3]Oslo University Hospital/Rikshospitalet, Oslo, NORWAY, [4]Massachusetts General Hospital, Boston, MA.

Purpose

Vessel caliber estimation by dynamic susceptibility contrast (DSC) MRI is an emerging technique for assessment of tumor vasculature and knowledge of the repeatability of the technique is critical for monitoring of therapy effectiveness. Using double baseline scans acquired as part of a clinical study in newly diagnosed glioblastoma (nGBMs) patients, we compared the repeatability of two methods for estimation of vessel caliber. Method A uses the ratio of cerebral blood volume (CBV) from contrast-enhanced gradient-echo (R_2*) and spin-echo (R_2) DSC images. Method B provides a semiquantitative vessel caliber index (VCI), correcting for regional diffusion coefficients and blood flow.

Materials & Methods

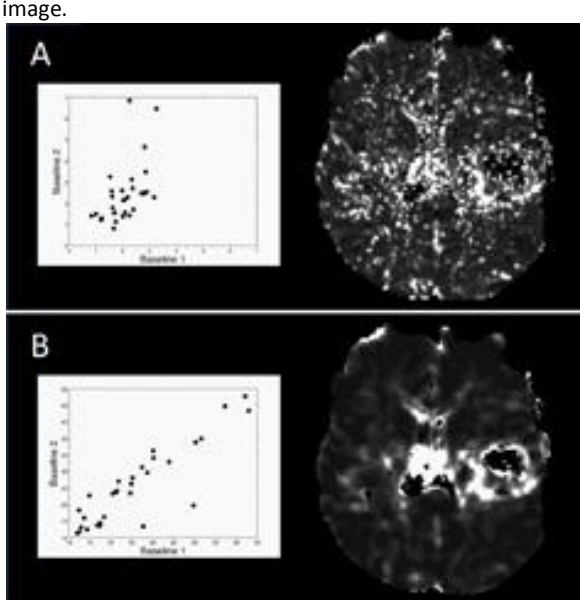
Thirty-three patients with nGBMs were included in this IRB-approved study after signing informed consent. Two baseline scans were acquired before treatment onset, two-four days apart. In addition to conventional MRI (pre/postcontrast T_1-weighted, FLAIR), DSC MRI was acquired as follows: 100 volumes combined gradient-echo (GE) and spin-echo (SE) EPI sequence; TE 31 ms and 94 ms, TR 1.48s, 0.1 mmol/kg of Gd-DTPA was injected at 5 cc/s after ~81s of imaging and predose of Gd-DTPA (0.1 mmol/kg) was used to minimize T_1 effects from contrast agent extravasation. Apparent diffusion coefficient (ADC) maps were obtained from diffusion-weighted MRI with 42 directions, b = 0/700 mm^2/s. Tumor ROIs were drawn by a neuroradiologist, outlining contrast-enhancing tumor on T1-weighted postcontrast images, and coregistered to DSC images using rigid coregistration. After correction for contrast agent leakage, vessel caliber maps were estimated as follows: Method A: $\Delta R_2^*/\Delta R_2$ ratio maps obtained from GE and SE CBV maps. Method B: First, a voxel-by-voxel 'Q' value was obtained by fitting the linear dependence of $\Delta R_2^*/\Delta R_2^{3/2}$ during the bolus passage. Second, VCI was estimated by the equation: $VCI = 0.867*(ADC*CBV)^{1/2}*Q$. For measures of repeatability we used intraclass correlation coefficient (ICC) and Spearman's rank correlation coefficient.

Results

The ICC for Method A was 0.5189 and for Method B 0.8993. The Spearman's rank correlation coefficient was 0.7214 ($p<.001$) for Method A and 0.865 ($p<.001$) for Method B. Figure 1 shows the scatter plots for the two methods as well as corresponding example vessel caliber

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

image.



Conclusion

Although the ΔR2*/ΔR2 ratio (Method A) is simple and easily implemented, Method B provides semiquantitative estimate of the vessel caliber with higher repeatability. This makes Method B a good candidate for use as a tumor imaging biomarker, especially in monitoring the vascular response of brain tumors to antiangiogenic therapeutic agents.

Early Changes in Relative Cerebral Blood Volume Obtained Using Ferumoxytol-Based Dynamic Susceptibility Contrast MR Perfusion in High-Grade Glial Neoplasms Treated with Bevacizumab

Prola Netto, J.[1]·Varallyay, C. G.[1]·Hamilton, B. E.[1]·Gahramanov, S.[1]·Fu, R.[1]·Nasseri, M.[1]·Neuwelt, E. A.[1,2]
[1]Oregon Health & Science University, Portland, OR, [2]Department of Veterans Affairs Medical Center, Portland, OR.

Purpose

Tumor neovascularization, as an important characteristic of high-grade gliomas, has become a target for anti-angiogenic treatment with bevacizumab. Dynamic susceptibility contrast (DSC)-based perfusion MRI using gadolinium-based contrast agents (GBCA) frequently is used on surveillance imaging to help evaluate active disease. Ferumoxytol, a high molecular weight iron oxide nanoparticle can be used to perform DSC-perfusion MRI, and minimizes errors caused by contrast leak, providing a more reliable measure of relative cerebral blood volume (rCBV) without the need for correction algorithm or preloading dose as is necessary with GBCA-based DSC-perfusion. The aim of this study is to determine early changes in rCBV obtained by using ferumoxytol-based DSC MR perfusion in high-grade glioma patients treated with bevacizumab.

Materials & Methods

Patients were enrolled from a prospective imaging study with brain tumors approved by the institutional review board. Informed written consent was obtained from all patients. Inclusion criteria for our study were patients with histologically proven high-grade glioma which received bevacizumab therapy after standard chemoradiation and underwent ferumoxytol MR perfusion before and after bevacizumab. Bevacizumab was given for clinical and/or radiographic progression in all patients. Anatomical axial T1 spin echo-weighted scans pre and postgadoteridol were acquired. Dynamic susceptibility contrast MR perfusion was performed in a 3T scanner using a 1mg/kg ferumoxytol bolus administered intravenously. Gadolinium-based contrast agents-enhanced axial T1 spin echo and DSC perfusion scans were coregistered before and after bevacizumab in each patient. Regions of interests (ROIs) were drawn manually to include the entire initially enhancing tumor on a representative axial slice. Mean and standard deviation of rCBV values were obtained, and histogram analysis performed. Histograms consisted of 20 bins of rCBV value sizes of 0.5 ranging from 0 to 9.5. Hypo-perfused subvolumes were defined as those areas with rCBV ≤ 0.75 and hyper-perfused as those with rCBV ≥ 1.75.

Results

A total of 27 enhancing masses in 23 patients were analyzed. The mean time of the first scan before bevacizumab was 15 days (range 1-70) and the first post-treatment scan was 27 days after bevacizumab (range 12-50). Mean rCBV in the enhancing area pre-bevacizumab was 1.29, significantly decreasing to 0.91 and 0.93 after bevacizumab administration when the ROI was drawn in the enhancing area pre- and post-bevacizumab ($p = 0.02$ and $p = 0.03$ respectively). Histogram analysis demonstrated a significant increase in the proportion of hypo-perfused voxels from 43% pre-bevacizumab to 56% post-bevacizumab ($p = 0.002$). There was a decrease in the proportion of hyper-perfused voxels from 27% pre-bevacizumab to 19% post-bevacizumab that was not statistically significant($p = 0.08$).

Conclusion

Changes in ferumoxytol-based DSC perfusion can be seen early after bevacizumab administration, with overall decrease in the mean rCBV in the enhancing area. This difference is due mainly to an increased proportion of hypo-perfused voxels rather than a decrease in the hyper-perfused voxels. These preliminary findings may indicate that bevacizumab does not mask the presence of areas of high rCBV and its administration should not be delayed in patients undergoing MR perfusion for evaluation of new or increasing areas of enhancement.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

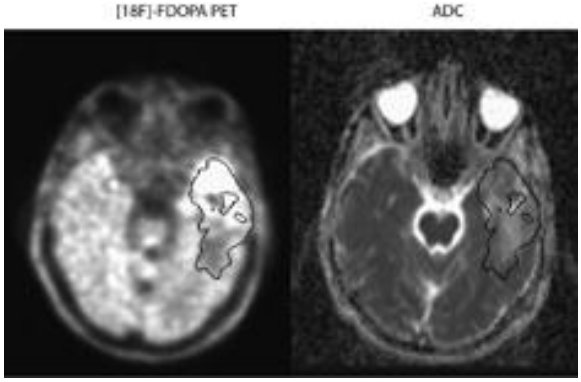
Spatial Correlation between Apparent Diffusion Coefficient and [18F]-FDOPA Positron Emission Tomography Uptake in Diffuse Gliomas

Leu, K.·Cloughesy, T. F.·Lai, A.·Nghiemphu, P. L.·Chen, W.·Czernin, J.·Pope, W. B.·Ellingson, B. M.
David Geffen School of Medicine at the University of California Los Angeles
Los Angeles, CA.

Purpose
To investigate the relationship apparent diffusion coefficients (ADC) and positron emission tomography (PET) L-3,4-Dihydroxy-6-18F-fluoro-phenyl-alanine (18F-FDOPA) uptake in gliomas.
Materials & Methods
A total of n = 28 patients with histologically confirmed gliomas [World Health Organization (WHO) grades II-IV] who had a T2-weighted/fluid-attenuated inversion recovery (FLAIR) and a diffusion-weighted magnetic resonance image (MRI) scan within three months of the 18F-FDOPA scan were enrolled in this study. Tumor regions were identified via hyperintensities on the T2/FLAIR scans. 18F-FDOPA and ADC maps for each patient were registered to a baseline T2/FLAIR volumetric image using an affine transformation. 18F-FDOPA uptake "hotpots" were defined as areas with uptake greater than the basal ganglia. Apparent diffusion coefficients values were captured within areas of T2/FLAIR lesions that overlapped with the PET "hotspots", called FLAIR(+), and those that did not, FLAIR(-). All statistical tests performed were two-tailed, paired t-tests.
Results
Median ADC was not found to be significantly different between 18F-FDOPA hot or cold spots within FLAIR ROIs [1.28um2/ms in FLAIR(+) versus 1.30um2/ms in FLAIR(-)]. In fact, only 13/28 patients had a lower median ADC in the FLAIR(+) regions. Overall, minimum ADC was significantly higher in the FLAIR(+) regions ($p<0.0001$). A similar trend was found among those with positive tumor recurrence at the time of MR and PET scanning, with only around half of patients illustrating a lower median ADC in FLAIR(+) regions. Interestingly, 10/12 patients who had scans while in the midst of their treatment regimens had a higher median ADC in the FLAIR(+) regions. In a few cases, 18F-FDOPA PET hotspots also were found outside of the T2/FLAIR lesions (Figure 1).



Conclusion
In general, regions with low ADC and elevated 18F-FDOPA PET appear to be spatially independent, suggesting ADC and 18F-FDOPA PET may provide complimentary information about tumor cellularity and metabolism, respectively. Minimum ADC was higher in FLAIR(+) compared with FLAIR(-) regions, suggesting the most metabolically active portions of the tumor may correspond to less dense, but more mobile tumor cells.

Postoperative Perfusion-Weighted MR Imaging and Tumor Progression/Recurrence in High-Grade Gliomas

Adapa, P.·White, M. L.·Zhang, Y.·Aizenberg, M. R.·Shonka, N.·Kazmi, S. A. J.·Yu, F.
University of Nebraska Medical Center
Omaha, NE.

Purpose
Utilizing the immediate postoperative perfusion-weighted imaging (PWI) MR exams for the prediction of tumor progression and recurrence of primary brain tumors is a novel concept. The current standard of postoperative MRI enhancement for analyzing residual tumor is known to be limited secondary to enhancement from postsurgical changes. This effect can be ameliorated but not completely eliminated with early scanning. Also, enhancement of a tumor does not evaluate angiogenesis. There can be areas of increased tumor angiogenesis that do not have blood-brain barrier breakdown and enhancement. Postoperative perfusion analysis of brain tumor patients allows for an evaluation of the remaining abnormal tumor angiogenesis which likely indicates areas of higher grade tumor. This study evaluates the immediate postoperative PWI for predicting tumor progression and recurrence in subjects with intracranial high-grade gliomas (HGG). The hypothesis is that HGG subjects with elevated PWI postsurgery will have earlier tumor progression/recurrence.
Materials & Methods
This is a single institution retrospective study investigating

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

the clinical utility of PWI analyzing when tumor progression/recurrence in HGG will occur. Thirty subjects, 15 males and 15 females, age range from 29-82 years (mean = 55 years) and with pathology proven Grade III and IV gliomas were analyzed. Six subjects were excluded from the final analysis due to the presence of motion artifacts or early loss to followup. The immediate postoperative MRI examinations included T1W pre and postcontrast, T2* PWI at 1.5T or 3.0T. Cerebral blood volume (CBV) maps of the T2* PWI were analyzed for areas of high perfusion. Maximum areas of CBV were measured and a ratio was calculated for this value (rCBV) versus a similar location in the opposite hemisphere. If no areas of elevated perfusion were noted then a maximum rCBV value of one was used indicating perfusion was the same as normal brain. Each of the subjects underwent postoperative chemotherapy and/or radiation therapy per standard of care. Time to recurrence was recorded as the date on which an MRI examination first demonstrated changes that were determined to be recurrence. Subjects' follow-up imaging, pathologic records and clinical records were evaluated to confirm progression/recurrence of HGG. A nonparametric Wilcoxon rank sum test was used for comparing the median values of maximum rCBV in subjects with progression/recurrence before 200 days or after 200 days.
Results
The maximum rCBV (median = 3.8) for subjects that had progression/recurrence of HGG in <200 days was significantly higher than the rCBV (median = 1) in subjects with recurrence/progression in >200 days ($p = 0.0018$). There were six cases that had not recurred with follow-up times of 213-433 days. These were placed in the > 200 day group for analysis.
Conclusion
Greater residual maximum rCBV postoperatively was associated with shorter time to progression and recurrence of HGG. This suggests that areas of residual elevated rCBV after surgery might need to be considered for more aggressive therapy. Protocol for treatment of postoperative residual high rCBV tissue remains to be determined and will be the subject of future studies.

Early Postoperative Diffusion-Weighted Imaging and Perfusion-Weighted Imaging Are Adjuvant Imaging Tools in Differentiating between Pseudo-Progression and Progression in Patients with Glioblastoma Treated with Temozolomide and Radiotherapy

Liu, X.[1]·Tian, W.[2]·Wang, H.[1]·Ekholm, S.[1]
[1]University of Rochester School of Medicine & Dentistry, Rochester, NY, [2]University of Rochester Medical Center, Rochester, NY.

Purpose
Radiotherapy and concurrent/adjuvant temozolomide treatment is gold standard regimen for patients with newly diagnosed glioblastomas. However, this treatment protocol may induce up to 20-50% patients presenting pseudoprogression within six months after radiation/temozolomide treatment, which is difficult to be distinguished from true tumor progression on conventional MRI. Previous literatures reported that the restricted diffusion in the early postoperative MRI (<72 hours after operation) of such glioblastoma patients indicates the postoperative injuries, which subsequently transfer into pseudoprogression. Therefore, the purpose of this study is to differentiate between the pseudo-progression and true tumor progression based on early postoperative diffusion-weighted imaging and perfusion-weighted imaging.
Materials & Methods
A total of 41 cases of glioblastomas with dynamic susceptibility contrast perfusion-weighted imaging and diffusion-weighted imaging acquired within postoperative 72 hours after resection were included in this study. Nine of the cases had to be excluded due to unacceptable imaging artifacts. Areas with visually detected low apparent diffusion coefficient (ADC) and increased relative cerebral blood volume (rCBV) in the peri-resection cavity regions were detected. Sequential MRI examinations at one month and six months after radiation/temozolomide treatment were performed to determine if these areas of enhancement represented pseudoprogression or true progression by means of the McDonald criteria. The difference of initial ADC and rCBV values in these pseudoprogression and tumor progression was evaluated with the Mann-Whitney U test.
Results
There were 48 postoperative peri-resection cavity regions with reduced ADC value, 33 among of them (68.8 %, mean ADC value 0.656 ± 0.324; rCBV value 0.597 ± 0.312), showed pseudoprogression on follow-up contrast enhancement T1WI, 15 areas (31.2%, mean ADC value 0.597 ± 0.268, p value = 0.33; rCBV value 1.83 ± 0.46, $p<0.001$) showed tumor progression. In addition, there were 12 true tumor progression regions with increased early postoperative rCBV value (1.61 ± 0.27), but without reduced ADC value (1.13 ± 0.35). Discussion: Our preliminary results showed that early postoperative

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

restricted diffusion alone has limited value in differentiating between the pseudo-progression and true tumor progression. However, the areas with early postoperative high rCBV are prone to progress as true tumor progression.
Conclusion
Our findings suggest that early postoperative increased rCBV value may be a useful novel imaging biomarker in differentiating between the pseudo-progression and true tumor progression in patients with glioblastomas treated with radiation and temozolomide.

Imaging Findings in Children Referred for Horner's Syndrome

Kadom, N.·Jubouri, S.
Children's National Medical Center
Washington, DC.

Purpose
To determine the spectrum of pathology found in children referred for imaging workup of Horner's syndrome.
Materials & Methods
Retrospective study, IRB approved. There was a single observer (radiology resident) who identified patients using a word search software tool (Montage) for radiology reports from 1991-2012. Search criteria were reports with a positive history of Horner's and an imaging study that was either a computed tomography (CT) or magnetic resonance imaging (MRI). Medical records search for clinical and ophthalmology data also was performed. The following variables were recorded: type of imaging study (CT versus MR, complete exam covering levels of first-third order lesions versus only partial anatomical coverage), age at time of imaging, age at time of Horner's onset, side of Horner's, ophthalmology findings (cocaine test, miosis, ptosis, anhydrosis, other), level of pathology based on final diagnosis (1st , 2nd and 3rd order), final diagnosis. Descriptive statistics with Stata v12.1.
Results
There were 69 patients, 31 boys and 38 girls. Mean age at the time of onset of Horner's syndrome was 3.7 years, mean age at time of imaging was 4.1 years. Side of Horner's was right in 31, left in 24, bilateral in one and unknown in 13. The majority of patients had documented miosis (n = 45), followed by ptosis (n = 43). Cocaine test was positive in seven, anhydrosis was not present in two patients and in all others not documented as positive. The most commonly performed imaging study was a complete MRI (n = 49), followed by partial MRI (n = 10), partial CT (n = 6) and complete CT (n = 4). There were 14 different diagnoses in 27 patients with a documented diagnosis of Horner's: congenital (n = 4), physiologic (n = 4), postinflammatory (n = 4), Chiari (n = 2), CN III palsy (n = 2), brain insult (n = 2), resolved (n = 2), vascular (n = 1), neuroblastoma (n = 1), brain tumor (n = 1), fetal injury (n = 1), autism (n = 1). Of note, 10 patients had ectopic cervical thymus but there was not enough documentation to see if this was clinically considered to be the cause of Horner's syndrome.
Conclusion
Rarely children presenting with Horner's syndrome may have malignant disease, such as neuroblastoma or brain tumor. Pathology accounting for Horner's syndrome in children can be found at any anatomical level corresponding to 1st, 2nd and 3rd order neurons. Therefore, every child with unexplained Horner's syndrome should undergo an imaging study that covers all anatomical levels. Vascular malformations causing Horner's can occur in children and therefore vascular imaging (CT angiogram, MR arteriogram) should be included in the imaging protocol. Due to radiation exposure concerns in children and better ability of MRI to detect subtle anomalies of the cavernous sinus, spinal cord and brain parenchyma, MRI should be the preferred imaging modality.

Visual Pathway Damage in Leber's Hereditary Optic Neuropathy: A Quantitative 3T MR Imaging Analysis

Politi, L. S.[1]·Montechiari, M.[1]·Ciasca, P.[2]·Iadanza, A.[1]·Bianchi Marzoli, S.[2]·Falini, A.[1]
[1]San Raffaele Scientific Institute, Milan, ITALY, [2]Auxologico Scientific Institute, Milan, ITALY.

Purpose
Leber's Hereditary Optic Neuropathy (LHON) is a rare genetic disease associated with mutations of mitocondrial DNA. MR imaging (MRI) findings in LHON are reported anecdotally, with contradictory results. The goals of this study were: i) to analyze the MRI findings in brain of LHON patients; ii) quantify size and T2 signal intensity changes along the anterior visual pathway (AVP); iii) correlate size and signal changes to genotype and to clinical and instrumental neuro-ophthalmologic parameters.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Materials & Methods
Nineteen [16 late-chronic (LC), 3 early-chronic (EC)] genetically confirmed LHON patients and 12 age- and sex-matched healthy controls (HC) underwent a complete neuro-ophthalmologic evaluation with visual acuity, visual field and peripapillary retinal nerve fiber layer (PRNFL) measurements and, on the same day, a 3T MRI examination. FSE T2, FLAIR, T2 SPIR and 3D-FFE T1 sequences were acquired. For each participant, brain lesion load was measured. Optic chiasm (OC) area and T2 signal were quantified on T2 coronal slices; intracranial optic nerves (ON) and optic tracts (OT) were similarly measured 6 mm ventrally and dorsally to the optic chiasm. For each subject the T2 signal intensities of the AVP were normalized to the genu of the corpus callosum and signal intensity ratios (SIRs) were obtained. The intraorbital ON and nerve sheath diameters were measured 9 mm dorsal to posterior pole of ocular globe. Mann-Whitney and Kruskal-Wallis tests were employed for statistical analyses; correlations between MRI results and neuro-ophthalmologic features were performed with Spearman's correlation and nonlinear regression analysis.
Results
White matter (WM) lesions were detected in 8/16 LC and 1/3 EC patients, without significant correlation among lesion load and visual impairment severity or PRNFL thickness. One LC patient presented selective T2 alterations of both Meyer's loops. T2 SIRs of intracranial ON, OC and OT were higher ($p \leq .001$) in patients compared to HC, but were not significantly different between LC and EC. Optic nerve, OC and OT were significantly smaller ($p \leq .001$) in LC compared to HC. A larger ($p = .009$) OC was found in EC than in HC. Average PRNFL of LHON correlated ($p \leq .001$) with size measurements of omolateral intracranial ON ($\rho = .771$), OC ($\rho = .833$) and controlateral OT ($\rho = .722$). A negative nonlinear correlation ($p \leq .001$) was found between AVP size measurements and disease duration [intraorbital ON ($\rho = -.861$), intracranial ON ($\rho = -.549$), OC ($\rho = -.908$) and OT ($\rho = -.640$)]. No correlation was observed between MRI parameters and genotype.
Conclusion
White matter lesion load did not correlate to the degree of visual impairment. In both LC and EC patients, significant SIRs increase was present along the AVP, probably due to edema and/or Wallerian degeneration. Anterior visual pathway size was decreased significantly in LC; conversely, the OC was swollen in EC. These findings may suggest a time-dependent evolution (edema followed by degeneration?) and may explain the contradictory results reported in literature, probably related to different phases of the disease. Anterior visual pathway size significantly correlated to average PRNFL measurement and inversely correlated to disease duration. Thus MRI can be useful in monitoring disease course and quantifying AVP changes in future clinical trials.

Morning Glory Disk Anomaly: Characteristic Orbital Findings at MR Imaging

Ellika, S. K.·Robson, C. D.·Heidary, G.·Paldino, M. J.
Childrens Hospital Boston
Boston, MA.

Purpose
The morning glory disk anomaly (MGDA) is a congenital optic nerve abnormality characterized by a funnel-shaped excavation of the posterior globe that incorporates the optic disk. Establishing the diagnosis of MGDA is crucial to guide appropriate ophthalmic management and to prompt a search for associated intracranial abnormalities. Although findings in MGDA at cross-sectional imaging have been reported in several case studies, reports of at most two patients do not allow an understanding of the consistency with which individual findings occur in this clinical setting. Furthermore, in our experience, the orbital findings of MGDA at high quality imaging are not only highly characteristic for this entity but are also of greater breadth than what has been reported previously. The goal of this study, therefore, is to characterize the spectrum and frequency of orbital findings in a series of patients with MGDA using MRI.
Materials & Methods
Pediatric patients with a diagnosis of MGDA confirmed at ophthalmologic exam were identified retrospectively. Imaging was reviewed by two pediatric neuroradiologists for: 1. Funnel-shaped morphology of the optic disk; 2. Elevation of the adjacent retinal surface; 3. Abnormal tissue associated with the distal intraorbital segment of the optic nerve (ipsilateral to the MGDA); 4. Effacement of the subarachnoid spaces of the distal optic nerve sheath resulting from this abnormal tissue; 5. Fat within the distal optic nerve sheath; 6. Enhancement within the distal optic nerve; 7. Discontinuity of the posterior uveoscleral coat at the optic nerve insertion.
Results
Six patients (age range: 8 months to 2 years) comprised the study group. MR imaging demonstrated three findings in all patients: 1. funnel-shaped morphology of the posterior optic disk (arrow, Figure1) with elevation of the adjacent disk margins in all patients; 2. abnormal tissue associated with the distal intraorbital segment of the ipsilateral optic nerve(arrowhead, Figure 1); this tissue was associated with effacement of the subarachnoid spaces; 3. discontinuity of the posterior uveoscleral coat. These findings were not observed in any of the unaffected globes of the study patients. Less consistent orbital findings included: 1. Fatty infiltration of the distal optic nerve sheath(n=3). 2. Enhancement within the distal optic nerve (n=2). 3. Small size of the globe containing the MGDA (n=2).

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Conclusion
Here we demonstrate several consistent orbital features of MGDA at MRI. These findings may allow for accurate differentiation from other ocular anomalies and have the potential to guide appropriate management of this patient population.

Normal MR Imaging Appearance of the LR-SR Band in One Hundred Consecutive Patients

Patel, S. H.[1,2]·Juliano, A.[1]·Moonis, G.[1]·Kazlas, M.[1]·Cunnane, M.[1]
[1]Massachusetts Eye and Ear Infirmary, Boston, MA, [2]Massachusetts General Hospital, Boston, MA.

Purpose
Orbital connective tissues are being recognized increasingly for their functional role in eye motility. Such structures include rectus muscle pulleys, which surround and inflect extraocular muscle paths, as well as the connective tissue bands which couple the pulley's actions to one another. One connective tissue band which recently has been investigated is the lateral rectus-superior rectus band (LR-SR Band). In myopic strabismus fixus or "heavy eye syndrome," it is hypothesized that degeneration of the LR-SR band allows inferior slippage of the lateral rectus muscle, producing characteristic esotropia and hypotropia. However, at present the evidence is preliminary, and no radiologic study has defined the normal MRI appearance of the LR-SR band. The purpose of this study is to characterize the normal 3T MRI appearance of the LR-SR band in patients without myopic strabismus fixus.
Materials & Methods
One hundred consecutive patients who underwent orbital MRI examinations at our institution from June 2012 - October 2012 were chosen. Exclusion criteria included: clinical diagnosis of myopic strabismus fixus; pathology affecting location of the LR-SR band; high axial myopia; staphyloma; strabismus unexplained by another cause. Characterization of the LR-SR band was performed on coronal non-fat suppressed T1-weighted images and coronal short tau inversion recovery (STIR) sequences.
Results
Of the selected 100 patients, 61 were female and 39 male, with average age of 49.6 ± 16.4 years. The LR-SR band was identified as an arc-like hypointense structure extending from the superior margin of the lateral rectus muscle to the lateral aspect of the superior rectus/levator palpebrae complex in 198 out of 200 imaged orbits (99%) on the coronal T1-weighted sequences, and 156 out of the 200 imaged orbits (78%) on the coronal STIR sequences. One hundred ninety-four of the 198 visible LR-SR bands (98%) appeared as a continuous, uninterrupted structure, and four out of the 198 visible LR-SR bands (2%) appeared as a discontinuous structure. The appearance of the band was identical on T1-weighted sequences without or with intravenous contrast. In 36 out of the 198 visible bands (18.2%), the posterior aspect of the band demonstrated superolateral bowing. In 155 out of the 200 orbits (77.5%), a distinct levator palpebrae superioris aponeurosis was visible that was clearly separable from the LR-SR band.
Conclusion
The LR-SR band is a readily identifiable structure on 3T MRI imaging of the orbit, most reproducibly seen on nonfat suppressed coronal T1-weighted imaging as a continuous, arc-like, hypointense structure extending from the superior margin of the lateral rectus to the lateral margin of the superior rectus/levator palpebrae muscle complex. The band usually is distinguishable from the levator palpebrae superioris aponeurosis, and occasionally demonstrates superolateral bowing of its posterior segment.

Contrast-Enhanced Radial 3D Fat-Suppressed T1-Weighted Gradient Echo (Radial-VIBE) Sequence: A Viable and Potentially Superior Alternative to Conventional T1-MPRAGE with Water Excitation and Fat-Suppressed Contrast-Enhanced T1-Weighted Sequence for Evaluation of the Orbit

Bangiyev, L.[1]·Raz, E.[1]·Block, T.[1]·Hagiwara, M.[1]·Yu, E.[2]·Fatterpekar, G. M.[1]
[1]New York University Langone Medical Center, New York, NY, [2]University of Toronto, Toronto, ON, CANADA.

Purpose
Contrast-enhanced fat-suppressed T1-weighted (T1W-FS) sequence and T1-MPRAGE with water excitation (WE) are routinely obtained to evaluate orbit pathology. However, this sequence can be marred by multiple artifacts. The purpose of our study was to evaluate the role of contrast-enhanced Radial-VIBE sequence when evaluating orbital studies and compare with routinely acquired sequences.
Materials & Methods
A retrospective study was performed in 46 patients (age 1-

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

81 years) who underwent contrast-enhanced MRI orbital studies on a 1.5T system. Each of these patients were evaluated with the Radial-VIBE, T1 MPRAGE-WE and contrast-enhanced T1W-FS studies. The free-breathing Radial-VIBE sequence was acquired with the following: slice thickness=0.8 mm; flip angle=12°; TR=4.57 ms; TE=2.06 ms; Matrix=256x256; Field of view=250x250 cm2. Two radiologists blinded to acquisition scheme evaluated multiple parameters of image quality including motion artifact, fat-suppression, clarity of scleral enhancement, clarity of vessels, clarity of muscles, clarity of optic nerve, clarity of brain parenchyma, and conspicuity of pathology. Each of these parameters was assessed on a 5-point scale with a higher score indicating more optimal exam. Mix-model analysis of variance was performed to compare the results. An interobserver variability assessment was performed using a Cohen K.

Results

Using a Kruskal Wallis test, we compared the results of axial Radial-VIBE, axial T1-MPRAGE and axial T1W-FS and we found significant higher values for all the parameters for the axial VIBE ($p<0.0001$). We compared the reconstructed Radial-VIBE and the coronal and T1W-FS using a Mann-Whitney U test and we found a significant difference with significant higher values for all the parameters for the coronal reconstructed Radial-VIBE ($p<0.0001$). Interobserver agreement in the qualitative evaluation using a Cohen's kappa analysis demonstrated average fair to good agreement for the following variables: motion artifacts=0.745, fat-suppression=0.678, clarity of scleral enhancement=0.688, clarity of vessels=0.655, clarity of muscles=0.675, clarity of nerves=0.518, clarity of brain parenchyma=0.710, pathology conspicuity=0.590. In addition, the obtained Radial-VIBE images can be reconstructed in multiple planes and can be evaluated for dynamic temporal assessment which is another significant advantage of this technique.

4D CT: How Many Phases Do We Need?

Mahajan, A.·Kadivar, K.·Gafton, A. R.·Sze, G.
Yale School of Medicine
New Haven, CT.

Purpose

4D CT recently has been purported as the imaging modality of choice for localization of parathyroid adenomas. This has been a recently described technique, where multiphase CT acquisitions are obtained after contrast administration, through the neck and upper chest. With increased number of scans through the upper neck and chest, there is increased radiation exposure to the thyroid gland. To avoid this, it would be ideal to curtail the study to the minimum number of phases required to obtain the desired information and avoid unnecessary radiation.

Materials & Methods

This is a retrospective evaluation of patients with primary hyperparathyroidism due to parathyroid adenoma. All patients underwent surgery and had clinical cure after surgery. Fifty-six patients with parathyroid adenomas were included in the study. The patients were scanned from the angle of the mandible to the tracheal carina. The scans were evaluated by two board-certified radiologists and each phase was scored according to the quality of information provided (0 - No Valuable information, 1 - Helpful information was obtained to assist in diagnosis and 2 - Diagnostic information). The scan protocols included a 5-phase, 4-phase and a 3-phase protocol. The 5-phase protocol included an initial noncontrast and 4 subsequent phases (30, 90, 150 and 420 secs after contrast administration) while the 4-phase protocol had an initial noncontrast and 3 postcontrast phases - 30, 90, 150 secs). Some patients also had a 3-phase study (1 Noncontrast and 2 postcontrast phases - 30 and 90 secs after contrast administration). Coronal and sagittal reformats were obtained after 1.25 mm reconstructions.

Results

Fifty-six patients with solitary or multiple adenomas were included in the study - 14 patients underwent the 5-phase protocol, 40 patients had 4-phase study and two patients had a 3-phase study. Noncontrast scan was found useful in 18 patients (32%), the arterial phase was helpful in 43 (77%) of patients, the 90 sec scan was helpful in 10 cases (18%), the 150 sec scan was helpful in one patients while the 420 sec scan did not add any additional information in the patient. Coronal reformats were helpful in 20% of patients to identify inferior parathyroid and ectopic mediastinal adenomas, which were hard to identify on the axial scans.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Conclusion
4D CT is a helpful study in diagnosing parathyroid pathology. Noncontrast and the early arterial phase were the most useful in making the diagnosis. The 90 sec phase helped in identifying lesions missed on the arterial phase; however, the 150 and 240 sec phases were not helpful in providing any incremental value in diagnosis. The coronal reformats also were helpful in identifying inferior and ectopic mediastinal parathyroid adenomas.

Polar Vessel: A Sign of Parathyroid Lesions on 4D CT

Bahl, M.[1]·Muzaffar, M.[2]·Vij, G.[1]·Scheri, R. P.[1]·Hoang, J. K.[1]
[1]Duke University Hospital, Durham, NC, [2]Carle Clinic, Urbana, IL.

Purpose
The characteristic sign of a parathyroid adenoma on multiphase parathyroid CT (4D CT) is enhancement on the arterial phase and washout on the venous phase. A second sign, the "polar vessel" sign, has been reported on ultrasound but is underappreciated on 4D CT. The purpose of this study is to determine the prevalence of the polar vessel sign on 4D CT and to determine features of parathyroid lesions that are associated with this sign.
Materials & Methods
We performed a retrospective review of consecutive patients with pathologically proven parathyroid lesions who had 4D CT between 2008 and 2012 at two institutions. Thirty-one patients (25 females, mean age 58 years, range 15-83 years) were identified for review after excluding six studies with poor image quality and/or lesions too small to be seen. 4D CT images were reviewed for the presence of the polar vessel sign (enlarged feeding artery or draining vein) and a second vascular finding of an enlarged ipsilateral inferior thyroidal artery. The parathyroid lesions also were characterized by location, CT dimensions, gross pathology weight, and arterial phase imaging attenuation (HU). The presence of the polar vessel sign on 4D CT was correlated with these characteristics.
Results
Four of 31 (13%) patients had multiglandular disease and five of 31 (16%) had lesions in ectopic locations. There were a total of 35 parathyroid lesions with a mean lesion weight of 0.66 g (SD 0.65 g), mean maximal CT diameter of 11.4 mm (SD 4.9 mm), and mean arterial attenuation of 156 HU (SD 55 HU). The polar vessel sign was seen in 26/35 (74%) of lesions. Compared to lesions without an associated polar vessel, lesions with a polar vessel had statistically significant higher mean maximum diameters (13.0 and 6.7 mm, $p < 0.01$) and higher arterial phase attenuation (172 HU and 109 HU, $p < 0.01$). There were no differences in location or gross pathology weight of lesions with or without the polar vessel. An enlarged inferior thyroidal artery was seen in only 3/28 (11%) patients with unilateral disease.

Conclusion
The polar vessel sign is present in three-quarters of parathyroid lesions on 4D CT and is more common in larger lesions and lesions with greater arterial phase enhancement. Radiologists can use the polar vessel sign on 4D CT to increase diagnostic confidence for candidate parathyroid lesions.

Dynamic CT for Parathyroid Disease: How Many Phases Do We Really Need?

Raghavan, P.·Durst, C.·Ornan, D.·Muherjee, S.·Patrie, J.·Xi, W.·Wintermark, M.·Shada, A.·Hanks, J. B.·Smith, P. W.
University of Virginia
Charlottesville, VA.

Purpose
Dynamic 4D CT has emerged as a reliable tool in the detection of parathyroid adenomas. A standard 4D protocol involves obtaining unenhanced (U), arterial (A), early (EV) and delayed venous (DV) phase images of the neck. Recent papers have attempted to eliminate one or more phases in order to decrease radiation dose. Our study aims to determine the ideal combination of phases that would minimize radiation dose without sacrificing diagnostic accuracy.
Materials & Methods
The records of 29 patients with primary hyperparathyroidism were reviewed. All patients had undergone preoperative 4D CT followed by surgical exploration. Four neuroradiologists blinded to the surgical outcome reviewed the imaging studies in five combinations (1- unenhanced and arterial phase; 2- unenhanced, arterial and early venous; 3- all four phases; 4- arterial alone: 5- arterial and early venous phases) with an interval of at least seven days between each review. The accuracy of interpretation in lateralizing an

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

abnormality to the side of the neck (Right, Left, Ectopic) and to a quadrant in the neck (Right and Left upper, Right and Left lower) was evaluated via binomial generalized estimating equation models.

Results

There was no statistically significant difference between the different combinations of phases in their ability to lateralize adenomas or to localize them to a quadrant (p = 0.930 and 0.969, respectively). The accuracy of each combination is summarized in the tables below.

TABLE 1. Estimated reader vs surgeon diagnostic agreement in lateralization of adenomas(%)

COMBINATION	ESTIMATED DIAGNOSTIC AGREEMENT	LOWER 95% CONFIDENCE LIMIT	UPPER 95%CONFIDENCE LIMIT
U,A	89.9	84.6	93.6
U,A,EV	87.9	83	91.6
U,A,EV,DV	89.9	84.8	93.5
A	89.7	84.4	93.3
A,EV	90.5	85.3	94.0

TABLE 2 Estimated reader vs surgeon diagnostic agreement in localization of adenomas to a quadrant (

COMBINATION	ESTIMATED DIAGNOSTIC AGREEMENT	LOWER 95% CONFIDENCE INTERVAL	UPPER 95%CONFIDENCE INTERVAL
U,A	87.2	83.2	90.4
U,A,EV	86.0	82.0	89.3
U,A,EV,DV	87.9	83.8	91.1
A	87.1	82.7	90.5
A,EV	87.2	82.9	90.6

Conclusion

Our findings indicate that four-phase acquisition is unnecessary and adequate diagnostic accuracy may be achievable by obtaining arterial phase images alone, with the advantage of a 75% reduction in radiation dose.

What to Do with the Incidental Thyroid Nodule on CT and MR Imaging?: A Survey of Radiologists' Reporting Practices

Riofrio, A. D.·Bashir, M.·Hoang, J. K.
Duke University Medical Center
Durham, NC.

Purpose

Incidental thyroid nodules (ITN) commonly are seen on imaging. There currently are no widely accepted guidelines for reporting ITN seen on CT and MRI. The aim of this study is to determine current reporting practices for radiologists from different subspecialties and practice types.

Materials & Methods

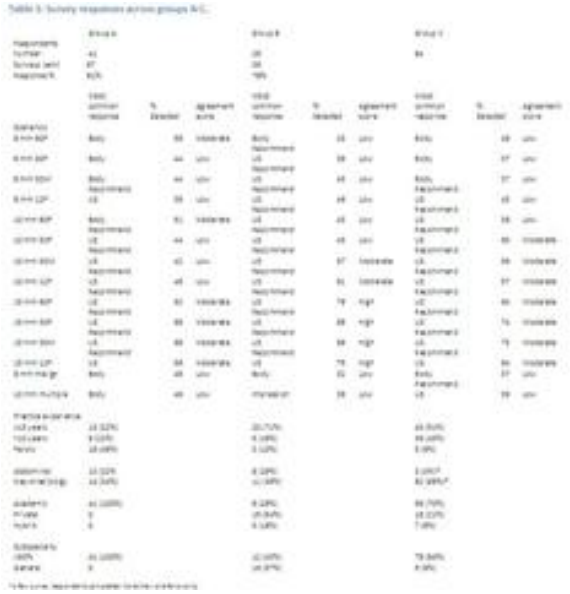
A survey was designed to query radiologists about their reporting practices for 14 scenarios of ITN differing in nodule size (8, 10, and 15 mm), multiplicity of nodules, age and gender of the patient, and presence of nonmetastatic lung cancer. The five possible choices for each scenario were A) do not report, B) leave in body of report, C) report in impression without recommendation, D) recommend ultrasound +/- biopsy, and E) no consistent practice. The survey was sent electronically to three groups: Group A - radiologists in all subspecialties at an academic institution, Group B - radiologists attending the ACR Head & Neck radiology course (predominantly private practice radiologists), and Group C - ASNR member radiologists (predominantly neuroradiologists). Responses were evaluated for the most commonly selected decision for each scenario and the proportion of radiologists choosing that decision. If the three groups chose the same decision for a given scenario, it indicated high agreement *between* the groups. Agreement *within* the same group was measured by the proportion of responses that selected the decision(High ≥75%, Moderate 50-74%, Low 25-49%, and Poor <25%). Demographic inquiries included years in practice, subspecialty training, and current practice type.

Results

One hundred fifty-three radiologists participated in the survey, including 41 in Group A, 28 in Group B, and 84 in Group C. Table 1 shows the responses for Groups A-C and agreement within each group. Management of 15 mm nodules was most uniform between the groups with all choosing "recommend ultrasound." There was also at least moderate agreement for this response within each group. The scenarios with least agreement between the groups

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

and lowest concordance within groups were 8 mm nodules in adults, 10 mm nodule in 60-year-old females, multiple nodules, and a nodule with lung cancer history.



Conclusion

Radiologist practices in reporting ITN on CT and MRI in adults vary widely, especially for nodules less than 15 mm, patients with multiple nodules, and nodules in oncology patients. Guidelines for the standardization of reporting practices may help alleviate radiologist uncertainty and provide consistency for referring clinicians. This survey may serve as one step towards the creation of such guidelines.

Incidental Thyroid Nodules Detected on Imaging: Can Workup Be Reduced by Using the Society of Radiologists in Ultrasound Guidelines and the 3-Tier System?

Hobbs, H. A.·Bahl, M.·Nelson, R. C.·Kranz, P. G.·Esclamado, R. M.·Hoang, J. K.
Duke University
Durham, NC.

Purpose

Incidental thyroid nodules (ITN) on imaging can be a challenging problem for radiologists and clinicians. However, guidelines can help to direct ITN workup. The Society of Radiologists in Ultrasound (SRU) published sonographic recommendations to direct FNA, and recently a 3-tiered system was proposed for workup of thyroid nodules seen on CT, PET and MRI. The intentions of both guidelines are, not to diagnose all cancers, but to diagnose "*clinically significant"* cancers, while avoiding unnecessary tests and surgery in patients with benign nodules. The aim of this study was to determine the number of nodule workups that could be reduced and the malignancies that would be missed if the SRU recommendations and 3-tier system were applied to imaging-detected ITN.

Materials & Methods

This is a retrospective study of 390 consecutive patients who underwent ultrasound-guided thyroid FNA from July 2010 to June 2011. Medical records were reviewed for patients with ITN first detected on imaging studies and their subsequent pathology results. The imaging studies that lead to the detection of the ITNs were reviewed by two radiologists. Readers recorded characteristics of the ITN and whether nodules met criteria per guidelines. Incidental thyroid nodules seen on ultrasound were categorized by SRU recommendations which includes solid nodules ≥15 mm, or nodules with microcalcifications ≥10 mm, coarse calcifications ≥15 mm, and solid-cystic component ≥20 mm. The 3-tiered system was applied to ITN seen on CT, MR and PET/CT. It recommends sonographic workup of nodules with high risk imaging features(suspicious lymph nodes, local invasion, PET focal metabolic activity), high risk history(age <35 years, active metastatic disease), or solid nodules ≥15 mm.

Results

There were 114/390(29%) patients(78 female, 36 male, mean age 60 years, range 14-91) documented as having nodules first detected incidentally by imaging studies. The prevalence of malignancy in nodules based on cytopathology and confirmed at surgery was 8/114(7%). Imaging studies were available for review on 108/114 patients. Of 108 patients, 47 were incidentally detected on ultrasound and the other 61 were seen on CT(37), MRI(11), and PET/CT(13). The SRU recommendations were applied to 47 patients with ITN detected by ultrasound (thyroid, parathyroid, and carotid ultrasound). This group had four malignancies. Fourteen patients did not meet SRU recommendations for workup and would not have undergone FNA. In these 14 patients, SRU recommendations missed one cancer which was a localized papillary thyroid carcinoma. The 3-tier system was used to categorize 61 patients with ITN on CT, MRI and PET/CT. This group also had four malignancies. Twenty-one patients did not meet criteria for the 3-tier system and would not have proceeded with sonographic workup if the system had been applied. There were no missed malignancies in the 21 patients.

Conclusion

Imaging is a common source for ITN, but the prevalence of malignancy in nodules receiving biopsy is low. The 3-tiered system and SRU recommendations can be used as guidelines for managing ITN and can reduce 31% of nodule workups. The SRU recommendations only missed one malignancy which was not aggressive by histological type, size and stage.

Endovascular Treatment of Head & Neck Arteriovenous Malformations

Dmytriw, A. A.·terBrugge, K. G.·Agid, R.
Toronto Western Hospital
Toronto, ON, CANADA.

Presentation Summary
Purpose: Head & Neck arteriovenous malformations (H&N AVM) are associated with considerable clinical and psychosocial burden and present a significant treatment challenge. We evaluated the presentation, response to treatment and outcome of patients with H&N AVM treated by endovascular means at our institution.
Materials and Methods: Patients with H&N AVM treated by endovascular means in our institution over a 19-year period (from 1993 to 2012) were evaluated retrospectively. These included AVMs involved the scalp, orbit, maxillofacial, and upper neck localizations. Patient's clinical files, radiological images, catheter angiograms and surgical reports were reviewed.
Results: 48 patients with H&N AVM (29 females, 19 males, 23 small, 25 large) were treated with endovascular therapy. Females were more likely to have large AVMs (1.5:1) and were twice more likely to present with hemorrhage. The goals of treatment were defined as curative (n=14), palliative (n=20) or pre-surgical (n=14). The total number of endovascular treatment sessions was 134 (average of 2.8 sessions per patient). Various approaches and embolization materials were used. The goal of treatment was met in 81.25% (39/48) of cases with cure in 25% (12/48). 16.7% (8/48) of patients were cured by embolization alone, 8.3% (4/48) cured by planned post embolization surgical excision. All cured lesions were small. (7/48) patients suffered transient, and 6% (3/48) suffered permanent treatment complications.
Conclusion: Endovascular treatment is effective for H&N AVMs and relatively safe. It is particularly effective for symptom palliation and as pre-surgical aid prior to surgery of large lesions. Embolization is curative in small lesions. In patients with large non-curable H&N AVMs endovascular therapy is often the only option.

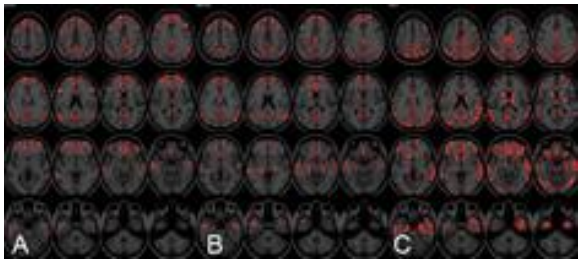
Resting-State Networks in Traumatic Brain Injury

Lin, L. Y.·Mac Donald, C. L.·Lee, M. H.·Snyder, A. Z.·Brody, D. L.·Shimony, J. S.
Washington University School of Medicine
St. Louis, MO.

Purpose
Survivors of traumatic brain injury (TBI) suffer cognitive dysfunction especially in tasks that depend on memory and control of attention. It is thought that the axonal injury and consequent disruption of functional networks contributes to the cognitive dysfunction. Resting-state fMRI (rsfMRI) is well established as a modality for evaluating the integrity of functional neural networks. Previous studies have shown reduced functional connectivity within the default mode network (DMN) associated with impaired attention in patients with TBI. The goal of this study was to investigate changes in several resting state networks in five severe and 11 moderate chronic TBI patients using a fuzzy-c-means clustering algorithm.
Materials & Methods
Sixteen patients with clinically diagnosed chronic TBI (ages 18-50) and 16 controls matched for age and handedness were scanned in a 3T Allegra MRI scanner (Siemens, Erlangen, Germany). Following previously described protocols, we acquired rsfMRI (4 cubic mm voxels, 438 frames), high-resolution MPRAGE and T2-weighted fast spin-echo scans. Postprocessing included compensation for asynchronous slice timing, retrospective correction for head motion and atlas transformation. A voxel-by-voxel correlation matrix was analyzed for each patient and averaged across the three groups (control, moderate, and severe). The fuzzy-c-means clustering algorithm was used to classify each group's averaged correlation matrix into seven resting state networks. The resulting connectivity maps were compared across groups.
Results
Differences were noted in several networks. The default mode network (Figure 1A: control; 1B: moderate TBI; 1C:severe TBI) showed decreased weight in the medial pre-frontal cortex and increased weight in lateral parietal and occipital cortices, and these changes varied with severity of injury. The dorsal and ventral attention networks showed loss in symmetry, most notably in the severe TBI patients. The language network showed decreased cortical weights with preservation of weights in deep nuclear structures. The fronto-parietal control network showed losses in deep nuclear and occipital cortex, and preservation in pre-frontal cortex.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Conclusion
These findings provide preliminary information regarding changes in resting state networks in patients with moderate and severe TBI. The changes in the default mode network and the attention networks may help us understand the cognitive dysfunction in patients with severe TBI. Loss of symmetry in the attention networks suggests corpus callosal disruption interfering with interhemispheric communication. Further investigation is needed to quantify the extent of changes and to correlate these with changes with formal cognitive measures and with clinical outcomes.

Assessment of Severe Traumatic Brain Injury with Quantitative Diffusion Tensor Imaging: A Five-Year Prospective Cohort

Khalilzadeh, O.[1]·Dinkel, J.[1]·Perlbarg, V.[2]·Gupta, R.[1]·Puybasset, L.[3]·Galanaud, D.[3]
[1]Massachusetts General Hospital, Boston, MA, [2]Université Pierre et Marie Curie-Paris, Paris, FRANCE, [3]Pitié Salpêtrière Hospital, Paris, FRANCE.

Purpose
Prediction of outcome in survivors of severe traumatic brain injury (TBI) is a major clinical challenge. There is not sufficient evidence on the long-term white matter brain changes in patients who survive after severe TBI. In this study, we used quantitative diffusion tensor imaging (DTI) to evaluate brain changes in 20 different white matter tracts over a span of five years after the injury. We assessed the prognostic value of DTI in prediction of long-term neurologic outcome in severe TBI patients.
Materials & Methods
This study was approved by the institutional review board of our hospital. Sixteen long-term survivors of severe TBI underwent brain MRI at three time-points: within the first six weeks after the injury, year two and year five post-TBI. Eight controls also were scanned at baseline and at two-year interval. The local diffusion parameters, namely, fractional anisotropy (FA), axial diffusivity and radial diffusivity (Lt), were calculated in each patient and control. The DTI parameters were calculated in 20 different brain regions, and were normalized using a set of controls. The changes in DTI values were compared between the three time-points. The association of DTI changes with patients' clinical outcome was also assessed.
Results
The baseline FA (or Lt) values were significantly lower (or higher) at genu/body of corpus callosum and right/left corona radiata in the patients as compared to the controls. In these regions, FA (or Lt) values were significantly lower (or higher) at the year two scan in comparison with the baseline values in TBI patients. After the year two time point, there was stabilization and no significant difference was observed between year two and year five. The normalized baseline FA cut-point of 0.87 at genu of corpus callosum was 80% sensitive and 70% specific in prediction of neurologic sequelae (such as amnesia, aphasia and motor dysfunction).
Conclusion
Fractional anisotropy and Lt changes in genu/body of corpus callosum and corona radiata have prognostic value in prediction of long-term neurologic sequelae in patients with severe TBI. These changes remain stable after two years from the injury, which points to little long-term postinjury repair and plasticity.

Individualized Analysis is a Better Predictor of Persistent Postconcussive Symptoms than Group Analysis: Potential Importance of Individual Variation

Rosenbaum, S. B.·Kim, N.·Smith, J.·Lewkowitz-Shpuntoff, H.·Provataris, J.·Zimmerman, M. E.·Lipton, R. B.·Branch, C. A.·Lipton, M.
Albert Einstein College of Medicine
Bronx, NY.

Purpose
At one-year post-mild traumatic brain injury (mTBI), as many as 80% of patients experience at least one persistent postconcussive symptom, and 30% meet criteria for a postconcussion syndrome diagnosis. Biomarkers that forecast long-term outcome at the time of injury do not exist. Low fractional anisotropy (FA) corresponds to traumatic axonal injury and is associated with worse outcomes. Previously, we have shown that there are associations between early DTI measures and persistent postconcussive symptoms, but it is not clear that these techniques can accurately discriminate between those with good versus poor outcomes. The purpose of this study was to compare a voxelwise, single-subject analysis of FA to a standard voxelwise group comparison (t-test),for their effectiveness in classifying patients as postconcussion syndrome positive [PCS (+)] versus postconcussion syndrome negative [PCS(-)], at one year post-injury.
Materials & Methods
This study was conducted with IRB approval and written,

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

informed consent, and complied with HIPAA. We enrolled 25 mTBI patients from a local emergency center and 40 healthy controls. 3T DTI (b=1000, 32 directions) was performed within two weeks of injury, and symptoms were assessed at one year post-injury, using the Rivermead Post-Concussion Symptom Questionnaire. Subjects who met ICD-10 diagnostic criteria for PCS were classified as PCS (+) and those who did not as PCS (-). Fractional anisotropy maps were regression-adjusted for age, gender and years education. Regions of abnormally low FA were identified using a voxelwise t-test ($p<0.05$ corrected) comparing the patient and control groups. Additionally, voxelwise Z-score maps were computed for each patient based on the control group, with bootstrap resampling of the variance and thresholding at $p<0.05$. Mean FA, RD, MD and AD across all voxels of abnormally low FA was calculated for each patient, for each method. Stepwise discriminant function analysis was used to determine which imaging predictors correctly classified subjects as PCS(+) versus PCS(-) at one year post-mTBI.
Results
Ten patients (40%) were classified as PCS (+). Mean FA across all voxels with abnormally low FA identified by the voxelwise t-test analysis discriminated between PCS(+) and PCS(-) (Wilks' lambda=0.822,p=0.035), correctly classifying 64.0% of cases (sensitivity=60.0%, specificity=66.7%). Mean FA and mean RD across all voxels of abnormally low FA identified for each patient by the voxelwise Z-score analysis significantly discriminated between PCS(+) and PCS(-) (Wilks' lambda=0.403, p<.000), correctly classifying 90.9% of cases, (sensitivity=78.8%, specificity=100%).
Conclusion
Abnormally low FA within two weeks of injury, identified using an individualized single-subject Z-score method, more accurately classified subjects as PCS(+) versus PCS(-) than a voxelwise group comparison. Because the individualized analysis is sensitive to intersubject spatial heterogeneity of abnormalities, it may better capture the full extent of mTBI pathology in each individual patient, and therefore predicts outcome (PCS) with a higher degree of accuracy. Moreover, the discriminant function more accurately classified subjects according to PCS diagnosis when using both RD and FA as predictors. This suggests that RD, which may indicate more severe TAI pathology, is an important element for prognostic models in mTBI. Larger-scale studies are necessary to confirm and generalize these findings.

Sex Differences in White Matter Abnormalities after Mild Traumatic Brain Injury on Diffusion Tensor Imaging: Localization and Correlation with Outcome

Alhilali, L. M.·Yaeger, K.·Fakhran, S.
University of Pittsburgh
Pittsburgh, PA.

Purpose
Many factors have been associated with clinical outcome after mild traumatic brain injury (mTBI); among the most controversial is gender. A possible neuroprotective effect of progesterone has been offered for anecdotal evidence of better outcomes in females. The purpose of this study was to evaluate sex differences in diffusion tensor (DTI) white matter abnormalities after mTBI using tract-based spatial statistics (TBSS) and compare associated clinical outcomes.
Materials & Methods
Diffusion tensor imaging was performed in 64 mTBI patients (42 males, 22 females) and 21 controls (10 males, 11 females) with normal conventional MRI. Neuropsychologic evaluation of mTBI patients was performed with the Immediate Post-Concussion Assessment and Cognitive Testing (ImPACT test). Fractional anisotropy (FA) maps for controls and mTBI patients were each aligned to a template with nonlinear alignment and projected onto two separate representative white matter skeletons, derived from each group's aligned images using Functional MRI (fMRI) of the Brain (FMRIB) Software Library package. Voxel-wise comparisons of FA between males and females were performed for controls and mTBI patients, using nonparametric randomized permutation tests with general linear model and multiple comparison correction. Clinical outcomes were assessed with serial neuropsychologic evaluation with the ImPACT test.
Results
Male and female groups were not significantly different in age in either the control ($p = 0.30$) or mTBI ($p = 0.34$) groups. Male and female mTBI patients did not have significantly different initial ImPACT symptom scores ($p = 0.33$). Males in the mTBI group had significantly decreased FA values in the uncinate fasciculi bilaterally compared to females ($p<0.05$), a tract connecting the frontal and temporal regions, two regions which demonstrate the highest concentration of extra-hypothalamic progesterone receptors. This difference was not seen in the control group. Male mTBI patients had a significantly longer time to symptom resolution ($p = 0.04$) compared to females. Time to symptom resolution strongly correlated with sex ($p = 0.004$), but did not correlate with initial symptom severity in either males ($p = 0.73$) or females ($p = 0.99$).
Conclusion
Relative sparing of the uncinate fasciculus is seen in females compared to males after mTBI, with gender being

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

a stronger predictor of time to clinical recovery than initial symptom severity.

Microbleeding and Cerebral Volume Reduction in Diffuse Axonal Injury Patients between One and Twelve Months of Trauma

Feltrin, F. S.[1]·Leite, C. C.[1]·Zaninotto, A. L. C.[2]·Guirado, V. M. P.[2]·Andrade, A. F.[2]·Teixeira, M. J.[2]·Cerri, G. G.[1]·Nascimento, S.[1]
[1]INRAD - HCFMUSP, São Paulo, BRAZIL, [2]HCFMUSP, São Paulo, BRAZIL.

Purpose
Evaluate the white matter atrophy and correlate it to the number of lesions acording to the microbleed anatomical and rating scale (MARS).
Materials & Methods
Approval for this study was obtained from the Institutional Research Ethics Committee and written informed consent was obtained from all subjects. Eleven subjects (5 male; age, 22.1 ± 2.0 years; range, 19 - 32 years) with a history of moderate or severe traumatic brain injury (TBI) were evaluated after 2, 6 and 12 months from the traumatic event by using MR imaging. Images were acquired at a 3.0T MR imaging scanner (Phillips Achieva, Best, The Netherlands). Patients were assessed by T2* and T1 3DFSPGR sequences. Automatic assessment of brain volumes were performed with FreeSurfer (http://surfer.nmr.mgh.harvard.edu/fswiki). The T2* images were evaluated by two radiologists and stratified according to the MARS scale. To assess correlations between the MARS scale, neuropsychologic data and volumetry, we used the Pearson correlation rank.
Results
The average white matter volume reduction was 5.20% (+/-1.4) in 12 months. The lesion number according to the MARS scale was 69 (+/- 65) microbleeds. The inverse order digit span was 3.8 (+/- 1.87). We found a significant correlation between the MARS scale and the volume loss in the first year.
Conclusion
The diffuse axonal injury first grading scale is the Adams and Genarelli scale, which divides the patients into three groups. However, there are big differences in the number of lesions inside each group. The MAARS scale is a new way to rate those patients according to the number of lesions, and here we show that this scale shows strong correlations with the volume loss of white matter in the first year.

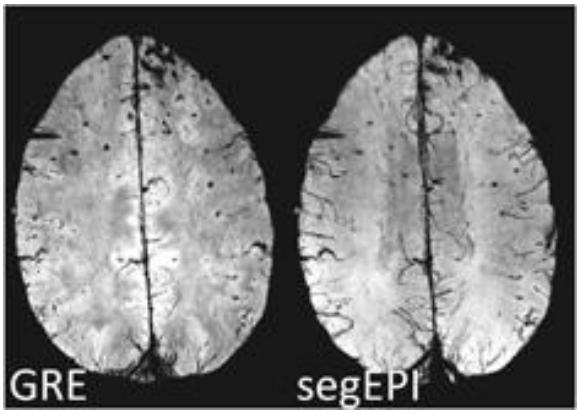
Microhemorrhage Detection in Traumatic Brain Injury Using Ultrafast Segmented Echo-Planar High-Resolution Susceptibility-Weighted Imaging Using Susceptibility-Weighted Imaging

Butman, J. A.[1]·Wang, W.[2]·Li, N.[2]·Pham, D. L.[2]
[1]The Clinical Center of the NIH, Bethesda, MD, [2]Center for Neuroscience and Regenerative Medicine, Bethesda, MD.

Purpose
Dramatic acceleration of GRE can be performed with segmented EPI (segEPI). Therefore, we sought to determine whether accelerated high resolution (0.5×0.5×2) SWI using 3D segEPI GRE covering the whole head (72 slices) can substitute for traditionally implemented 3D GRE SWI for the detection of traumatic intracranial microhemorrhages in routine clinical use.
Materials & Methods
3D GRE and 3D segEPI SWI were performed in 46 consecutive patients enrolled in a natural history study of traumatic brain injury on a 3T system. Scan times were 9m47s for the 3D GRE and 1m30s for the 3D segEPI SWI. Contrast and acceleration parameters for the GRE were TR=64/TE=25/FA=20°/GRAPPA=2 and for the segEPI were TR=40/TE=25/FA=15°/ETL=15. Geometric parameters were matrix 448×343, resolution 0.5×0.5×2 mm and (72 slices). Phase emphasis was applied by (i) global phase unwrapping procedure (ii) followed by high pass filtering (iii) multiplication of the magnitude and filtered phase. Microbleeds were counted in two separate sessions separated by over two weeks. The order of presentation of GRE and segEPI between the two sessions and the case order were randomized. Magnitude, filtered phase, phase emphasized SWI and minimum intensity projections were available.
Results
Microbleed counts with the two methods were correlated (slope=0.84, r2=0.96). Using the 3D GRE, the number of microbleeds was slightly higher 13.7± range=0-179 than for 3D segEP1, 10.7± range 0-171 p=0.014. Patients were classified as TBI+ or TBI- based on the presence or absence of microbleeds. Half (23) of the 46 TBI patients were positive by both methods, and 16/46 were negative. Discordance was present in seven, five positive on 3D GRE only and two positive on segEPI only. Diagnostic classification agreement between the two tests was good (kappa = 0.69).

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Conclusion
Dramatic acceleration of SWI imaging can be obtained by incorporating segmented EPI into the traditional 3D GRE sequence. For the particular parameters chosen in this study, an over 6-fold acceleration was achieved allowing high resolution 0.5×0.5×2 mm voxels covering the whole brain (72 slices) in 1½ minutes. Here we show that both methods perform comparably in the detection of microbleeds. In classifying patients with TBI based on detection of microbleeds, both methods show good agreement. Because there is no gold standard, it is not clear whether the high degree of image quality and the high level of concordance between the two methods indicate that segEPI can replace GRE for detection of microhemorrhage when time constraints are critical.

KEYWORDS: 3T, Microbleeds

White Matter Microstructural Injury in Mild Traumatic Brain Injury: Findings Relative to Timing of Injury

Agarwal, V.[1]·Wo, S.[2]·Henry, L.[1]·Kontos, A. P.[1]·Collins, M. W.[1]·Delfyett, W. T.[1]
[1]University of Pittsburgh Medical Center, Pittsburgh, PA, [2]University of Pittsburgh School of Medicine, Pittsburgh, PA.

Purpose
Mild traumatic brain injuries (mTBI), or concussions, remain a challenging and controversial neurologic injury. Conventional magnetic resonance imaging (MRI) of mTBI often is normal and there is currently no reliable biomarker. Diffusion tensor imaging (DTI) has been suggested as a potential imaging biomarker of mTBI. Previous DTI studies in mTBI have shown varying results; some studies demonstrate decreases in fractional anisotropy (FA) following mTBI while others demonstrate no change or even an increase in FA. This variability may be multifactorial and in part may be related to timing of imaging relative to injury. The purpose of this study is to document the presence of microstructural white matter damage in patients with mTBI with reference to the timing of imaging relative to injury.
Materials & Methods
An IRB approved, HIPAA compliant retrospective analysis of DTI data (1.5T; 25 directions; b=1000) was performed on 248 patients who underwent MR imaging as part of evaluation for concussion over the past five years at our institution. Demographic, clinical data including date of injury and neurocognitive test results (ImPACT) were recorded. Timing of injury relative to scanning was defined as acute (within three days), subacute (three-21 days) and chronic (greater than 21 days). Comparison was made to healthy control DTI data (N=38) obtained from the International Consortium for Brain Mapping (ICBM) online database. After initial postprocessing including eddy current correction, FA images derived from DTI were compared using whole brain histogram analysis and voxelwise analysis using Tract-Based Spatial Statistics (TBSS). Fractional anisotropy data were projected onto a white matter skeleton and between-group statistical analysis performed. Voxel clusters of significant between-group differences were overlaid onto the mean FA map with threshold set for corrected p-value of 0.01.
Results
Of the 248 patients, clinical data were available on 149 patients (36% female; age range 10-63 years with average age 24.1 years). There were two patients scanned in the acute phase, 40 in the subacute phase and 110 in the chronic phase. Histograms of white matter FA show an overall shift towards lower FA in concussed patients compared with controls for all three groups. There was a slightly greater shift in the histogram curve of FA in the acute phase compared with the subacute and chronic phases. Tract-Based Spatial Statistics analysis showed areas of significantly decreased FA ($p < 0.01$) in the corpus callosum and deep frontal white matter for acute, subacute and chronic cases.
Conclusion
We present the largest known overall series of mTBI patients evaluated with DTI to date. Regardless of the timing of injury relative to scanning, microstructural white matter injury in patients with mTBI is evidenced by an overall shift to decreased white matter FA in concussed patients compared with controls. While certain specific anatomical areas (corpus callosum and deep frontal white matter) demonstrate significant decreases in FA, our data suggest that in the setting of mTBI, global decreases in white matter FA accompany these more focally affected areas.

Diffusion Tensor and Susceptibility-Weighted Imaging Assessment of National Football League Players

Niogi, S. N.[1]·Luther, N.[1]·Kutner, K.[1]·Christos, P. J.[1]·Shetty, T.[2]·Barnes, R.[3]·Weiss, L.[3]·Warren, R. F.[2]·Rodeo, S. A.[2]·Zimmerman, R. D.[1]·Tsiouris, A. J.[1]·Härtl, R.[1]
[1]Weill Cornell Medical College, New York, NY, [2]Hospital for Special Surgery, New York, NY, [3]New York Giants Professional Football Organization, New York, NY.

Purpose
Given the heightened awareness and concern of the potential somewhat intuitive risks associated with sports-related concussion, there is a justifiable need to better understand the anatomical and functional changes that may occur. Unlike other cases of isolated concussion such as motor vehicle accidents, athletic competition has the added risk factor of repetitive head injuries over the lifetime of a career. Elucidating the extent of traumatic brain injury (TBI) at the professional level, with the longest exposure and presumably greatest cumulative risk of TBI, may help define post-traumatic anatomical changes at the most extreme levels of play. The purpose of this study was to identify whether anatomical changes occurred in National Football League (NFL) players measurable by magnetic resonance diffusion-tensor imaging (DTI) and susceptibility-weighted imaging (SWI).
Materials & Methods
New York Giants Professional football players with and without a history of concussion and normal controls underwent conventional clinical magnetic resonance imaging (MRI) in addition to DTI and SWI. In a prospective fashion, players with concussion during gameplay were assessed by a study neurologist, underwent ImPACT neurocognitive testing, and MRI including DTI and SWI within one week of injury. Diffusion tensor imaging analysis was performed by both region-of-interest (ROI) and voxel-based methodologies. For ROI analysis, comparison of Z-score distributions of player fractional anisotropy (FA) values to normals was performed in 11 high-risk tracts based on prior studies. Voxel-based analysis was performed to compare players to controls, players with concussion history to players without concussion history, and players with greater than four years of professional experience to those less.
Results
Thirty-one players were enrolled. Twenty-one had positive concussion history, including 12 players who suffered an acute concussion. Mean playing experience was 3.1 years. When FA was compared in players to 22 controls, no significant decrease in Z-score distributions was found. No difference was seen in either ROI or voxel-based analysis when subgroups of players with acute concussion history and players with ≥4 years of professional football experience were compared to normals. No player had an FA value >2.5 standard deviations below the normals' means. Susceptibility-weighted imaging revealed chronic microhemorrhage in one player.
Conclusion
Difffusion tensor imaging and SWI revealed no significant evidence of white matter injury or acute microhemorrhage in professional football players with acute concussion or chronic concussion history. Additionally, no differences in white matter integrity were seen in players based on years of experience. Diffusion tensor imaging, while promising, remains under development and continues to be an investigational technique in the assessment of TBI. Clinical decision-making should not be based on this modality at present. Susceptibility-weighted imaging continues to be a critical tool for clinical assessment to detect diffuse axonal injury-related microhemorrhage and other abnormalities, but is likely insensitive to possible subtle changes seen with mild football-related concussion.

National Football League Hard Knocks: Fractured Inter-Network Connectivity in Subjects with Remote Repetitive Mild Traumatic Brain Injury

Airan, R. D.·Coughlin, J. M.·Sair, H. I.·Pomper, M. G.
Johns Hopkins Medical Institutions
Baltimore, MD.

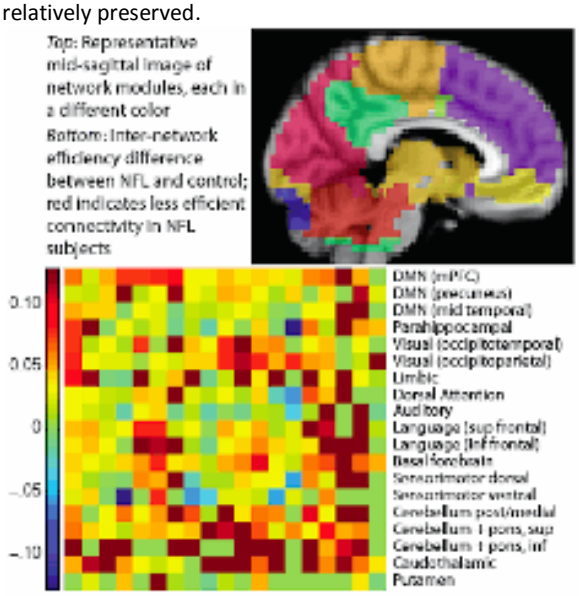
Purpose
High profile cases of former National Football League (NFL) players demonstrating behavioral dysfunction decades after play have generated interest in understanding the late sequelae of chronic traumatic encephalopathy (CTE). Pathologic and structural brain abnormalities have been described in those known to have suffered repeated concussions. However, brain functional sequelae have been less clearly delineated. Here, we analyze resting-state functional connectivity in former NFL athletes to determine potential functional endophenotypes of CTE.
Materials & Methods
NFL players (n=14; ages 52-74) and age/sex-matched controls (n=4) underwent 3T MRI including T1 MPRAGE and seven minute eyes closed, resting awake BOLD fMRI (TR=2sec) sequences. Data were preprocessed using FSL (FMRIB, Oxford, UK), SPM8 (Wellcome Trust, UK) and custom MATLAB (Mathworks, MA) scripts to complete slice-timing correction, rigid-body motion correction, segmentation and normalization to the MNI 2mm template, COMPCOR nuisance regression, bandpass temporal filtering (0.01-1Hz), and spatial smoothing (6mm Gaussian kernel). Whole brain gray matter was parcellated automatically into 875 regions of interest (ROIs). For each ROI, the first eigenvariate of voxel timecourses was extracted. Pearson correlation coefficients between each pair of the 875 ROI timecourses were calculated. The set of average control correlation coefficients were fed as an undirected weighted adjacency matrix (thresholded at r^2=0.08) into the infomap modularity algorithm. For each

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

network, the intranetwork efficiency of the thresholded adjacency submatrix was calculated, with a similar measure applied to the internetwork efficiency.

Results

As shown in the figure, 19 networks spanning all of brain gray matter were found that are consistent with those demonstrated in the literature, without using any a priori information of expected network structure. (Figure, *top*: representative midsagittal slice of network modules overlayed onto a standard template). The differences in network efficiency between NFL players and controls for each pair of networks (Figure, *bottom*: red indicates decreased internetwork efficiency in NFL players) show that this population of NFL players has trend-wise reduced overall internetwork efficiency, with significantly ($p<0.05$) increased efficiency between the temporal default mode and limbic networks, and between parahippocampal and ventral sensorimotor networks. Intranetwork efficiency is relatively preserved.



Conclusion

NFL players show reduced overall internetwork efficiency with focally significant increases in limbic-temporal and parahippocampal-ventral sensorimotor connectivity. This fracturing of normal connectivity patterns into temporoparietal subnetworks may provide a functional substrate of CTE. Further studies will assess the potential diagnostic performance of fractured internetwork efficiency for predicting neurocognitive and affective dysfunction in patients at risk for CTE.

Brain Iron Estimation Using Magnetic Field Correlation and Relaxation Rate in Mild Traumatic Brain Injury

Savino, M. R.·Zhou, Y.·Novikov, D. S.·Lui, Y. W.
New York University Langone Medical Center
New York, NY.

Purpose

Magnetic field correlation (MFC) is a novel MR imaging technique that quantifies magnetic field inhomogeneities (MFI) at the mesoscopic scale, commensurate with cell dimensions (~1-10 µm). In brain, the MFIs are caused, among other factors, by iron. We recently showed increased thalamic MFC in patients with mild traumatic brain injury (MTBI), believed to reflect neuropathologic iron. In this study, we aim to show correlation between MFC and tissue relaxation R2* and R2 rates in these patients, to further validate MFC as a reliable MFI metric.

Materials & Methods

Recruited were eight patients with clinically defined MTBI 1 year postinjury and six age-matched, healthy controls. A Siemens 3T MR scanner was used with an asymmetric spin echo (ASE) pulse sequence (TR/TE=3420/40ms; time shifts t_s=0, -4ms, and -16ms; isotropic resolution=1.72mm; 48 axial slices, four averages) for MFC estimation. For R2 estimation, zero shift images with TE=34 ms also were obtained. A 3D gradient echo (GRE) obtained with multi-echo (ME) acquisition and first-order 3D flow-compensated was acquired with eight TEs ranging from 6.12 to 41.82 ms and echo spacing of 5.1 ms (TR=60 ms, flip angle=20°, voxel size=0.5×0.5×1.0 mm^3). Bilateral thalami were outlined manually on three continuous slices as regions of interest (ROI) for each subject. Magnetic field correlation was calculated with inhouse software and initial R2* was estimated by monoexponential fitting. The signal time curve then was visually inspected to assess for constancy of R2*.

Results

MFC_{total}=MFC_{meso}+MFC_{macro} contains the contributions from mesoscopic MFIs and macroscopic B_0 inhomogeneities. Both the MFC_{total} ($P<0.05$) and MFC_{meso} ($P<0.01$) were increased significantly in the thalami of MTBI patients compared to controls. Moreover, there was significant correlation between the MFC_{meso} and R2* values ($r=0.76$, $P=0.03$), and a trend between MFC_{total} and R2* ($r=0.65$, $P=0.08$), in MTBI patients. The time dependence of the R2* relaxation is fairly monoexponential for controls, yet strongly non-monoexponential through at least TE=50 ms in MTBI patients (Figure 1). No significant correlations existed in the control group or between the molecular relaxation rate R2 and MFC.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

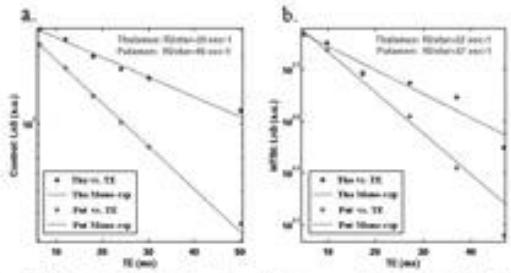

Figure 1. Multi-echo R2* relaxation. Examples from control subject (a) and MTBI patient (b). In the control, R2* signal decay is practically monoexponential, whereas in the MTBI patient, R2* signal is non-monoexponential in both deep gray matter structures. The rate R2*, estimated as the slope of the signal decay as a function of (TE), does not appear to be constant in the MTBI group through TE=50 ms, indicating that there are magnetic field inhomogeneities on the mesoscopic level of at least the size of ~10 μm, presumed to be caused by the presence of abnormal iron clustering at a cellular level.

Conclusion

This study shows an association between the mesoscopic contribution to MFC and R2* in patients one year after MTBI, supporting the utility of MFC in brain imaging. Microscopic (molecular) and macroscopic MFIs are essentially uniform within a single voxel, therefore the non-monoexponential R2* signal decay seen in MTBI subjects further validates the presence of iron-induced MFI on a cellular level, revealed by MFC_{meso}.

Role of Low-Dose Nonenhanced Brain CT in the Neurosurgical and Neurologic Intensive Care Unit

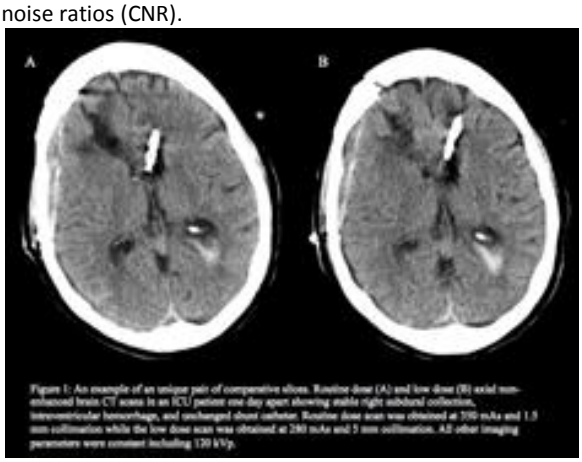
Hoch, M.[1]·Sethi, V.[2]·Shah, P.[1]·O'Connor, E.[1]·Hershey, B.[1]·Ali, S.[1]·Dass, C.[1]
[1]Temple University Hospital, Philadelphia, PA, [2]Temple University Medical School, Philadelphia, PA.

Purpose

To identify a patient population subject to serial short-term follow-up CT evaluation that may benefit from low dose CT examination. Most neurosurgical/neurologic intensive care unit (NICU) patients undergo multiple serial CT scans during a single hospitalization. After the initial routine scan, we explored if low dose follow-up scans could effectively evaluate NICU patients without sacrificing diagnostic accuracy.

Materials & Methods

Following IRB approval, a retrospective chart review was performed identifying 19 NICU patients (ages 18-73 years, mean 49 years) who had three axial nonenhanced brain CT examinations within a span of 72 hours in the following sequence: initial routine dose, followed by low dose, and finally routine dose. Included studies showed a persistent finding on the initial and final scans. From these routine and low dose scans, 59 unique pairs of comparative individual slices were selected (Figure 1). Two board-certified neuroradiologists, each blinded to the scan parameters and patient information evaluated the selected slices. The readers were asked if each image was diagnostically acceptable for interpretation and to note the presence or absence of the following findings: infarction, hemorrhage, herniation, and catheter location. All CT scans were performed on Siemens Sensation 16- or 64-slice machines. Routine scans were acquired with mAs ≥ 310 and collimation of 1.2 - 1.5 mm, while low-dose scans had mAs ≤ 280 and collimation of 5 mm. All other imaging parameters including 120 kVp were kept constant. Regions of interest placed over gray and white matter were obtained from each slice to calculate contrast-to-noise ratios (CNR).



Results

There was very high (95.3%) interobserver agreement in identifying pertinent findings on routine and low dose brain CT examinations among the sampled NICU patients (Table 1). Compared to routine dose, low dose CT imaging delivered a 26.07% reduction in average CTDIvol. Despite an average CNR reduction of 29.23%, low-dose imaging provided equal if not better diagnostic accuracy.

Table 1: Findings Made on Routine vs Low Dose CT

	Routine Dose			Low Dose		
	Reader 1	Reader 2	Concordance	Reader 1	Reader 2	Concordance
Venticular Catheter/ICP Monitor Location	10	10	100%	10	10	100%
Midline Herniation	17	20	85%	19	19	100%
Extracranial Herniation	4	4	100%	4	3	75%
Infarction	15	16	94%	17	17	100%
Intra-axial Hemorrhage	30	31	97%	31	30	97%
Extra-axial Hemorrhage	32	32	100%	38	37	97%

Conclusion

Low-dose brain CT is diagnostically acceptable when applied to the adult NICU population, emphasizing the concept of ALARA (As Low As Reasonably Achievable).

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Further collaboration with referring clinicians may allow development of additional dose reduction protocols.

MR Imaging Findings of Preterm Infants with Surgical versus Medical Necrotizing Enterocolitis

Ramos, Y. M.·Kline-Fath, B.·Merhar, S.
Cincinnati Children's Hospital
Cincinnati, OH.

Purpose
To evaluate the degree of brain injury on MRI in infants with medically managed necrotizing enterocolitis (NEC) versus those with spontaneous intestinal perforation/surgically managed NEC. Since patients with surgically managed NEC have worse neurodevelopmental outcomes than those with medically managed NEC (Hintz et al 2005), and poor neurodevelopmental outcomes have been associated strongly with abnormal MRI findings (Miller 2005, Woodward 2006), we hypothesize that the surgical group will demonstrate more severe injury on MRI.
Materials & Methods
Term equivalent brain MRI was performed on all surviving preterm infants with NEC at our institution during the period of July 2011 to October 2012. The studies were reviewed by two pediatric neuroradiologists blinded to all clinical information except postconceptual age at the time of scan. A brain injury scale modified from Miller et al (2005) was utilized to grade intracranial injury. MR imaging findings evaluated included white matter injury, ventriculomegaly, intraventricular hemorrhage, cerebellar hemorrhage and size of extra-axial spaces. Multiple linear regressions were performed in SAS comparing clinical variables with brain injury score as the continuous outcome.
Results
A total of 20 infants were evaluated (11 in the medical group and nine in the surgical group). Birth weight ($p = 0.06$) and gestational age (GA) ($p = 0.046$) were correlated with total brain injury score. On multiple linear regression analysis, after controlling for GA, the brain injury scores were significantly higher in the surgical group versus the medical group ($p = 0.01$). When the sites of injury were compared directly, it was noted that infants in the surgical group statistically had more white matter injury ($p = 0.01$) and greater ventriculomegaly ($p = 0.04$) than those in the medical group.
Conclusion
Infants with surgical NEC have more severe brain injury on MRI at term equivalent age than infants with medical NEC, which likely explains the poorer neurodevelopmental outcomes in the surgical group. In addition, infants with NEC requiring surgery have increased white matter injury and ventriculomegaly. The higher white matter injury may support microglia activation from more severe infection/inflammation resulting in injury to oligodendryocyte progenitors.

Predictive Value of NICHD Neonatal MR Imaging Scoring Criteria for Neurodevelopmental Outcome at Twenty-Four Months after Therapeutic Hypothermia

Rollins, N. K.[1]·Morriss, M. C.[1]·Sanchez, P.[1]·Heyne, R.[1]·Chalak, L.[2]
[1]Childrens Medical Center, Dallas, TX, [2]University Texas Southwestern Medical Center, Dallas, TX.

Purpose
MR imaging is an imaging surrogate for neurodevelopmental problems in survivors of perinatal hypoxic-ischemic injury (HIE). The NICHD Neonatal Research Network (NRN) recently has revised the MRI criteria for assessing brain injury after HIE treated with whole-body cooling; criteria to be used in subsequent randomized controlled trials of deeper longer cooling. We evaluated the predictive value of the NICHD NRN scoring criteria.
Materials & Methods
Prospective cohort of inborn infants (≥36 weeks' gestation) with perinatal academia s/p cooling for moderate/severe HIE at a single institution from 10/2005-10/2010. Perinatal MRI (T1 SE or FLAIR, T2 FSE, and DWI b = 1000) were scored by two pediatric neuroradiologists blinded to outcome using NICHD-NRN MRI scores (Shankaran, 2012): 0 = negative, 1a = "minimal cerebral lesions only with no basal ganglia/thalami (BGT) or watershed (WS) lesions"; 1b = "more extensive cerebral lesions without BGT or WS lesions"; MRI scores 2a = "any BGT or WS lesions without additional cerebral lesions"; score 2b = "any BGT or WS lesions with additional cerebral lesions" and score 3 = "hemispheric devastation". Primary outcome measure was BSID-III scores in cognitive, language and motor domains at 18-24 months: < 70 = severe and 70-85 = moderate disability respectively; >85 = normal. Sensitivity, specificity, and positive and negative predictive values were calculated.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Results

There were 90 newborns; 10 (11%) died and 68/80 (85%) underwent MRI at eight (median) days of age followed by BSID-III at 18-24 months of age. MR imaging was 0 in 36 (53%) patients; five (14%) had BSID scores <85 in cognitive or language but not motor domains. Eighteen (26%) had MRI scores 1a-b; eight had BSID scores <85 in cognitive or language domains. Fourteen (20%) had MRI scores 2a, b, or 3; BSID scores were <85 in all and <70 in 10 (93%) which consistently affected motor domains. Table 1 indicates predictive values; MRI scores of 2 a&b and 3 were 100% predictive of any abnormal outcome while lesser degrees of brain injury has lower specificity and positive predictive value. However, a normal MRI was not consistently associated with a normal outcome.

Table 1.

Predictive Value of NRN MRI scoring system

	Sensitivity	Specificity	PPV	NPV
MRI score >0	81%	62%	40%	92%
MRI score 2a or >	62%	92%	71%	89%

Conclusion

In this clinical setting, seemingly minor degrees of WMI may be associated with significant problems in cognition and language but not motor domains in early childhood. Higher MRI scores are highly predictive of abnormal outcome with cognitive and motor deficits in early childhood.

Tract-Based Mean Apparent Diffusion Coefficient in Hypoxic-Ischemic Encephalopathy as a Predictor of Outcome at Thirty-Two Months

de Macedo Rodrigues, K.[1]·Jacob, F.[1]·Fons Estupina, M.[1]·McLean, A.[2]·Paldino, M.[1]·Khwaja, O.[1]·Soul, J.[1]·Stamoulis, C.[1]·Grant, P.[1]
[1]Boston Children's Hospital, Boston, MA, [2]Brigham and Women's Hospital, Boston, MA.

Purpose

Perinatal hypoxic-ischemic encephalopathy (HIE) remains a major cause of disability in the U.S. and worldwide. Many studies have tried to identify imaging-based biomarkers, particularly from diffusion-weighted images, which may be predictive of clinical outcome in patients with HIE. We previously have investigated mean apparent diffusion coefficient (ADC)and fractional anisotropy (FA) of the corticospinal tract (CST), inferior fronto-occipital fasciculum (IFOF), corpus callosum (CC) and its subdivisions (genu: GCC, splenium: SCC) derived from tractography as a predictor of gross motor outcome at 14 months of age. In this study, we investigated these parameters as potential predictor of combined motor and cognitive outcomes.

Materials & Methods

We retrospectively evaluated 21 term neonates with a clinical diagnosis of HIE and that had undergone MRI within the four days of life, including diffusion tensor imaging with 30 noncollinear directions suitable for tractography reconstruction. Six neonates with similar imaging data collected within the first five days of life, and no diagnosis of HIE were included as normative controls. Tractography was reconstructed using Diffusion Toolkit.Tracts were manually dissected on TrackVis. Clinical data were gathered by means of chart review. Presence of seizures was noted, and clinical outcome was classified as good/bad based on the NICHD hypothermia trial classification. No disability or mild disability was considered as good outcome whereas moderate or severe disability or death, considered as bad outcome. Logistic regression models were developed to assess the correlation between clinical outcomes and imaging parameters. Statistical analysis was performed in Matlab.The study was approved by the Committee on Clinical Investigation at Boston Children's Hospital.

Results

Mean age at scan was 2.3 days for the HIE group and 4.7 days for the control group. Seven neonates in the HIE group had bad outcomes and 14 had good outcomes. Median age at last clinical evaluation was 32.5 months (range 7-48 months). Sixteen infants with HIE had abnormal MRIs and five had normal MRIs. Eight neonates had seizures. Mean ADC of right and left CST and left IFOF were found to be statistically significant predictors of clinical outcome. Similarly, mean ADC of the same tracts also were statistically significant predictors of seizures, which suggests that the presence of seizures may potentiate ADC decreases. Finally, mean ADC of GCC, left CST and right CST were statistically distinct in HIE patients with normal MRI, HIE patients with abnormal MRI, and controls. This suggests that dispite the appearance of a normal ADC map, for at least some tracts, HIE patients have statistically distinct ADC from controls.

Conclusion

Our findings suggest that mean ADC of left CST, right CST and LIFOF may be predictors of outcome at 32.5 month of age after perinatal HIE. Since it represents the entire white matter tract, tractography reconstruction is potentially more robust than the highly subjective two-dimensional ROI placement on ADC maps. Finally, our results suggest that clinical read can potentially miss areas of significantly decreased ADC and a more quantitative evaluation is desired.

Role of Cranial Ultrasound in Predicting Cerebrovascular Complications in Pediatric Patients Treated with Extracorporeal Membrane Oxygenation

Alqahtani, E.·Zamora, C.·Bembea, M.·Berkowitz, I.·Carson, K. A.·Huisman, T. A. G. M.·Tekes, A.
The Johns Hopkins University
Baltimore, MD.

Purpose

Extracorporeal membrane oxygenation (ECMO) is used in the treatment of cardiopulmonary failure in children who fail to respond to maximal medical treatment. Patients on ECMO are at high risk of cerebrovascular complications (CVC) due to systemic heparinization, sepsis, acidosis, young age and carotid artery cannulation. We aim to evaluate the value of resistive index (RI) measurements in the anterior cerebral artery to predict CVC such as intracranial hemorrhage (ICH) and ischemic events in children with ECMO.

Materials & Methods

The institutional review board approved this study. Data were collected retrospectively from 2008 to 2012. A retrospective chart review of patients ≤ 3 months old who received ECMO and head ultrasound (US) with baseline and compression RI measurements between 2008 and 2012 was conducted. RI measurements were acquired utilizing curved and linear array transducers in the sagittal plane through the anterior fontanelle. Two RI measurements were obtained; gentle transducer pressure on the anterior fontanelle was applied for 3-5 seconds during the second measurement. Gender, gestational age, method of delivery, age at cannulation, type of ECMO, duration and indication for ECMO were obtained from patients' records. Association between different outcome, clinical variables and RI measurements were assessed using Kruskal-Wallis, Cochran-Armitage, and Fisher's exact tests.

Results

Thirty-six patients were included in the study (Table 1). Twenty-seven patients had no complications. Nine patients developed CVC (ICH n=6, and ischemia n=3). All US findings were confirmed by a CT or MRI. Only the age at initiation of ECMO had statistically significant correlation with increased risk of CVC (P<0.05). The incidence of CVC was 38% (exact 95%CI=19-59%) for ECMO at age 0-2 days, and 0% (exact 95% CI=0-26%) for ECMO at age > 2 days - Fisher's exact p=0.02. The difference between the baseline and compression RI values and the percent change on the first day of ECMO were statistically significant between CVC and no complications groups (p=0.03 and p=0.02 respectively) (Table 2), with an odd ratio of 13.35 and 95% confidence interval of 2.28-infinity. In pairwise comparisons, the significant difference was between the ICH group and the other two groups.

Table 1: Clinical characteristics of patients treated with ECMO

		No CVC n= 27	ICH n=6	Ischemia n=3	P value
Gender	Male	13 (48%)	5 (83%)	1 (33%)	
	Female	14 (52%)	1 (17%)	2 (67%)	0.32

	Range	(1-38)	(3-24)	(7-11)	0.65
Indication for ECMO	Congenital diaphragmatic hernia	7 (26%)	2 (33%)	1 (33%)	0.86
	Congenital heart disease	6 (22%)	0 (0%)	1 (33%)	
	Meconium aspiration	5 (5%)	2 (33%)	0 (0%)	
	Pulmonary hypertension	4 (4%)	1 (17%)	0 (0%)	
	Other	5 (26%)	1 (17%)	1 (33%)	
CVC: Cerebrovascular complications					
ICH: Intracranial hemorrhage					

Table 2: Day 1 RI measurements in children treated with ECMO

		No CVC n= 27	ICH n=6	Ischemia n=3	P value
Baseline RI	Median	0.54	0.63	0.45	
	Range	(0.28-0.86)	(0.46-0.84)	(0.34-0.68)	0.23
Compression RI	Median	0.55	0.5	0.45	
	Range	(0.27-0.85)	(0.33-0.58)	(0.43-0.63)	0.61
Difference in RI (Baseline RI - compression RI)	Median	0.01	0.06	0	
	Range	(-0.13-0.24)	(0.03-0.11)	(-0.05-0.09)	0.03
Percent change ((Baseline RI - compression RI)/Baseline RI)	Median	1.64	14.40%	0.00%	
	Range	(-25.00-50.00)	(5.77-26.83%)	(-7.35-26.47%)	0.02
RI: Resistive index					
CVC: Cerebrovascular complications					
ICH: Intracranial hemorrhage					

Conclusion

Initiation of ECMO in the first two days of life sets a higher risk for possible CVC. Differences between baseline RI and compression RI as well as their percent change on the first day of ECMO can be predictive of ICH. These results should be validated in future with larger prospective studies.

Reproducibility, Reliability, and Utility of ABC/2 in Calculating Infarct Volumes in the Perinatal Arterial Ischemic Stroke Population

Mirsky, D. M.[1]·Stence, N. V.[1]·Bernard, T. J.[1]·Armstrong-Wells, J.[2]
[1]Children's Hospital Colorado, Aurora, CO, [2]University of Colorado Denver, Aurora, CO.

Purpose
Perinatal arterial ischemic stroke (PAS) is a leading cause of lasting disability. Similar to adult stroke, counseling and prognostic decisions are based off of initial infarct volume on neuroimaging. These decisions may be time-dependent, necessitating a quick, accurate estimation of true infarct volume. ABC/2 method is a fast and reproducible way to calculate infarct volume in adult and childhood acute hemorrhagic stroke. It has been shown, however, to overestimate true infarct volume in the adult arterial ischemic stroke population. Therefore, we sought to determine the accuracy and reproducibility of ABC/2 in assessing acute infarct volume with diffusion-weighted imaging in PAS. Our ultimate goal is to use these data as a platform for further studies looking into the true clinical utility of ABC/2 volumes in our unique population.
Materials & Methods
We reviewed all PAS cases in our prospective cohort study from 08/01/2000 - 1/01/2012. We studied 25 consecutive patients with acute ischemic stroke. The criteria for acute symptomatic PAS included: 1) documented clinical presentation consistent with PAS such as seizure or encephalopathy; 2) MRI showing infarction in an arterial distribution with an acuity consistent with the neurologic signs and symptoms; and 3) greater than 28 weeks gestational age and less than 28 days of life. Two blinded pediatric neuroradiologists (DMM & NVS) determined volumes with the ABC/2 method, and the results were compared with those of the gold standard (manual planimetric method). Given the homogeneity of head circumferences in our study population, we did not adjust for total brain volumes (ABC/XYZ). Data were log transformed to approximate normal distribution in our samples. Student's *t*-test and Mann-Whitney U were used when appropriate, while linear regression was utilized to assess correlation between methods. A p-value of < 0.05 was considered significant.
Results
There were no differences in mean values between ABC/2 and planimetric volume calculations (mean 46 cm^3 versus 32 cm^3, respectively, $p = 0.01$), with good correlation ($R2 = 0.84$). However, the ABC/2 technique overestimated infarct volume by a median false increase (variable ABC/2 volume minus planimetric volume) of 8 cm^3 representing a 61% increase over the value of the gold standard (variable ABC/2 volume over planimetric volume).
Conclusion
Similar to other stroke populations, in the perinatal arterial ischemic stroke population, ABC/2 is a quick and reproducible way for clinicians to calculate stroke volume in the emergent setting. However, given that it consistently overestimates the true infarct volume compared to the gold standard planimetric volume method, caution should be used when relying solely on ABC/2 for prognostic counseling. Therefore, further studies are warranted to validate the true implications of ABC/2 calculation, risk assessment, and outcomes after PAS.

Diffusion Tensor Imaging of Pediatric Intramedullary Spinal Cord Neoplasms Characterizes Tumor Margins and Predicts Resectability but not Histology

Choudhri, A. F.[1,2]·Whitehead, M. T.[1,2]·Montgomery, B. K.[3]·Boop, F. A.[1,2]
[1]University of Tennessee Health Science Center, Memphis, TN, [2]Le Bonheur Children's Hospital, Memphis, TN, [3]University of Missouri-Kansas City, Kansas City, MO.

Purpose
Diffusion tensor imaging (DTI) and diffusion tensor fiber tracking (DT FT) are valuable tools for mapping white matter pathways in the brain, which more recently have been applied to the spinal cord. Previous work has suggested that DT FT on intramedullary spinal cord neoplasms (ICN) in adults can differentiate astrocytomas from ependymomas as astrocytomas due to infiltration of fibers by astrocytomas and splaying by ependymomas. We sought to determine whether DT FT can aid in characterizing the margins and predicting the histology of pediatric ICN.
Materials & Methods
Six children (5M/1F, age 4-18 years) with ICN were evaluated with preoperative DTI and DT FT. Diffusion tensor imaging was performed using axial and sagittal acquisition with 20 ($n = 3$) and 25 ($n = 3$) noncollinear directions of encoding with 2 mm slice intervals and a 128 x 128 matrix. Concomitant conventional MR imaging without and with gadolinium administration was performed. All DT FT was processed prospectively by a neuroradiologist and reviewed with the neurosurgeon prior to surgical resection.
Results
Diffusion tensor fiber tracking showed splaying of cord fibers in six of six pediatric ICN, without evidence of infiltration. Histology was pilocytic astrocytoma in five patients and ependymoma in one. Postoperative MRI revealed gross-total resection in six of six patients. All patients had improved postoperative neurologic symptoms, without new neurologic deficit.
Conclusion
Diffusion tensor fiber tracking can aid in preoperative planning of ICN by confirming a discrete margin of a lesion.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Diffusion tensor fiber tracking cannot predict tumor histology in a pediatric population. Prior adult studies which suggest DT FT can predict histology likely were related to the infiltrative nature of adult cord astrocytomas rather than a true histologic distinction. Splaying of fibers without infiltration on DT FT suggests discrete margins which may allow attempt at gross-total resection.

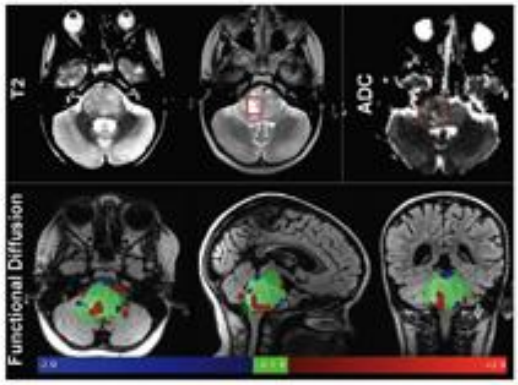
Functional Diffusion Mapping of the Heterogeneous Response to Immunotherapy in Pediatric Brainstem Gliomas: Initial Experience

Furtado, A. D.[1]·Ceschin, R.[1]·Young Poussaint, T.[2]·Ellingson, B. M.[3]·Okada, H.[1]·Jakacki, R.[1]·Pollack, I. F.[1]·Panigrahy, A.[1]
[1]Children's Hospital of Pittsburgh of the University of Pittsburgh Medical Center, Pittsburgh, PA, [2]Boston Children's Hospital, Pittsburgh, PA, [3]University of California Los Angeles, Los Angeles, CA.

Purpose
Little is known about imaging patterns of treatment response in immunotherapy of pediatric brain tumors. Diffusion MRI measures water mobility at the microstructural level within tissue, and has been shown to be a sensitive and earlier indicator of response to therapy. Functional diffusion mapping (FDM) is a novel method for quantifying heterogeneous tumor response by calculating voxel-wise changes in ADC; however, FDM techniques have never been applied to pediatric brain tumors nor have they been applied to examine immunotherapy response. The purpose of this study was to: (1) describe the incidence of tumor necrosis in immunotherapy of pediatric brainstem gliomas and (2) apply FDM techniques to examine serial ADC changes in the prenecrotic regions.
Materials & Methods
Newly diagnosed HLA (human leukocyte antigen) A2-positive brainstem gliomas were treated prospectively with immunotherapy after radiotherapy. Cystic necrosis was defined by focal T2 signal hyperintensity similar in signal intensity to CSF. Functional diffusion maps were created by coregistering ADC maps on post-treatment time points to a baseline pretreatment ADC map, then performing voxel-wise subtraction. Voxels were labeled red, blue, or green based on whether ADC increased, decreased, or did not change beyond a preset threshold (Figure 1 - bottom row).
Results
A total of 16 patients with newly diagnosed brainstem gliomas were included in this study (eight boys, eight girls, mean age = eight years). Approximately 37% of patients demonstrated necrosis at baseline, 75% of patients developed new areas of necrosis during immunotherapy, and 56% of the developing new necrotic areas were characterized as large uni-focal lesions (Figure 1 - top row - square). In a subset of patients, FDMs demonstrated elevated ADC values in the prenecrotic regions that eventually developed cystic necrosis (Figure 1 - bottom row).



Conclusion
Immunotherapy of pediatric brainstem gliomas is associated with a heterogeneous tumor response characterized by a high incidence of subsequent cystic/necrotic lesions. Functional diffusion mapping techniques may aid in the microstructural characterization of the evolution of prenecrotic regions which can improve our knowledge of response metrics using this novel therapy.

3T Intra-Operative MR Imaging Results in Improved Gross-Total-Resection Rates in the Management of Pediatric Central Nervous System Neoplasms

Choudhri, A. F.[1,2]·Auschwitz, T.[1]·Whitehead, M. T.[1,2]·Klimo, P.[1,2]·Boop, F. A.[1,2]
[1]University of Tennessee Health Science Center, Memphis, TN, [2]Le Bonheur Children's Hospital, Memphis, TN.

Purpose
High field strength intra-operative magnetic resonance imaging (iMRI) has emerged as a powerful adjunct for resection of brain tumors. However, its exact role has not yet been firmly established. We analyzed a prospective database after installation of a 3T iMRI at a tertiary care children's hospital to determine the impact this technology had on the surgical management of a variety of tumors in children.
Materials & Methods
We evaluated 18 consecutive months of patients undergoing brain tumor resection after installation of a 3T iMRI (IMRIS, Winnipeg, Canada) in a children's hospital. Tumor location, histology, surgical approach, OR time, presence and volume of residual tumor, need for tumor

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

and nontumor-related reoperation, and anesthesia and MRI-related complications were evaluated.
Results
One hundred thirty-five patients (52 females) underwent iMRI-guided surgery. Of these, 115 were 18 years or younger (mean 8.6 ± 4.7 years). There were 60 posterior fossa tumors. The most common tumors were pilocytic astrocytoma (28%) and medulloblastoma (20%). An average of 1.2 scans were performed per patient (maximum four intraoperative scans). There were no MRI-related safety issues. Additional tumor was resected after scanning in 24% of patients. Ninety-five percent of patients with a preoperative goal of gross-total resection achieved this goal. The 30-day reoperation rate was 0% and no patient required another postoperative MRI scan during the same hospital stay. Challenges included interpreting linear enhancement along the resection cavity, interpreting images after multiple boluses of contrast and image-distortion due to patient positioning.
Conclusion
Intra-operative MRI is safe and reduces the need for early reoperation or repeat sedation for postoperative scans in children with brain tumors. There is a learning curve with this technology that applies to all members of the OR team. By allowing a reduced postoperative disease burden, this hopefully will improve the efficacy of adjunct chemotherapy and radiation and translate into improved long-term patient survival.

Diagnostic Accuracy of Diffusion Tensor Imaging for Pediatric Cervical Spinal Cord Injury

Barakat, N.[1]·Mulcahey, M.[2]·Gaughan, J.[1]·Shah, P.[1]·Faro, S.[1]·Samdani, A.[2]·Mohamed, F.[1]
[1]Temple University, Philadelphia, PA, [2]Shriners Hospitals for Children, Philadelphia, PA.

Purpose
Spinal cord DTI data can be obtained reliably in healthy children and children with spinal cord injuries (SCI) using inner field-of-view imaging, and shows moderate to good validity against MRI and International Standards for Neurological Classification of SCI(ISNCSCI). Sacral sparing endpoint is important in determining conversion from complete to incomplete injury but is difficult to evaluate in children. The purpose of this study was to evaluate the predictive validity of DTI by examining its diagnostic accuracy for pediatric SCI.
Materials & Methods
Thirty-five subjects were scanned using a 3T scanner: 25 controls(age 13.4±3.9 years) and 10 patients(age=13.5±4.6 years) with cervical SCI. Subjects/parents provided written informed assent and consent. Diffusion tensor imaging was performed using an inner field-of-view pulse sequence. Diffusion tensor imaging indices(FA,AD,RD) were extracted from regions of interest drawn at axial slices along the cervical spinal cord. MR imaging findings were classified “normal” or “abnormal” if increased intramedullary signal on T2-weighted images were seen with or without cord atrophy. Patients were evaluated using ISNCSCI and underwent examination of muscle strength, sensation and sacral sparing. Mean values were compared by group (controls, SCI with intact clinical endpoint, SCI with absent clinical endpoint) and by cord region (motor level, MRI level and regions above/below motor and MRI level of injury). The clinical endpoints used to group subjects with SCI were anal contraction(AC), deep anal pressure(DAP) and S4-5 sensation. Single and multiple variable logistic regressions were used to analyze DTI parameters as predictors of DAP,AC,S4-5 sensation, motor level and MRI level of injury. Specificity, sensitivity, receiver operating characteristics area under the curve(ROC AUC) and corresponding 95% confidence intervals (CI) were calculated(Table). Resampling methods were used to validate estimates from the final models.
Results
There were significant differences in FA between controls, SCI group with intact sacral sparing and SCI group with absent sacral sparing ($p<0.003$). AD values were significantly different among controls, SCI group with AC and SCI group without AC ($p<0.003$). However, for the remaining comparisons of both AD and RD, differences were significant only between controls and SCI group with absent DAP and S4-5 sensation($p<0.003$). There was strong association between FA,AD,RD,AC,DAP,S4-5 sensation, MRI findings and severity of injury. Univariate analysis indicated FA to be the strongest predictor of each clinical endpoint. However, DTI values in combination showed strongest diagnostic accuracy for predicting the presence of AC (AD,RD), DAP(FA), S4-5 sensation (FA,RD), motor level (FA,AD,RD) and MRI level (FA,AD,RD). Bootstrap and Jackknife median values indicated consistency of the parameter estimates.

Multivariate Analysis showing specificity, sensitivity, ROC AUC and 95% CI

	Predictor	Specificity (95% CI)	Sensitivity (95% CI)	ROC AUC (95% CI)
Anal Contraction (AC)	AD,RD	0.74 (0.71,0.77)	0.80 (0.75,0.84)	0.93 (0.91,0.94)
Deep Anal Pressure (DAP)	FA	0.53 (0.50,0.56)	0.70 (0.60,0.79)	0.88 (0.85,0.90)
S4-5	FA,RD	0.81 (0.78,0.83)	0.80 (0.75,0.85)	0.93 (0.92,0.95)
Motor Level	FA,AD,RD	0.67 (0.65,0.70)	0.85 (0.78,0.90)	0.92 (0.91,0.94)
MRI Level	FA,AD,RD	0.83 (0.80,0.85)	0.89 (0,84, 0.93)	0.92 (0.90,0.94)

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Conclusion
Our observation that FA values differ between subjects with SCI who have sacral sparing and those who do not have sacral sparing is novel and has important clinical relevance as this endpoint has low validity and reliability in children.

Correlation of Pediatric Spinal Cord Atrophy Measures with Diffusion Tensor Imaging Metrics

Barakat, N.[1]·Covington, A.[1]·Shah, P.[1]·Faro, S.[1]·Mulcahey, M.[2]·Mohamed, F.[1]
[1]Temple University, Philadelphia, PA, [2]Shriners Hospitals for Children, Philadelphia, PA.

Purpose
Spinal cord injuries (SCI) can cause anterograde retrograde spinal cord degeneration, gliosis and disruption of spinal cord tracts, which can ultimately result in spinal cord atrophy. Diffusion tensor imaging (DTI) parameters can be used to evaluate the microstructure of the spinal cord and yield additional quantitative information characterizing the degree of injury. The aim of this study was to evaluate the correlation between DTI parameters and tissue volume in children with and without SCI.
Materials & Methods
Twenty age-matched subjects (mean age=12.9 years); 10 controls and 10 with SCI were recruited. Subjects/parents provided written informed assent and consent. Diffusion tensor imaging data were acquired on a 3.0T MR scanner using inner field-of-Imaging to cover the cervical spinal cord (C1-T1). Diffusion tensor imaging parameters included: 20 directions, b=1000s/mm^2, voxel size=1.2x1.2x3mm^3, axial slices=35-45, TR=6100-8000ms, TE=115 ms, averages=3 and TA=7 min. T1- and T2-weighted scans also were performed. Anesthesia, cardiac and/or respiratory gating were not used. Motion correction of the DTI images was performed. Tensor estimation was done using MedINRIA. Regions of interest (ROIs) were drawn at axial slice location. Fractional anisotropy (FA), axial diffusivity (AD) and radial diffusivity (RD) were extracted. Spinal cord volume (mm^3) was measured on axial FSE T2-weighted images using Analyze software. Intramedullary lesions were included and extramedullary lesions were excluded. Regions of interest were drawn so that there was a consistent sparing of the outer margin of the spinal cord that represented approximately one voxel width to minimize volume averaging with the CSF. Regions of interest were reviewed and edited by a board-certified neuroradiologist. Correlations between FA, AD, RD and volume were established using Pearson's correlation in JMP SAS.
Results
In patients FA values showed a strong positive correlation with atrophy measures (r=+0.6, p<0.001). A strong negative correlation was seen between RD values and cord volume (r = -0.4, p<0.001) (Figure). Axial diffusivity values had moderate negative relationship with atrophy (r=-0.3, p<0.001). No correlations were observed in the controls group (r<0.01, p<0.6) for all DTI metrics.

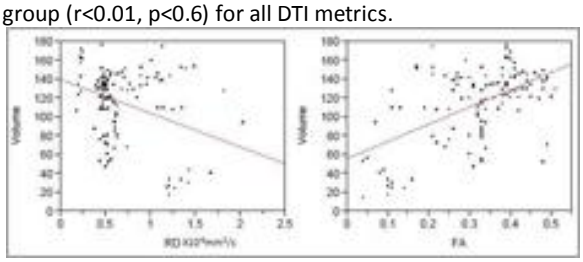

Figure. Pearson's correlation between DTI metrics (FA, RD) and atrophy volume measures.
Conclusion
Our findings showed moderate to strong correlation between DTI metrics and spinal cord volume in children with SCI. Fractional anisotropy showed positive correlation with atrophy measures, in contradistinction to RD and AD which showed negative correlations. These preliminary results are very promising and warrant further analysis with various clinical endpoints.

Wallerian Degeneration in Pediatric Spinal Cord Injury Using Diffusion Tensor Imaging

Barakat, N.[1]·Faro, S.[1]·Shah, P.[1]·Gaughan, J.[1]·Mulcahey, M.[2]·Mohamed, F.[1]
[1]Temple University, Philadelphia, PA, [2]Shriners Hospitals for Children, Philadelphia, PA.

Purpose
Previous studies have shown that diffusion tensor imaging (DTI) data of the cervical spinal cord can be obtained reliably in typically developing children and children with spinal cord injuries (SCI) using inner field-of-view imaging, and that DTI indices showed moderate to good validity against MRI at injury level. However, in addition to damage at the lesion site, the spinal cord undergoes degeneration above (retrograde) and/or below (antegrade) the point of injury. The purpose of this study was to evaluate the sensitivity of DTI in assessing the extent of Wallerian degeneration in pediatric spinal cord injury.
Materials & Methods
Ten patients with SCI (mean age = 13.5 ± 4.6 years, time since injury = 7.09 ± 3.95) were scanned using a 3T scanner. Mode of injury level = C4. Subjects and parents provided written informed assent and consent. Diffusion tensor imaging, T1- and T2-weighted scans were obtained. Imaging parameters included: 20 diffusion directions, b = 1000s/mm2, voxel size = 1.2x1.2x3mm3, axial slices = 35-

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

45 (depending on the subject's height), TR = 6100-8000 ms, TE = 115 ms, number of averages = 3 and acquisition time = 6-7 min. Motion correction was performed using Automatic Image Registration. Tensor estimation was done using MedINRIA. Fractional anisotropy, AD and RD values were extracted from regions of interest drawn at axial slice locations (disk levels and middle portions of cervical vertebral body). The highest spinal cord level of abnormality defined by MRI was assigned 0 and levels above were +1, +2, +3, etc., levels below were assigned -1, -2, -3⋯ etc. The approximate distance between level 0 and ±1 was 9 mm. Differences in mean DTI parameters were compared between cervical levels above and below the level of injury using ANOVA for repeated measures. Non-normally distributed data were transformed to ranks.
Results
There were no statistically significant differences in FA and RD mean values between injury site (level 0) and spinal cord levels above and below injury ($p>0.05$). There were no significant differences in AD values at and below injury site ($p>0.05$). However, significant differences were observed in AD values between injury site and levels above injury level ($p<0.05$).
Conclusion
In summary, FA and RD were sensitive in detecting diffusion abnormalities distant to the site of injury, suggesting retrograde and antegrade Wallerian degeneration, even at levels with normal MRI findings.

(46) ASHNR Programming: Contemporary Imaging of the Temporal Bone

O-441 **5:00 PM - 5:30 PM**

Clinically Based Anatomy of the Temporal Bone

Chapman, P. R.
University of Alabama Birmingham
Birmingham, AL.

Presentation Summary
Presentation will review the practical anatomy of the temporal bone as it pertains to routine CT and MRI imaging of the temporal bone. The presentation will address the fundamental techniques required for CT and MRI imaging, discuss the limits of each modality, and focus on the detailed radiologic anatomy the internal auditory canal, the inner ear, and middle ear. Emphasis will be placed on distinguishing normal appearance and normal variations from subtle or early pathologic processes.

O-442 **5:30 PM - 6:00 PM**

A Geographic Approach to Infectious and Inflammatory Disease of the Temporal Bone

Shatzkes, D. R.
Lenox Hill Hospital
New York, NY.

Presentation Summary
Though the presentation will generally follow the advertised geographic approach, there are several truisms that are worth remembering with regard to temporal bone inflammation: •The middle ear and mastoid cavities can be considered an extension of the upper respiratory tract, connected via the Eustachian tube and lined by similar mucosa. These cavities, in turn, connect to air cells elsewhere in the temporal bone, most notably at the petrous apex. Hence, a similar pattern of inflammatory disease will affect air cells at all of these sites. •The external ear and auditory canal are covered by skin rather than mucosa. Thus, inflammatory (and neoplastic) processes at these sites are more aligned with disease affecting the skin elsewhere in the body. •While inflammatory disease of the temporal bone can be classified broadly into acute and chronic processes, it is important to remember that these generally DO NOT represent a continuum. **Acute otomastoiditis (AOM)** is caused by a bacterial infection of the middle ear. Children are predisposed because of the orientation and length of their Eustachian tubes, and the presence of adenoids. Uncomplicated AOM is rarely imaged. **Chronic otomastoiditis (COM)** is virtually synonymous with chronic Eustachian tube obstruction or dysfunction; infection is rarely present. Chronic otomastoiditis can be further broadly classified as cholesteatomatous or noncholesteatomatous COM. Some of the site-specific entities that will be discussed are: 1. External Ear: - Acute: acute otitis externa, necrotizing otitis externa; - Chronic: Cholesteatoma, keratosis obturans, exostoses. 2. Tympanomastoid Cavity: - Acute: AOM complications including coalescent mastoiditis, sigmoid sinus thrombosis, intracerebral abscess; - Chronic: o Cholesteatoma: Pars flaccida, pars tensa, o Noncholesteatomatous COM: granulation tissue, cholesterol granuloma, ossicular fixation/erosion. 3. Inner Ear: - Acute: Labyrinthitis (viral, bacterial, luetic, mycotic); - Chronic: Labyrinthitis ossificans. 4. Petrous Apex: - Acute: Petrous apicitis; - Chronic: Cholesterol granuloma, cholesteatoma, mucocele.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Tumors of the Temporal Bone: From EAC to IAC

Harnsberger, H.
University Of Utah
Salt Lake City, UT.

Presentation Summary
In this presentation an anatomy-based differential diagnosis list of tumors for the external auditory canal (EAC), middle ear, inner ear, and facial nerve will be reviewed. In each location the clinical presentation, specific imaging findings of each tumor and differential diagnosis features will be presented. Where possible, characteristic imaging findings unique to a specific tumor will be highlighted. By area benign and malignant tumors reviewed include: 1. External auditory canal, Benign: Exostoses, osteoma. Malignant: EAC squamous cell carcinoma. 2. Middle ear, Benign: Glomus tympanicum and jugulare paraganglioma, facial nerve schwannoma, adenoma and meningioma, Langerhans cell histiocytosis. Malignant: Rhabdomyosarcoma. 3. Inner ear, Benign: Intralabyrinthine schwannoma, endolymphatic sac tumor, meningioma. 4. Facial nerve, Benign: Facial nerve schwannoma, facial nerve hemangioma (venous malformation). Malignant: Perineural parotid malignancy.

Future of fMRI: From Animals to Humans

Polimeni, J. R.
Massachusetts General Hospital
Charlestown, MA.

Jonathan R. Polimeni, Ph.D., is an Instructor in Radiology at Harvard Medical School and an Assistant in Biomedical Engineering in the Department of Radiology of the Massachusetts General Hospital. Dr. Polimeni received his B.S. in Electrical and Computer Engineering from the Johns Hopkins University. He received his Ph.D. in Electrical and Computer Engineering from Boston University where he worked in the Computational Neuroscience and Computer Vision Laboratory under Professor Eric Schwartz. His Ph.D. work was in the measurement and modeling of visuotopic maps in macaque and human visual cortex. His postdoctoral work was at the Athinoula A. Martinos Center for Biomedical Imaging at the Massachusetts General Hospital within the Imaging Physics group under Prof. Lawrence Wald. He joined the faculty of the Martinos Center in 2010. In 2011 he was awarded an NIH Career Development Award (K01) from the National Institute of Biomedical Imaging and Bioengineering. His research focuses on the development and application of high-resolution 7T fMRI, the characterization of the spatial specificity of the fMRI signals, and on the study of the functional architecture of the human visual cortex. He is currently working on testing whether the hemodynamic response is regulated finely enough to support cortical layer-specific fMRI.

Presentation Summary
What are the spatial resolution and temporal resolution of fMRI achievable today, and what are the resolution limits? This presentation will provide an overview of new technologic advances in fMRI acquisition techniques together with recent discoveries into the physiologic mechanisms of blood flow regulation in the cerebral cortex. The goals of the presentation will be to examine how tightly coupled the hemodynamic response may be to neural activity at fine scales and how to leverage knowledge of cerebral vascular anatomy and physiology to obtain accurate measurements of brain activity with fMRI. Cutting-edge optical imaging techniques used in animal models have provided valuable new insights into cerebral

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

hemodynamics, and the data suggest that the blood flow response to neural activity may be much more finely controlled than previously believed. As technologies such as ultrahigh-field MRI and massively parallel receive coil arrays become more common, this tight coupling between neural activity and blood flow can be exploited to provide more faithful representations of neuronal population responses with fMRI. During this presentation, we will review some recent studies that have achieved high spatial and temporal accuracy with fMRI. As an example we will consider a new line of inquiry into the possibility of a cortical layer-specific fMRI response. Throughout, we will point out the current limitations of fMRI and discuss how emerging technology can help to further increase the accuracy into the future.

Presentation Summary
Tinnitus is an incredibly common condition in the world, and is suffered by countless millions of people in the U.S., some of whom will be referred for imaging evaluation. Tinnitus is the perception of sounds by an individual in the absence of an external sound. It may be a ringing, buzzing, or other monotonous tone. The tone may vary with time, and can be pulse-synchronous, or may be unvarying. Continuous tinnitus is the unvarying form, and pulsatile tinnitus refers to a sound which varies with the cardiac cycle. Tinnitus may be an unremitting problem in patients, and may lead to referral for imaging. In this regard, it is a very problematic item of history for the radiologist, as it is a symptom with an incredibly wide range of potential etiologies. There is little acceptance of a standard imaging algorithm for diagnosing a potential cause of tinnitus. As expected, the pulsatile form may be vascular in nature, and a potential cause may be found more commonly on imaging, but the study to be recommended also is widely debated, without consensus. Continuous tinnitus is a particularly vexing clinical issue. Tinnitus without a radiologic abnormality is likely the most common form of tinnitus, and the radiologist may recommend a perfectly appropriate examination without a discovered diagnosis. Pulsatile tinnitus may be associated with vascular pathology, and with other lesions as well. A reasonable differential diagnosis includes arterial and venous anomalies, vascular neoplasia, and other less common but potentially diagnosable and treatable conditions, such as otospongiosis. Continuous tinnitus can be caused by a very wide range of pathology, including intracranial and IAC neoplasms, TMJ disease, brainstem lesions, intracranial hypotension or hypertension, or simply presbycusis. The diagnostic study ordered may be dependent on clinical factors, such as patient age, onset of symptoms, or potentially causative conditions. CT and MRI may be utilized, and CTA and MRA as well as venous studies may be useful in arriving at a cause. Temporal bone CT studies often are ordered, as are CTA. CT angiography has been proposed as a reasonable “one stop shopping” exam, yielding both vascular information and high quality temporal bone CT studies. However, brainstem, IAC and posterior fossa disease still is best studied with MR with and without contrast.

Hindbrain and Midbrain Development

Barkovich, A.
University of California San Francisco Medical Center
San Francisco, CA.

Presentation Summary

Although the brain stem and cerebellum often are not scrutinized as carefully as the cerebrum, malformations of these structures are not uncommon. An understanding of these structures is best achieved by a general understanding of the anatomy of the structures of the brain stem and cerebellum, the steps involved in their formation and the most important genes involved in these steps. This presentation will give a brief overview of development and anatomy, followed by a classification of malformations that is based upon disturbances in normal development. I. Malformations secondary to early anteroposterior and dorsoventral patterning defects, or to misspecification of mid-hindbrain germinal zones. A. Anteroposterior patterning defects: 1. Gain, loss or transformation of the diencephalon and midbrain. 2. Gain, loss or transformation of the midbrain and rhombomere 1. 3. Gain, loss or transformation of lower hindbrain structures. B. Dorsoventral patterning defects: 1. Defects of alar and basal ventricular zones. 2. Defects of alar ventricular zones only. 3. Defects of basal ventricular zones only. II. Malformations associated with later generalized developmental disorders that significantly affect the brainstem and cerebellum (and have pathogenesis at least partly understood). A. Developmental encephalopathies associated with mid-hindbrain malformations. B. Mesenchymal-neurepithelial signalling defects associated with mid-hindbrain malformations (includes Dandy-Walker malformations). C. Malformations of neuronal and glial proliferation that prominently affect the brainstem and cerebellum. D. Malformation of neuronal migration that prominently affect the brainstem and cerebellum: 1. Lissencephaly with cerebellar hypoplasia. 2. Neuronal heterotopia with prominent brainstem and cerebellar hypoplasia. 3. Polymicrogyria with cerebellar hypoplasia. 4. Malformations with basement membrane and neuronal migration deficits. E. Diffuse molar tooth type dysplasias associated with defects in ciliary proteins (Joubert and related syndromes): 1. Syndromes affecting the brain with low frequency involvement of the retina and kidney. 2. Syndromes affecting the brain, eyes, kidneys, liver and variable other systems. III. Localized brain malformations that significantly affect the brainstem and cerebellum (pathogenesis partly or largely understood, includes local proliferation, cell specification, migration and axonal guidance). A. Multiple levels of mid-hindbrain. B. Midbrain malformations. C. Malformations of rhombomere 1 including cerebellar malformations. D. Pons malformations. E. Medulla malformations. IV. Combined hypoplasia and atrophy in putative prenatal onset degenerative disorders. A. Pontocerebellar hypoplasia. B. Mid-hindbrain malformations with congenital disorders of glycosylation. C. Other metabolic disorders with cerebellar or brainstem hypoplasia or disruption. D. Cerebellar hemisphere hypoplasia (rare, more commonly acquired than genetic, often associated with clefts or cortical malformation).

Genetic-Phenotype Correlations in Hindbrain/Midbrain Malformations - Part I

Ishak, G. E.
Seattle Children's Hospital
Seattle, WA.

Presentation Summary

Malformations of the midbrain and hindbrain (MBHB) are relatively under appreciated due to historical difficulties with imaging and pathologic evaluation. Recent improvements in neuroimaging, neuropathology and neurogenetics have made it possible to distinguish many developmental disorders of the MBHB, revealing their substantial contribution to neurodevelopmental dysfunction. We will present a case-based overview of common MBHB malformations including clinical presentation, imaging features, diagnostic work up and genetic causes of some malformations. Disorders will include pontocerebellar hypoplasias, dystroglycanopathies, tubulinopathies, rhombencephalosynapsis, Joubert syndrome, and other disorders that are relatively common or have added to the understanding of human brain development. Identifying specific disorders has important implications for additional diagnostic work up, prognosis, recurrence risk and medical monitoring for complications. We also will highlight recent advances in imaging and genetics applied to MBHB malformations. The information provided will increase recognition of specific imaging features of MBHB malformations, as well as promote a broader understanding of the clinical implications of these diagnoses.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Identifying specific disorders has important implications for additional diagnostic work up, prognosis, recurrence risk and medical monitoring for complications. We also will highlight recent advances in imaging and genetics applied to MBHB malformations. The information provided will increase the recognition specific imaging features of MBHB malformations, as well as promote a broader understanding of the clinical implications of these diagnoses.

Susceptibility-Weighted MR Imaging in Multiple Sclerosis

Auger, C.
Hospital Vall D'Hebron
Barcelona, SPAIN.

Dr. Cristina Auger was born in Barcelona in 1968. She is a full-time neuroradiologist, who gained her MD in 1992 at the University of Barcelona. After formal training in Radiology, she became staff pediatric neuroradiologist at the Department of Radiology at Vall d'Hebron Hospital (Barcelona, Spain). In 2005, she became staff neuroradiologist at the Department of Radiology at University Hospital Vall d'Hebron, and since 2010 Head of Neuroradiology at the MR unit in the same institution. She is author or co-author of 10 original papers published in peer-reviewed journals. Her main interests are multiple sclerosis and neurooncology.

Presentation Summary
Histological stains have shown that various neurologic and psychiatric disorders, including Alzheimer disease, Huntington disease, and Parkinson disease may be associated with elevated focal accumulations of iron. Abnormal iron accumulation also has been detected pathologically in reactive microglia, ameboid microglia, and macrophages in the brain of multiple sclerosis (MS), although it is not yet clear if this accumulation is implicated in MS pathology or merely reflects an epiphenomenon. Several MR techniques have been proposed for in vivo assessment of iron content in central nervous system tissues. The basic principle behind all these techniques is the interaction between high-molecular-weight iron complexes such as ferritin or hemosiderin and water molecules, which leads to decreased T2 and T2* relaxation times in iron-laden tissues. Susceptibility-weighted imaging (SWI), is one of these techniques, which compared to others has the advantage of easily being implemented in clinical practice. Susceptibility-weighted imaging combines magnitude and phase images to enhance contrast, and has shown high sensitivity in demonstrating iron in the form of hemosiderin or ferritin within brain tissue. Recent experience with the implementation of SWI at 3.0T in the routine diagnostic workup of MS has shown that most focal chronic, and acute, demyelinating lesions can be depicted as areas of low signal intensity likely representing iron deposition. In future studies, quantitative MRI analyses of brain iron in a clinical follow-up setting might help to elucidate the implication of iron accumulation in MS. Susceptibility-weighted imaging also takes advantage of the magnetic susceptibility effects from paramagnetic deoxygenated hemoglobin. Using deoxyhemoglobin as an intrinsic contrast agent, SWI affords to acquire images that can be used to visualize venous structures. The quantitative measures of the number of detected venous structures on SWI have show a significant reduction of periventricular white matter venous vasculature visibility in MS patients as compared to healthy control subjects, likely indicating reduced metabolism or morphologic changes of venous vasculature. This observation supports the hypothesis that vascular abnormalities play a role in the pathogenesis of MS. Nevertheless, additional studies are required before SWI can be considered a biomarker in MS. These additional studies should demonstrate their reproducibility, sensitivity to disease evolution and treatment changes, and their value in reflecting and predicting the accumulation of irreversible disability. All

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

these necessary efforts are especially important nowadays, when there is a growing interest in developing neuroprotective or regenerative agents in MS, which consequently demands new imaging strategies for achieving and monitoring the neurodegenerative component of MS.

O-453 **5:08 PM - 5:23 PM**

MRI in New Multiple Sclerosis Lesions

Rovira, A.
Hospital Vall d'Hebron
Barcelona, SPAIN.

Presentation Summary

Disease activity in multiple sclerosis (MS) is strongly linked to the formation of new lesions, which comprises a complex sequence of inflammatory, degenerative and reparative processes. However there is dissociation between disease activity (clinical or radiologic) and progression, a phenomenon that can be explained by a process of exhaustion of both structural and functional redundancies (as demonstrated with functional MRI) that increasingly prevents repair and recovery. Conventional magnetic resonance (MR) imaging techniques, such as T2-weighted and gadolinium-enhanced T1-weighted sequences, which are highly sensitive in demonstrating the spatial and temporal dissemination of demyelinating plaques in the brain and spinal cord in MS, can provide a quantitative assessment of inflammatory activity and lesion load in patients suffering from this disease, and are being used increasingly in monitoring disease activity and progression not only in clinical trials but also in individual patients. Serial analysis of new lesion formation by means of MR imaging provides relevant data related to both inflammatory activity and repair mechanisms, which should be considered for assessing specific therapeutic effects of new treatments (anti-inflammatory, neuroprotective, regenerative). Longitudinal and cross-sectional MR studies have shown that contrast enhancement occurs in almost all new MS plaques in patients with relapsing-remitting MS or secondary progressive MS and can sometimes be detected even before the onset of clinical symptoms. New contrast-enhancing lesions are nearly always associated with a hyperintense lesion in the same location on T2-weighted images. The extent of these new T2 lesions usually contract over time (3-5 months) and their intensity is reduced as edema resolves and some tissue repair occurs, leaving a much smaller T2 permanent “footprint” of the prior inflammatory event. Serial changes in lesion intensity and size on contrast-enhanced T1-weighted, and on unenhanced T1- and T2-weighted sequences are two related but temporally disjoined processes, as after cessation of gadolinium uptake transient significant T1/T2 changes T2 exists over a 3-6 months period. According to these changes MS lesion formation and activity can be divided into two phases: an acute phase characterized by contrast uptake reflecting blood-brain barrier disruption, and a subacute phase characterized by changes in lesion signal intensity and size on unenhanced T1- and T2-weighted images. Characteristics of the subacute phase of lesion formation reflect the balance between injury and repair capacity, and changes in this behavior may represent a shift from inflammatory toward degenerative disease activity and greater proximity to a progressive stage of the disease.

Individual Level Classification Analyses of Brain MRI in Neurodegenerative Diseases

Haller, S.
University Hospital Geneva
Geneva, SWITZERLAND.

Dr. Haller received his MD from medical school at the University of Tübingen, Germany. He completed the MS at the Max Planck Research School of Neural and Behavioral Tübingen, Germany. He specialized in Radiology and diagnostic Neuroradiology at the University Hospital of Basel, Switzerland. Thereafter, he completed his Privatdozent (venia docendi, senior lecturer) in Neuroradiology at the University Hospital Geneva, Switzerland. Currently, he is senior staff Neuroradiologist at the University Hospital Geneva, Switzerland, with a special interest in advanced neuroimaging techniques in particular in the domains of neurodegenerative and neurovascular diseases. Dr. Haller has received several awards from the European Society of Neuroradiology (ESNR) and at least five awards from the Swiss Society of Radiology (SSR).

Presentation Summary

Overview - This presentation will discuss recent advances in early and individual detection of neurodegenerative diseases, in particular Alzheimer dementia (AD) based on support vector machine (SVM) pattern recognition analyses. Background - The incidence of AD is increasing. Standard MR imaging is performed routinely in the work up of dementias notably to exclude other diseases such as normal pressure hydrocephalus or meningioma, which are present in approximately 1% of cases. The typical atrophy of the hippocampus and bi-parietal cortex is only a late sign, hence visual inspection of standard MRI is cases noncontributive in most cases in the early phase of neurodegeneration. Challenge - Mild cognitive impairment (MCI) is a state of impaired cognition, which does not yet fulfill the criteria for dementia. Mild cognitive impairment is a very heterogeneous group, and only about 50% of MCI cases will progress to develop dementia. This means that in a classic therapeutic trial, 50% of MCI cases will remain stable even without treatment. The challenge is to identify those MCI cases who will progress later on at an individual basis with respect to both individual patient care and potential treatment trials. Group level versus individual

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

level analyses - Typical advanced image analysis techniques of gray matter (e.g., voxel-based morphometry, VBM) or white matter (e.g., tract-based spatial statistics, TBSS) are group level comparisons. While such analyses are fascinating from a research perspective identifying disease-related changes in brain morphometry, these results cannot be applied to clinical practice for the identification of individual patients. Individual level classification analyses such as support vector machines (SVM) are fundamentally different approaches aiming to identify individual cases. The basic principle of such pattern recognition analyses can be illustrated in the example of face recognition. A single feature, for example the nose, is generally not sufficient to detect an individual subject - even though the nose might show group differences. In contrast, individual faces can be identified by the combination of multiple features such as nose, ear, chin, eyebrow, etc. even though each feature per se is not necessarily significantly different between groups. Conclusion - The current presentation will discuss principles of individual level classification analyses and results to identify progressive versus stable MCI based on diffusion tensor imaging (DTI) white matter (accuracy up to 95%) and susceptibility-weighted imaging (SWI) iron deposition (accuracy up to 85%). Finally, future perspectives for multimodal individual level classification analyses will be discussed.

O-455 **5:53 PM - 6:00 PM**

Focal Hypoperfusion in Early Dementia as Assessed with Arterial Spin Labeling MRI

Steketee, R.
University Medical Center Rotterdam
Rotterdam, NETHERLANDS.

Rebecca Steketee has a master's degree in neuropsychology and cognitive neuroscience and is currently a PhD student at the department of Radiology at Erasmus MC - University Medical Center, Rotterdam, the Netherlands. She investigates the use of advanced MR neuroimaging techniques in the diagnosis of early dementia, with a particular interest in arterial spin labeling (ASL) MRI.

Presentation Summary
Early diagnosis of dementia is challenging as brain atrophy may not yet be apparent. Changes in cerebral blood flow (CBF) preceding atrophy may be detected with arterial spin labeling (ASL). This study aims to assess ASL for diagnosing early dementia. Fifteen patients with suspected diagnosis of dementia (mean age 63 years, seven male, mean Mini Mental State Examination 26) and 15 controls (mean age 59 years, eight male) underwent 3D PCASL and T1-weighted MR scanning at 3T (GE Healthcare, U.S.). Data were coregistered and normalized using SPM8 (London, UK). Region of interest (ROI) analysis of the CBF maps, masked for gray matter only, was performed with MarsBaR (Marseilles, FR), in regions involved in dementia and regions initially spared. Mean CBF values were compared between groups using 2-sample t-tests. Age and gender were not different between groups ($p>0.05$). Mean CBF values in dementia-related brain regions were significantly lower in patients than controls ($p<0.05$, right/left medial temporal lobe: 30/30 versus 37/38; right/left precuneus: 29/29 versus 43/42; right/left posterior cingulum: 35/34 versus 56/58 ml/100cc GM/min). No difference was found in regions not implicated in dementia (right/left precentral gyrus: 29/30 versus 35/36; right/left occipital gyri: 24/25 versus 31/29 ml/100cc GM/min for patients and controls respectively). Patterns of hypoperfusion assessed with ASL in early dementia are concordant with those in established dementia and those assessed with positron emission tomography, indicating the contribution of ASL in the early diagnosis of dementia. Future aims are to assess ASL for early differentiation between types of dementia.

O-456 **6:00 PM - 6:15 PM**

Arterial Spin Labeling MRI in Clinical Practice: Current and Future Applications

Smits, M.
Erasmus Medical Center - University Medical Centre Rotterdam
Rotterdam, NETHERLANDS.

Marion Smits is Associate Professor of Neuroradiology and combines her clinical work as a neuroradiologist with scientific research into advanced MR neuroimaging, such as functional MRI, diffusion tensor imaging (DTI) and perfusion imaging. She uses these techniques to visualize the brain's function and microstructure, and to study pathophysiological and regenerative processes in a variety of neurological diseases, such as stroke, dementia and brain tumors. Marion combines her clinical expertise with scientific research and active participation in key European organisations, including the European Society of Radiology (ESR), the European Society for Magnetic Resonance in Medicine and Biology (ESMRMB), European Organisation for Research and Treatment of Cancer (EORTC) and the European Institute for Biomedical Imaging Research (EIBIR). On a national level she is core member of the Young Health Council of the Netherlands, an advisory organ to the Dutch Ministry of Health. As permanent faculty member of several European and national course organisations she lectures frequently on advanced MR neuroimaging. She is Course Director of the European School of MRI fMRI&DTI course, and has been elected Scientific Programme Committee chair of the ESMRMB scientific annual meeting 2015 in Edinburgh (UK). Full list of publications: www.marionsmits.net/publications LinkedIn: nl.linkedin.com/in/marionsmits

Presentation Summary
Arterial spin labeling (ASL) is a noninvasive MRI technique

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

with which cerebral blood flow (CBF) can be measured quantitatively. It uses inversion or saturation pulses to label arterial blood. Two images of the brain are acquired: one without and one with labeling of arterial blood. By subtracting the two images, all static signal is cancelled out, resulting in an image of labeled spins only. Although the first publications of ASL MRI date over 10 years back, it is only now that ASL is commercially available on MRI systems from all major vendors and is making its way into clinical practice. The main areas of interest for current and future clinical application of ASL MRI of the brain are dementia, cerebrovascular disease and neuro-oncology. Arterial spin labeling is proposed as a diagnostic alternative to fluorodeoxy-D-glucose (FDG) PET in the workup of dementia patients. Arterial spin labeling has several advantages over FDG PET. Crucially, it can be added easily to the routinely performed structural MRI examination. Feasibility studies show that ASL provides reliable CBF maps in dementia. In patients with established Alzheimer disease and frontotemporal dementia, hypoperfusion patterns are seen that are similar to hypometabolism patterns seen with FDG PET. Current and future studies in this field will need to demonstrate the validity of ASL in the diagnostic workgup of the individual patient, early in the disease process. In cerebrovascular disease, ASL is of particular interest owing to its quantitative nature as well as its capability to determine cerebral arterial territories using vessel-selective techniques. In acute stroke, the source of the collateral blood supply in the penumbra may be visualized, which then can be targeted selectively with thrombolytic and neuroprotective agents. In chronic cerebrovascular disease, the extent and severity of compromised cerebral perfusion can be visualized, which may be used to guide therapeutic or preventative intervention. Arterial spin labeling has further clinical potential for the detection and follow up of arteriovenous malformations, depicting increased venous flow due to arteriovenous shunting. Studies on ASL in brain tumor imaging indicate a high correlation between areas of increased CBF as measured with ASL, and increased cerebral blood volume as measured with dynamic susceptibility contrast-enhanced perfusion imaging. Major advantages of ASL for brain tumor imaging are the fact that CBF measurements are not influenced by breakdown of the blood-brain barrier, as well as its quantitative nature, facilitating multicenter and longitudinal studies.

Neuroradiology in Translational Medicine

Politi, L. S.
San Raffaele Scientific Institute
Milano, ITALY.

Dr. L. S. Politi received his degree in medicine and surgery at the University of Catania in 1988. He performed his residency at the Radiology Department of the Faculty of Medicine, University of Florence from November 1198-November 2002. He was a Clinical Assistant, followed by a Senior Clinical Assistant, Neuroradiology Department, San Raffaele Hospital and Scientific Institute, Milan, Italy. Dr. Politi currently is Head of Clinical Unit, Neuroradiology Department, San Raffaele Hospital and Scientific Institute, Milan, Italy. He is also Group Leader of the Neuroradiology Department and Coordinator of Neuroimaging Research at the Preclinical MRI facility, Imaging Core. He is currently Assistant Professor, Vita-Salute at San Raffaele. Dr. Politi received the Lucien Appel Prize of the European Society of Neuroradiology in 2006.

Presentation Summary
We will present MR-based cellular and molecular imaging techniques for monitoring stem cell transplantation in neurologic diseases. We will discuss optimal conditions for dynamic MR visualization of murine and human neural and hematopoietic stem cell homing to disease sites in the brain and other target organs of several mouse models of human disease, and how these preclinical results can be exploited to monitor the first patients enrolled in stem cell-transplantation trials. Further, we will underline how the results obtained in preclinical neuroimaging experiments can give a precious contribution in the design of new clinical trials, in terms of definition of cell doses, route of administration, therapeutic window and mechanisms of action.

Diagnoses Not to Miss in the Head and Neck

Michel, M. A.
Medical College of Wisconsin/Froedtert Hospital
Milwaukee, WI.

Presentation Summary
Although it is important to recognize and correctly diagnose all pathology within the head and neck, there are several diagnoses that are particularly important NOT to miss. In the time allotted for this talk, not all of the important conditions can be discuss, so I have selected a few based upon my opinion and the collective opinions of my head and neck colleagues. The conditions were not selected based upon how commonly they occur, but because they are frequently missed or misinterpreted, because early recognition may prevent morbidity and mortality to the patient, or because making the correct diagnosis on imaging can significantly alter the way the patient is managed. Diagnoses given honorable mention, but not discussed in detail include: 1) Calcific prevertebral tendonitis; 2) Bisphosphonate-related osteonecrosis of the jaws; 3) Enlarged vestibular aqueduct syndrome; 4) Complications of otomastoiditis; 5) Otosclerosis; 6) Isolated sphenoid sinus disease; and 7) Mylohyoid muscle defect containing salivary tissue. **Fibro-osseous Lesions on MRI.** The term "fibro-osseous" (FO) generally refers to a class of benign bony abnormalities and they are common in the craniofacial skeleton. The histologies most often included in this group include osteomas, ossifying fibromas, and fibrous dysplasia. They can have very similar appearances on imaging and on pathology, particularly when they have a mix of both fibrous and osseous components. The MR imaging appearance of FO lesions can be confusing. Depending upon the amount of fibrous tissue present, they can appear quite heterogeneous and variably enhance. When there are large ossified portions, these areas can be very hypointense and mimic air signal. Many of the FO lesions do not require treatment and making the diagnosis correctly with imaging may spare the patient any unnecessary procedure. **Invasive Fungal Sinusitis.** Invasive fungal sinusitis (IFS) is important to diagnosis early and it may progress rapidly and has a high mortality rate. Invasive fungal sinusitis occurs in immunocompromised patients or in patients with other predisposing conditions. Although bone erosion may be present, one of the main pathways of spread beyond the sinonasal cavities is via the blood vessels (angioinvasive). Because of this, complications of vascular narrowing, dissection, and vessel occlusion, in addition to soft tissue destruction, are not uncommon. Fungal processes may demonstrate foci of hypointense long-TR signal on MRI due to the presence of fungal hyphae and metal chelates. Fungal disease also can appear mass-like and may be confused for neoplasm. Therefore, it is important to include IFS in the differential diagnosis of a sinonasal mass lesion if the patient is immunocompromised. **Non-Hodgkin Lymphoma in the H&N.** There are multiple forms of Non-Hodgkin lymphoma in the head and neck. Lymphoma may involve the cervical nodes, the non-nodal lymphatic tissues of Waldeyer ring, or extralymphatic tissues. The most common type seen in the U.S. is the B-cell type. It is an important diagnosis because the imaging features can be suggestive of the diagnosis and it is treated nonsurgically, therefore imaging can guide management. Lymphomas are pliable soft tissue masses and tend to mold themselves around normal structures. Lymphoma can have variable effects on adjacent bone, causing either benign-appearing remodeling or more aggressive, malignant-appearing destruction. Because they are highly cellular tumors with increased nuclear to cytoplasmic ratios, lymphomas may be somewhat hyperdense to other soft tissues on CT, show hypointense signal on long-TR MR sequences, and enhance homogeneously after contrast administration. **Perineural Tumor Spread.** Identifying perineural tumor spread (PNTS) in patients with head and neck malignancy is the job of the head and neck imager. Not only does the presence of PNTS change the patient's prognosis and alter the therapy they may receive, the presence of PNTS may be suggestive of the histology of the tumor. The 5^{th} and 7^{th} cranial nerves are involved most frequently and the most common primary neoplasms include squamous cell carcinoma, adenoid cystic carcinoma, melanoma, and lymphoma. Perineural tumor spread is associated with an increased incidence of local tumor recurrence, development of metastatic disease, and decreased five-year survival. The trigeminal nerve is involved most often by cancers of the facial skin, oral cavity, and nasopharynx. Facial nerve involvement is seen with parotid malignancies and cancers involving the external auditory canal and skin

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

around the auricle. Signs of PNTS on imaging include thickening and increased enhancement of the nerve, foraminal enlargement, and denervation changes in the musculature supplied by the nerve. **Cystic Adenopathy versus 2nd Branchial Cleft Cyst.** One of the most common presentations of HPV positive oropharyngeal (OP) carcinoma is the development of a new node in an adult patient. The vast majority of patients with stage III or IV HPV+ OP cancers have adenopathy at presentation and these tumors have a tendency to produce necrotic/cystic nodes and the primary tumor may be very small. These nodes can occur in a location similar to a 2nd branchial cleft cyst and can be mistaken for a congenital cyst. Although the two can have a very similar imaging appearance, one should make the diagnosis of a branchial cleft cyst in an adult patient with a new neck mass with caution and consider and OP malignancies regardless of whether or not there is a smoking history. **Odontogenic Sinusitis.** An odontogenic source of sinusitis should be suspected if predominantly or exclusively unilateral maxillary sinus disease is present on imaging. The inflammation results from odontogenic disease in the alveolar ridge, usually from the molar teeth. Typically periapical lucency is noted around the root of the tooth that is the source of the inflammation and a fistula from the periapical lucency to the alveolar recess of the maxillary sinus may be seen. It is important for the radiologist to identify the odontogenic source of the sinus disease as treatment must address the diseased tooth. Treatment of the sinus alone may be a cause of surgical failure and recurrent disease.
Retropharyngeal Adenopathy. The presence of retropharyngeal adenopathy may upstage a patient in the setting of neoplastic disease and may put a patient at risk for the development of a retropharyngeal abscess in the setting of infection. It is the job of the radiologist to identify pathologic retropharyngeal space (RPS) nodes as they cannot be seen or palpated clinically. Squamous cell carcinoma is the most common primary histology to involve the RPS lymph nodes and the nasopharynx is the most common primary site of neoplasia to involve these nodes. The RPS nodes are a primary drainage pathway for the sinonasal (SN) cavities, so scrutiny of the RPS is necessary in patients with SN cancers.

Mimics and Misses in the Head and Neck

Ginsberg, L. E.
M.D. Anderson Cancer Center
Houston, TX.

Presentation Summary
Mimics and Misses are inherent to the practice of head and neck radiology. Though categorizing and reviewing misses of mine and others will not prevent all future misses, nevertheless such a review is instructional (and entertaining). This presentation, emphasizing head and neck cancer, will seek to list common mistakes, calling attention to underlying root causes, and offering strategies that may help to avoid them. In addition to missing lesions, subject material will include mimics of pathology and misinterpretations.

O-462 **9:45 AM - 10:15 AM**

Findings in the Chest on Neck CT: What to Do!

Elicker, B. M.
UCSF Medical Center
San Francisco, CA.

Dr. Elicker completed medical school at New York Medical College and a residency in diagnostic radiology at Yale/New Haven hospital. After completing a fellowship in thoracic imaging at the University of California, San Francisco he joined the faculty. He is currently the chief of Cardiac and Pulmonary imaging at UCSF and is very active in lung cancer imaging. He is a two time recipient of the UCSF Hideyo Minagi outstanding teaching award.

Presentation Summary
Introduction - Neck CTs often include significant portions of the upper lungs. Neuroradiologists should have an understanding of common findings in the lungs and their significance, including the need for additional testing. This lecture will focus and two categories of findings: incidental lung nodules and inflammatory diseases that may be seen in the upper lobes. *Nodules* - Lung nodules are a common incidental finding that may be seen in up to 50% of patients. Greater than 95% of nodules are benign, even in patients with a cigarette smoking history, however malignancy is always a consideration. Several imaging features are diagnostic of benignity and do not require any additional evaluation or follow-up imaging. These include benign patterns of calcification (diffuse, central, ring-like or popcorn), the presence of fat and greater than two years of stability. When these features are absent, the role of CT is to determine the likelihood of malignancy. In general nodules that are likely malignant undergo immediate workup (biopsy, bronchoscopy, surgery, etc.) and nodules that are likely benign get followed with CT. Features suggestive of malignancy include large size (average diameter >1.5 cm), spiculated border and growth. Ground glass attenuation nodules have a much higher risk of malignancy compared to solid nodules, however these malignancies tend to be more indolent and are often followed with CT. If a nodule is seen in the lung apices on a neck CT, it is reasonable to recommend an immediate dedicated chest CT as a baseline. There are two exceptions to this rule in which case follow up is not necessary: 1. Solid nodule ≤4 mm in patients at low risk for malignancy (nonsmoker, no history of malignancy). 2. Ground glass nodules ≤5 mm (regardless of whether they are a smoker or nonsmoker). *Inflammatory diseases* - Active inflammatory or infiltrative processes may be diffuse or may preferentially involve the upper lungs. Diffuse processes include infection (usually viral or PCP),

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

pulmonary edema, acute respiratory distress syndrome (i.e., ARDS) and hemorrhage. On CT these are usually indistinguishable from one another and typical findings include symmetric bilateral ground glass opacity and consolidation. Processes that may predominant in the upper lungs include bacterial pneumonia, granulomatous infections (tuberculosis, histoplasmosis and coccidioidomycosis) and sarcoidosis. The neuroradiologist should be able to distinguish active inflammation in the upper lungs from scarring due to old/inactive disease. Scarring presents as linear or band-like opacities that extend to the pleura. Distortion of the normal lung architecture and traction bronchiectasis often are associated. Consolidation and/or multiple small nodules are the most common findings seen in inflammatory processes that predominate in the upper lobes. Cavitation within areas of consolidation often is seen with granulomatous infections. The nodules of infection usually involve the airways. A centrilobular distribution is typical of endobronchial spread of infection. Centrilobular nodules involve the central portion of the lung and are located at least 5-10 mm from the pleura. Sarcoidosis, in contrast, shows a lymphatic distribution of small nodules. Nodules are clustered in the subpleural lung, and around the central airways and arteries.

MR Neurography Techniques

Chhabra, A.
Johns Hopkins University Hospital
Baltimore, MD.

Avneesh Chhabra is a clinical scientist and is Assistant Professor Radiology & Orthopedic Surgery at the MSK section, Diagnostic Division of Russell H. Morgan Department of Radiology & Radiological Sciences, Johns Hopkins University, Baltimore, MD. He is double boarded in Radiology from Delhi University, India and Drexel University, Philadelphia, PA. Dr. Chhabra received his MSK Radiology fellowship from Temple University, Philadelphia, PA. Dr. Chhabra is multi-specialty trained with expertise in MSK, Body and Neuro imaging. During his tenure at Johns Hopkins, he has cultivated high-resolution MR Neurography. He has received several research grants, including the prestigious GERRAF fellowship to study the clinical impact of these techniques. He has received multiple travel grants and awards at national and international conferences, including the young investigator award at the Society of Skeletal Radiology meeting in 2011. Dr. Chhabra has published more than 70 peer-reviewed articles, has given more than 100 presentations, written multiple book chapters, and the 1st book on MR Neurography.

Extremity Nerve Imaging

Amrami, K. K.
Mayo Clinic Radiology
Rochester, MN.

Dr. Kimberly A. Amrami is currently Professor of Radiology, College of Medicine, Mayo Clinic. Dr. Amrami's education is as follows: She received a BA degree from the University of Minnesota in Hebrew Language and Literature; a BS degree from the University of Minnesota in Secondary Education with an Elementary endorsement; an MD degree from the University of Minnesota. Also at the University of Minnesota she performed a Residency in Diagnostic Radiology and at Mayo Clinic in Rochester a Fellowship in Musculoskeletal Radiology. Dr. Amrami has board certifications as follows: American Board of Radiology (Diagnostic Radiology); National Board of Medical Examiners (Diplomate). Certifications from Mayo Clinic include: Quality Academy (Mayo Clinic Quality Fellow: Bronze Level Certification and Silver Level Certification). Dr. Amrami has received more than 15 Honors and Awards, received at least 9 professional positions and major appointments. She has held and continues to hold many professional and community memberships, as well as societies and services. Her Journal responsibilities have included such titles as Associate Editor, Contributing Editor, Editorial Board Member, and peer reviewer. At Mayo Clinic, Dr. Amrami holds various administrative responsibilities and committee memberships along with various other activities.

Presentation Summary
Imaging of peripheral nerves has been revolutionized by

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

the advent of MR neurography. This technique emphasizes imaging the nerve itself rather than inferring nerve involvement based on changes in muscles in a given nerve territory. MR neurography requires strict attention to technique and the use of the best available tools. The core imaging principles include high-resolution imaging at full or high field strength, use of the best available receiver coils and high-resolution T1- and T2-weighted imaging with robust fat suppression for fluid sensitive sequence. More recent advances include the use of diffusion-weighted imaging and tractography as well as novel pulse sequences which selectively suppress background signal, including vascular signal. Nerve imaging in the extremities can be complicated by challenges in locating pathology based on clinical exam or EMG, both of which are operator dependent. An EMG indicating radial nerve pathology may not include precise localization so that imaging may involve looking at multiple segments (i.e., arm, elbow or forearm). In the lower extremities, for example, a clinical foot drop could be caused by an abnormality in the lumbosacral plexus, the peroneal division of the sciatic nerve - or anywhere along the common or deep peroneal nerve. The use of all available information is imperative and knowledge of the nerve anatomy of the extremities is critical. When the lesion is located characterization should include high-resolution T1- and T2-weighted image with robust fat suppression for the T2-weighted sequences. Multiple planes may be needed to fully characterize a lesion and the judicious use of contrast often is helpful in distinguishing inflammatory lesions such as CIDP from tumors or perineurioma. Lesions should be characterized as single or multiple and the distribution notes. The effect of primary nerve pathology on downstream musculature also is an important clue as to what exactly is causing the problem. Common primary lesions include benign neurogenic tumors. Malignant tumors, either primary or metastatic, do occur although with less frequency. Another common problem in extremity nerve imaging is nerve entrapment with or without the development of a traumatic neuroma or neuroma in continuity. Trauma of all kinds can affect peripheral nerves from mechanical irritation due to healing fractures to actual nerve transections. Access to the complete medical record can help narrow the differential. Imaging peripheral nerves in the extremities can be a complex and sometimes frustrating process but successful imaging can add significantly to patient care - especially when localization and characterization of a lesion is sought prior to targeted biopsy. High-resolution MRI also often can characterize benign neurogenic lesions with a degree of confidence that often obviates the need for biopsy. When close attention is paid to technique and when the exam is tailored to the need of the individual patient and clinical problem MRI can add tremendous value for patient care.

Point Counterpoint Discussion - Part II

Bilello, M.
University of Pennsylvania
Philadelphia, PA.

Presentation Summary
The basic process of medical image analysis, whether by radiologist or computer, consists of the extraction of key features (KFs) from the image, and the subsequent development of a differential diagnosis (DDx). The KFs derive from signal, spatial or temporal domains of image data, and usually represent the critical abnormal visual "Findings" of the study. The DDx is simply the list of diseases most compatible with the KFs of the image. Human KF extraction is based on pattern recognition, which depends on deconstruction and parallel processing of image data in multiple pathways of the human visual system. Human DDx development typically depends on the heuristic inference of disease likelihood, given image KFs. While probably not obligatory, computer KF extraction and DDx development can be, and often is, implemented in a remarkably comparable fashion to human image analysis processes. The computer is programmed to deconstruct image data into separate domains that are processed in a parallel fashion in order to extract the same KFs that a human observer might report. Then, through a separate inference engine such as a Bayesian network, neural network or rule-based algorithm, the computer can generate a DDx similar to that of a radiologist. This and the following presentation will elaborate on the principles of image analysis and illustrate the similarity of human and computational image analysis processes. A critical aspect of medical image analysis relates to temporal changes,

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

such as the growth or regression of lesions such as MS or tumor over time. This is a task particularly well suited to computer analysis whereby the computer program is not necessarily required to make a diagnosis, but rather tracks changes over time of a known disease entity. We will review how temporal changes are detected by computer, including the need to perform registration (i.e., bring image information from one time point to another). We will present a practical example of such a system, a locally developed program for the detection of change in lesion load in multiple sclerosis. Finally, after reviewing the general properties of radiology CAD systems, we will show examples of current computer image analysis software applied to neuroradiology, found in the scientific literature or available from commercial vendors.

Advances in Arterial Spin Labeling - Recipient of the Scholar Award 2009-2010

Zaharchuk, G.
Stanford University
Stanford, CA.

Presentation Summary
In this presentation, I will discuss the rapidly growing field of noncontrast arterial spin labeling (ASL) for use in brain imaging applications. This will include a discussion of "second generation" ASL, performed with pseudocontinuous labeling, 3D readout, and background suppression. When these things are brought together, the result is higher SNR whole brain perfusion imaging with minimal susceptibility artifacts and fast imaging times, making it an easy and useful sequence to apply in clinical patients. I will emphasize the flexibility of the ASL method, which has the potential to measure not just brain perfusion, but also to identify collaterals, to map vascular perfusion territories, and to identify small arteriovenous malformations (AVMs). I will present examples of how ASL can be used clinically in a diverse group of clinical conditions, including stroke, seizure, AVM, dural AVF, and brain tumors. Finally, I will address differences between vendor implementations and review the consensus statement on the recommended parameters for clinical ASL based on the recent ISMRM Perfusion Workshop.

Assessing Cerebrovascular Reserve Capacity in Carotid Steno-Occlusive Disease

Derdeyn, C. P.
Mallinckrodt Institute
St. Louis, MO.

Presentation Summary
Patients with atherosclerotic occlusive disease may have reduced flow to the distal territory, owing to poor sources of collateral flow. Conversely, many patients with occlusive disease, even complete occlusion, have normal flow owing to good collateral sources. When perfusion pressure - the difference between mean arterial pressure and the venous backpressure - falls in any arterial territory, the brain and brain vasculature may compensate through two mechanisms. The first is arterial dilation and the second is an increase in the amount of oxygen removed from the blood. Autoregulatory vasodilation is a response by penetrating capacitance arterioles to either reductions in arterial pressure or reduced arterial oxygen content. Neuronal, muscular, and physiologic factors are involved in this complex reflex. Arterial resistance is reduced, allowing flow to continue at near normal rates over a wide range of pressures. At some threshold point, however, further reductions in pressure exceed the ability of vasodilation to compensate and flow will fall passively as a function of pressure. This situation is known as autoregulatory failure. The primary compensatory reflex to reduced blood flow is an increase in tissue oxygen extraction. For a given tissue metabolic rate for oxygen consumption, a reduction in the delivery of oxygen (cerebral blood flow, CBF) will require an increase in the

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

amount of oxygen extracted by the blood (oxygen extraction fraction, OEF). Normal OEF is 30 to 40% and this can increase instantaneously to up to 80%. The precise mechanism by which this occurs is not clear. Oxygen is not transported and reaches the brain tissue by passive diffusion. Tissue oxygen tensions are not reduced when flow falls. It is likely that OEF increases owing to a constant flux of oxygen between the tissue and the blood. When flow falls, there is a relative increase in the amount of oxygen that is used by the brain. In humans, these compensatory mechanisms are identified by several different physiologic imaging methods. Paired flow tests assess the ability of the cerebrovasculature to increase blood flow or blood velocity to a vasodilatory stimulus. If flow fails to increase, pre-existing autoregulatory vasodilation is inferred. Static measurements of cerebral blood flow, blood volume, and mean transit time are another method for identifying the presence of autoregulatory vasodilation. Finally, OEF may be measured directly. It is critical to note that these methods are not interchangeable - different physiologic mechanisms are being assessed. Several of these techniques have been tested as predictors of future stroke risk. The data linking hemodynamic impairment and the risk for future stroke will be reviewed.

Evaluating CT Perfusion Using Outcome Measures of Delayed Cerebral Ischemia in Aneurysmal Subarachnoid Hemorrhage: ENRS Award Winner

Ivanidze, J.·Anumula, N.·Johnson, C. E.·Comunale, J. P.·Tsiouris, A. J.·Riina, H. A.·Segal, A. Z.·Stieg, P. E.·Zimmerman, R. D.·Mushlin, A. I.·Sanelli, P. C.
New York Presbyterian Hospital
New York, NY.

Purpose
Delayed cerebral ischemia (DCI) is a serious complication following aneurysmal SAH and remains a leading cause of morbidity and mortality. Our aim was to evaluate CTP in aneurysmal SAH by using outcome measures of DCI.
Materials & Methods
This was a retrospective study of consecutive patients with SAH enrolled in a prospective institutional review board-approved clinical accuracy trial. Qualitative CTP deficits were determined by twi neuroradiologists blinded to clinical and imaging data. Quantitative CTP was performed by using a standardized protocol with region-of-interest placement sampling of the cortex. Primary outcome measures were permanent neurologic deficits and infarction. The secondary outcome measure was DCI, defined as clinical deterioration. CT perfusion test characteristics (95% CI) were determined for each outcome measure. Statistical significance was calculated by using the Fisher exact and Student *t* tests. Receiver operating characteristics curves were generated to determine accuracy and threshold analysis.
Results
Ninety-six patients were included. Permanent neurologic deficits developed in 33% (32/96). CT perfusion deficits were seen in 78% (25/32) of those who developed permanent neurologic deficits and 34% (22/64) of those without (P < .0001). CT perfusion deficits had 78% (61%-89%) sensitivity, 66% (53%-76%) specificity, and 53% (39%-67%) positive and 86% (73%-93%) negative predictive values. Infarction occurred in 18% (17/96). CT perfusion deficits were seen in 88% (15/17) of those who developed infarction (Figure 1) and 41% (32/79) of those without (P = .0004). CT perfusion deficits had an 88% (66%-97%) sensitivity, 59% (48%-70%) specificity, and 32% (20%-46%) positive and 96% (86%-99%) negative predictive values. Table 1 demonstrates the quantitative CBF, CBV and MTT values for the primary outcome measures of permanent neurologic deficits and infarction. DCI was diagnosed in 50% (48/96). CT perfusion deficits were seen in 81% (39/48) of patients with DCI and in 17% (8/48) of those without (P < .0001). CT perfusion deficits had 81% (68%-90%) sensitivity, 83% (70%-91%) specificity, and 83% (70%-91%) positive and 82% (69%-90%) negative predictive values. Quantitative CTP revealed significantly reduced CBF and prolonged MTT for DCI, permanent neurologic deficits, and infarction. Receiver operating characteristics analysis showed that CBF and MTT had the highest accuracy. Table 2 demonstrates the quantitative CBF, CBV and MTT values for the secondary outcome measure of DCI.
Conclusion
CT perfusion may add prognostic information regarding DCI and poor outcomes in aneurysmal SAH.

Functional Neuroimaging to Characterize the Effect of Chemotherapy on Visual System Development in Children Treated for Retinoblastoma: SENRS Award Winner

Helton, K. J.·Demtchouk, V.·Parra, C. A.·Scoggins, M.·Zou, P.·Lin, Y.·Qaddoumi, I.·Wilson, M.·Ogg, R.
St. Jude Children's Research Hospital
Memphis, TN.

Purpose
Retinoblastoma (RB) is the most common intraocular tumor in childhood, and fatal when untreated. Treatment coincides temporally with the rapid development of the eyes and central nervous system. Little is known about the influence of chemotherapy (CX) on visual development; we hypothesized that the functional MRI (fMRI) can characterize the effects of CX on vision.
Materials & Methods
After IRB approval, fMRI was used to longitudinally investigate primary visual cortex (V1) response to photic stimulation in 60 children being treated for RB [41 unilateral (UL), 19 bilateral (BL), median age at diagnosis 13.3 months], for a total of 225 exams. After baseline fMRI, enucleation was performed on patients with advanced UL or BL disease and patients were staged. Stratum A was early stage UL or BL, and received low dose CX. Stratum B was advanced stage BL and received aggressive CX. Stratum C was advance stage UL, with low risk receiving no CX(C-), and intermediate and high risk receiving aggressive CX(C+).
Results
As reported previously (Barb, et al., IOVS 2011), fMRI response in V1 was predominantly negative in the anterior region of V1 (blue overlay in figure, typical patient), with more variable positive in posterior region of V1 (red overlay in figure). Mean values of activation parameters are summarized in the figure. Mixed-effect modeling showed a significant effect of CX on both the peak fMRI response ($p < .001$) and the volume of cortex activated ($p = 0.002$), but only the activated volume was significantly affected by stratum ($p = .03$).
Conclusion
Primary visual cortex fMRI response was decreased after exposure to chemotherapy in children treated for RB. Functional neuroimaging will be useful to evaluate the impact of disease and treatment on visual system development in children with RB. Additional research is needed to clarify the effects of CX on cortical activation and the neural-hemodynamic coupling that mediates fMRI signals.Clinical relevance/application: The clinical decision to enucleate for RB disease control versus preserve the eye for vision is difficult. Functional MRI can clarify visual function; understanding CX effects on vision is critical.

Direct Puncture Treatment of Orbital and Peri-Orbital Vascular Malformations: WNRS Award Winner

Nesbit, G. M.·Priest, R.·Ng, J. D.·Hamilton, B. H.
Oregon Health and Science University
Portland, OR.

Purpose
Vascular malformations of the orbit are difficult to treat due to the complex anatomy and the tendency of these low-flow lesions to decompress at surgery. Direct puncture and treatment may provide alternatives in the management of these lesions.
Materials & Methods
Retrospective review of the INR database revealed 17 orbital or periorbital vascular malformations treated with direct puncture and instillation of a therapeutic agent from 2003 - 2012. Specific diagnosis was based on clinical, pathologic, and therapeutic response features. A chart review of these patients and their specific followup was undertaken. Complete response was defined as complete removal of the malformation and/or eradication of any symptoms present to treatment. A partial response was defined as improved but continuing symptoms or problems arising from the lesion. No response was defined as no improvement in symptoms and need for ongoing or further intervention. Complications of the treatment were defined as a worse symptoms at 30 days and classified as temporary or permanent.
Results
The lesions consisted of two lymphatic and 15 venous malformations. The intra-orbital needle placement was performed with ultrasound guidance in two and Xper-CT guidance in nine patients, and, in the periorbital lesions involving the eyelids or sclera, ultrasound on manual palpation was used. The sclerosant used was doxycycline in the lymphatic malformations, and either alcohol, sotradecol, in one case with coils and thrombin, or bleomycin. Overall, 15 of 17 had a complete or parital response with two having no response. Postoperative orbital swelling was seen in the majority of patients, which resolved within 4-10 days, with mild diplopia note due to mass effect. No visual loss or ophthalmoplegia was seen and no complications noted.
Conclusion
Direct puncture and injection of a sclerosant appears to be a viable alternative to surgical resection in symptomatic lymphatic and venous malformations of the orbit and periorbita, and has become the first-line of treatment at our institution.

Comparative Analysis between the Cross Sign versus Apparent Diffusion Coefficient and Fractional Anisotropy Measurements for the Detection and Monitoring of Multiple System Atrophy

Park, J.·Guzman, R.·Sayre, J.·Perlman, S.·Ellingson, B.·Fogel, B.·Salamon, N.
University of California Los Angeles
Los Angeles, CA.

Purpose
To determine retrospectively if quantitative diffusion tensor imaging (DTI) metrics of white matter integrity are superior to conventional magnetic resonance imaging (MRI) findings for detecting abnormalities in patients with multiple system atrophy (MSA). We also sought to determine if there was a temporal relationship between time elapsed from disease onset and the presence of a cross sign.
Materials & Methods
Conventional MRI images from 31 patients (with a total of 50 studies) with clinical diagnoses of MSA-P and MSA-C were interpreted by a neuroradiologist for the presence or absence of the cross sign. An expert neurologist determined the clinical diagnosis, as well as ataxia severity and asymmetry for each patient. For quantitative analysis, we compared apparent diffusion coefficient (ADC) and fractional anisotropy (FA) values in the pons, and middle cerebellar peduncles of 19 patients who also had concurrent DTI examinations (four patients had repeat studies, resulting in 23 studies total). Apparent diffusion coefficient and FA values were compared to normal controls. Analysis was conducted using a region of interest method. A statistical comparison of the cross sign and DTI values was performed using a McNemar's Chi-square test. Furthermore, for the four patients who had repeat DTI examinations (mean two years after first study), a paired samples T-test was performed to determine if there were significant changes in FA and ADC. Correlation of imaging findings with clinical ataxia scores was performed.
Results
Average patient age at time of first imaging study was 59.7 years (range 47-75 years). For all 50 traditional MRI examinations (performed mean 4.2 years from symptom onset), the cross sign was present in 80% of patients (found to be more reliable after two years from initial symptom onset (Table). Apparent diffusion coefficient and FA values in the pons and middle cerebellar peduncles were significantly higher in MSA patients than in controls. In patients with both quantitative ADC/FA analysis and traditional MRI studies (n=19), changes in ADC and FA were significantly more sensitive than the presence of the cross sign (p=.025). In addition, in the four patients with serial DTI studies, significant decreases in FA values were noted in the pons (p=.046) and the middle cerebellar peduncles (p=0.18).

Relationship between time elapsed from symptom onset with presence of the cross sign

Number of years elapsed from diagnosis	0-2	3-5	6+
Positive cross sign/total studies performed(% positive)	9/14 (64%)	21/24 (87%)	10/12 (83%)

Conclusion
While the cross sign is classically associated with MSA, it has limited sensitivity, particularly in the first two years from symptom onset. Apparent diffusion coefficient and FA values in the pons and middle cerebellar peduncles detected early pathologic involvement prior to the development of the cross sign. Furthermore in a small sample size, significant decreases in FA were seen over time. Quantitative DTI in conjunction with traditional MRI offers a valuable tool to improve the detection of MSA, as well as to potentially monitor disease progression.

Use of Tractography in Normal Pressure Hydrocephalus

Solomon, D. L.[1]·Mian, A. Z.[1]·Killiany, R. J.[1]·Solomon, M. A.[2]·Koo, B. B.[1]
[1]Boston University School of Medicine, Boston, MA, [2]Los Gatos MRI, Los Gatos, CA.

Purpose
Normal pressure hydrocephalus (NPH) is a clinical diagnosis with no formal definition. Normal pressure hydrocephalus classically is described as a clinical triad of gait abnormality, dementia, and urinary incontinence. Few patients present with all three symptoms, leaving clinicians to rely on a “preponderance of evidence” approach, involving weighing triad symptoms with radiologic findings, CSF opening pressure, and response to Tap Test, external lumbar CSF drainage, lumbar infusion test, and finally shunting. Apart from searching for enlarged ventricles out of proportion to sulcal atrophy, Evan's ratios greater than 0.3, and callosal angles greater than 40 degrees, radiologists are primarily engaged in a process of exclusion for NPH cases. This study proposes tractography as a tool for radiologists to consider when evaluating suspected NPH patients.
Materials & Methods
A retrospective study of 17 patients over age 55, nine classified as “definite” or “probable NPH” by referring physicians and eight normal controls, who underwent brain MRI imaging in a 3T magnet. Diffusion tensor imaging and tractography data were acquired using Philips Fibertrak software, postprocessing was done using FMRIB

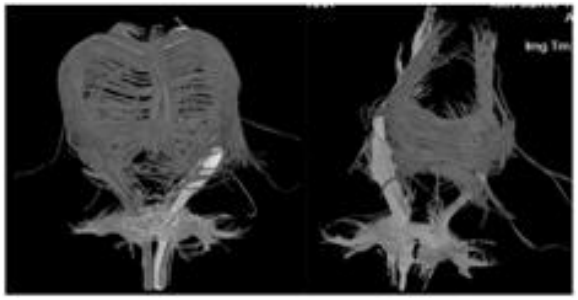
Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Software Library (FSL), and fractional anisotropy (FA) comparisons were performed using tract-based spatial statisics (TBSS).

Results

Normal pressure hydrocephalus patients were found to have higher FA values than normal controls in the upper corticospinal tract and lower FA values in the corpus callosum, to $p \leq 0.05$ levels, consistent with previous reports. Normal versus NPH FA values in the corpus callosum are 0.72 and 0.60, respectively, while normal versus NPH values in the upper corticospinal tract are 0.45 and 0.63, respectively. Normal pressure hydrocephalus tractography images were characterized with a distinct "heart-shaped" artifactual sign.

NPH Normal



Conclusion

We believe, using probabilistic tractography techniques, there is artifactual connection between the callosal radiation fiber analogs and the fiber analogs of the corticospinal tract when the pressure effects of NPH cause a decrease in FA values of the callosal radiations and an increase in the FA values the corticospinal tract. Since the "heart-shaped" tractography pattern does not appear in Alzheimer disease, which also demonsrates ventricular enlargement, tractography may provide radiologists a new clinical tool for evaluation of patients under suspicion of NPH.

Neuritis Optica Evaluation: A Functional and Structural MR Imaging Study

Rueda-Lopes, F. C.[1,2]·Miraldi, F.[1,2]·Bahia, P.[2]·Domingues, R.[1]·Alves-Leon, S.[2]·Gasparetto, E. L.[1,2]
[1]DASA, Rio de Janeiro, BRAZIL, [2]UFRJ, Rio de Janeiro, BRAZIL.

Purpose

Severe neuritis optica (NO) is a hallmark of neuromyelitis optica (NMO). Multiple bilateral attacks or a single one may lead to blindness. Still, the majority of patients partially recover somehow after attacks, probably due to the degree of the visual tract impairment. Our objective was to investigate NMO patients using the resting-state functional magnetic resonance imaging (RS fMRI) and structural analysis compared to the controls, regarding the visual network, in order to evaluate the cortical adaptations in NMO and also its structural damage.

Materials & Methods

We studied 28 NMO spectrum patients [myelitis (6), NO (22)] [mean age 38 years (SD +/- 3,2, 18 female)], and also 19 sex- and age-matched controls. All participants signed informed consent. MR imaging was performed in a 1.5T scanner, including diffusion tensor imaging (DTI) in 30 directions and RS fMRI was performed during rest. Diffusion tensor imaging data were postprocessed using tract-based spatial statistics (TBSS) to aligned all patients and obtain fractional anisotropy (FA) values from the visual pathway. Functional MRI data were postprocessed using MELODIC, part of FSL4.1. The fMRI data set was decomposed using independent component analysis (ICA) to identify large-scale patterns of functional connectivity. After that, a "dual-regression" approach was carried out allowing voxel-wise comparisons of resting functional connectivity between groups, generating threshold-free cluster enhancement (tfce) and p-corrected maps of comparison. Synchronization values of the visual network of patients and controls were compared and their correlation with FA from the visual pathway was assessed, using Pearson. A p-value of 0.05 was considered statistically significant.

Results

Fourteen components were computed in the entire subject group by ICA. Visual network was clearly detected among the subjects and was compared between both groups. There were increased synchronization values in the whole occipital cortex in NMO patients compared to controls ($p<0.01$) in both maps. The average synchronization value in patients was 3.484238 (2.700344 SD) compared to controls,119129 (1.411825 SD), with a p-value of 0.05. The DTI data were obtained from 23 patients, including patients without clinical NO. A total of 15 events of NO on each side (30 in total) were evaluated. The average FA value in the right visual pathway was 0.60 (0.03 SD) and in the left side 0.59(0.03 SD), p-value of 0.56. A weak negative correlation was obtained between synchronization visual network value and right FA (-0.013) and it was positive in the left side (0.075). A positive correlation was obtained between right ON and right FA(0.17) and negative with left ON and left FA (-0.05).

Conclusion

Neuromyelitis optica patients have higher synchronization values found in the occipital cortex in patients compared to controls, as a form of compensation for the NO. Although the correlations between clinical symptoms, structural damage and functional compensation obtained were weak, they all point toward a more subtle structural damage on the right side (as the correlation between NO and FA is higher) and thus a more difficult functional compensation (as the correlation between fMRI and FA is

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

negative - more structural damage, less fMRI compensation).

Effect of Extrinsic Variables on Diffusion Tensor Parameters in White Matter

Khalilzadeh, O.[1]·Dinkel, J.[1]·Perlbarg, V.[2]·Galanaud, D.[3]·Puybasset, L.[3]·Gupta, R.[1]
[1]Massachusetts General Hospital, Boston, MA, [2]Université Pierre et Marie Curie-Paris, Paris, FRANCE, [3]Pitié Salpêtrière Hospital, Paris, FRANCE.

Purpose
Quantitative diffusion tensor imaging (DTI) of brain is becoming increasingly popular in neuroradiology practice. Several factors including patients' demographics, scanner type, and imaging protocol can significantly alter DTI measurements, making them incomparable. Even for a single scanner, the echo time (TE) affects DTI measures. To make quantitative DTI clinically useful as a measure of disease, methods to normalize diffusion parameters are essential. This study evaluates the affect of extrinsic parameters such as TE, age, head positioning, and motion on the measured diffusion parameters in a well balanced clinical setting, using data of a single scanner.
Materials & Methods
This study was approved by the institutional review board (IRB#: 2012P002245) of Massachusetts General Hospital. Diffusion tensor imaging data of 204 consecutive subjects, who were scanned over a period of three months using a single MR scanner (GE Medical Systems, Milwaukee, WI) in the emergency department, were analyzed. Repetition time (TR), field strength, type of head coil, slice thickness, number of diffusion directions, and b values were similar for all scans; different scans ranged in the TE from 85 ms to 102 ms. Only subjects with normal MRI finding were included in this study, and patients with DTI artifacts were excluded. Using a custom-designed automated software package, DTI parameters, namely, fractional anisotropy (FA), axial diffusivity (L1) and radial diffusivity (Lt), were calculated in 20 different white matter brain regions. The dependence of these parameters on TE, age, head rotation angle, and head motions was analyzed.
Results
There was a significant ($p<0.01$) positive association between TE and FA in different white matter regions including left ($r = 0.466$) and right ($r = 0.470$) corona radiata, left ($r = 0.369$) and right ($r = 0.428$) external capsule, left ($r = 0.469$) and right ($r = 0.499$) cerebral peduncle, internal capsule and body of corpus callosum ($r = 0.350$). Radial diffusivity was inversely associated ($p<0.01$) with TE in these regions. There was a significant ($p<0.05$) negative association between mean head motions (or age) and FA. A prediction model based on TE, age, head angle rotation and head motion could account for up to 65% of variance in FA measurements of different white matter regions. In subjects with low head motions (less than median), age<50, and less than 10 degrees head rotation this model could predict up to 74% of variance in FA measurements.
Conclusion
In clinical practice, DTI parameters of the white matter are dependent on several factors such as TE, age, head rotation angle, and head motion, which contribute to measurement variability. A model to normalize DTI measures can curtail this variability by as much as 74%.

Diffusion Tensor Imaging Detects Microstructural Reorganization in the Brain Associated with Chronic Irritable Bowel Syndrome

Ellingson, B. M.·Mayer, E.·Harris, R. J.·Ashe-McNally, C.·Naliboff, B.·Labus, J. S.·Tillisch, K.
David Geffen School of Medicine at the University of California Los Angeles
Los Angeles, CA.

Purpose
Irritable bowel syndrome (IBS) is a common gastrointestinal disorder characterized by recurring abdominal pain associated with alterations in bowel habits. The purpose of the current study was to determine whether patients with chronic visceral pain associated with IBS have microstructural differences in the brain, as measured using diffusion tensor imaging (DTI), compared with healthy control subjects (HCs), indicative of long-term neural reorganization of chronic pain pathways and regions associated with sensory integration.
Materials & Methods
All patients in this study signed institutional review board-approved informed consent. Diffusion tensor imaging was performed in a large sample of phenotyped IBS ($n = 33$) and HCs ($n = 93$) in using a 64 direction acquisition protocol with $b = 1000s/mm2$. Irritable bowel syndrome patients were phenotyped by gender, symptom severity, and symptom duration. Voxel-wise DTI comparisons including symptom and gender covariates were performed in areas of white matter and central gray matter regions. Probabilistic tractography was performed between relevant structures associated with chronic pain pathways and the number of fiber tracts were compared between IBS and HCs.
Results
Patients had lower FA in thalamic regions, in the basal ganglia (globus pallidus, putamen) and in sensory/motor association/integration regions (suggestive of reduced directional coherence) as well as higher FA in frontal lobe regions and the corpus callosum (suggestive of increased directional coherence). Irritable bowel syndrome patients

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

also had reduced ADC within the globus pallidus and higher ADC in the thalamus, internal capsule, and coronal radiata projecting to the sensory/motor regions. Sex differences in FA and MD also were observed in IBS patients, but not HCs. Probabilistic tractography confirmed a higher degree of connectivity in pathways between the thalamus and prefrontal cortex passing through the anterior cinculate cortex (ACC), as well as the connectivity between the medial dorsal thalamic nuclei and ACC. Symptom severity was found to be negatively correlated with FA in the globus pallidus (P = 0.0397), number of fiber tracts found connecting the thalamus and primary sensory cortex (P = 0.0209), and the log transformed number of fibers connecting the thalamus and insula (P = 0.0466), and positively correlated with ADC in the white matter regions adjacent to the primary sensory cortex (P = 0.0190).
Conclusion
Together, these results support the hypothesis that patients with chronically recurring visceral pain from IBS have long-term microstructural changes within the brain, particular in regions associated with integration of sensory information and corticothalamic modulation.

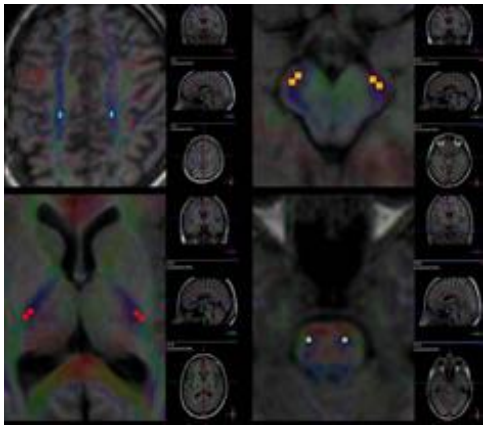
Transcranial Magnetic Stimulation and Magnetic Resonance with Diffusion Tensor Imaging in Amyotrophic Lateral Sclerosis Patients: Combination and Correlations of their Measurements

Stecco, A.·Nasuelli, N.·Mazzini, L.·Cantello, R.·Perchinunno, M.·Carriero, A.
ASU Maggiore della Carità
Novara, ITALY.

Purpose
To determine the diagnostic accuracy of MRI with DTI and TMS with MEPs in UMN assessment in ALS patients; secondary goal to assess if there is a correlations between DTI metric and MEPs.
Materials & Methods
Seventeen patients (10 males and seven females; age range 25-74 years, mean 47) affected by ALS, underwent a TMS and MRI DTI evaluation within 30 days, during their follow-up evaluation. Nine of them had a clinical presentation at upper limbs, five at lower limbs, four as a bulbar type. Twelve were classified (El Escorial) as definite ALS, three probable ALS and two possible, with a ALS-FRS range of 17-40, mean of 33. By TMS, cortical motor threshold (MT) at rest, central motor conduction time (CMCT), cortical MEPs and spinal MEPs have been recorded. MR imaging DTI acquisitions have been performed with a 64 directions oriented tensor, on a 1.5T magnet, without ECG/PPU trigger. The DTI has been acquired on the brain with a 8-channels Head Sense Coil. Diffusion tensor imaging postprocessing has been conducted on a dedicate workstation loaded with proprietary DTI and FiberTracking software, and a two-observer (in consensus), voxel-by-voxel single-point ROI-based analysis on the following several anatomical levels: semioval centers (SC), internal capsule - posterior limb (IC), cerebral pedicle (PED), pons (PON). The color-coded FA map and a 3DT1-weighted axial image served as reference for ROI positioning assistance. Fractional anisotropy and ADC values have been recorded and compared to an institutional healthy volunteers database already existing. Statistical analysis has been carried out by mean of Wilcoxon-Mann-Whitney test and Cochrane Q test, together with sensitivity assessment. SAS v.8.2 and Excel 2007 have been adopted.
Results
Only the internal capsule level FA measurements (mean FA = 0.64) differed statistically from the mean and range (0.74; 0.67-0.81) of values from the control data. Sensitivity assessment of MEPs (with or without a clinical sign) and DTI, showed a slight superiority of DTI if compared to MEPs alone, but when MEPs are combined with the clinical sign show a better sensitivity. The same behavior and results showed for TCMC.



Conclusion
MEPs TCMC and DTI with FA measurement at the internal capsule level, appear to study with the same sensitivity the quality of cortico-spinal tract in ALS patients in evaluating UMN. The clinical signs, if present, add sensitivity to TMS evaluation.

Cerebral Hyperintense White Matter Lesions: Does Increasing Lesion Volume Correlate with Decreased White Matter Fractional Anisotropy?

Cecava, N.[1]·Sherman, P.[1]·Kochunov, P.[2]·McGuire, S.[1]
[1]San Antonio Military Health System, San Antonio, TX, [2]University of Texas Health Science Center at San Antonio, San Antonio, TX.

Purpose
Disease-related and idiopathic, age-related hyperintense white matter (HWM) lesions commonly are encountered on brain magnetic resonance imaging, but their clinical significance often is difficult to discern. Fractional anisotropy (FA) obtained with diffusion tensor imaging (DTI) is a marker for white matter neural tract integrity. This study aims to evaluate the relationship between HWM lesion volume and location-matched FA in a normative population and a population of high altitude U2 pilots following repeated hypobaric exposure with clinical and imaging evidence of neurologic insult.
Materials & Methods
MR FLAIR HWM lesion volume in the frontal lobes and FA in corona radiata were compared in subjects in two separate cohorts: (1) 101 U-2 pilots with history of repeated hypobaric exposure and (2) 89 normative subjects matched for age and education to the pilot cohort. Sixty-six of 101 U-2 pilots had HWM lesions and 52 of 89 normative subjects had HWM lesions. Previous data analysis established a statistically significant elevation in total HWM lesion volume within the pilot cohort as compared to the normative cohort. The imaging data were collected using a 3T MRI scanner and high-resolution (1mm isotropic) 3D FLAIR and DTI sequences. Data analysis included a Spearman's rank-order correlation and statistical significance evaluation.
Results
Increasing frontal HWM lesion volume did not correspond with a statistically significant decrease in corona radiata FA in either cohort. The Spearman's correlation suggested a random relationship of HWM lesion volume and FA (U2 pilot cohort: ρ (99) = -0.028, P =0.781) (Normative cohort: ρ (87) = -0.182, P = 0.088).
Conclusion
Hyperintense whit matter lesions long have been considered to be markers of white matter injury, whether from a known insult or aging. Some authors have postulated that decreased FA may be an early marker in progressive white matter tract damage, with HWM being a latter marker in the injury spectrum. However, this study suggests FA and HWM lesions may not have a strict inverse relationship in either a normative population or a population with pathologically increased HWM lesions such as the studied U-2 pilot population. Further studies will be necessary to evaluate the dynamics of FA in normal aging and in the acute and chronic phases following neurologic injury.

Diffusion Tensor Imaging and Multiple Sclerosis: Patterns of Diffusion Abnormality

Suri, A. K.[1,2]·Fleysher, R.[1]·Wagshul, M. E.[1]·Lipton, M. L.[1,3]
[1]Albert Einstein College of Medicine, Bronx, NY, [2]Bronx Psychiatric Center, Bronx, NY, [3]Montefiore Medical Center, Bronx, NY.

Purpose
Access the concordance of signal abnormalities observed on T2W FLAIR images with the distribution of abnormal fractional anisotropy (FA) individual multiple sclerosis (MS) patients.
Materials & Methods
Imaging of five MS patients was performed at 3T, including T2-weighted FLAIR (TR/TI/TE; 11000, 2800, 125 ms) and diffusion tensor imaging (DTI) (2mm isotropic resolution, 32 directions, b=1000). Fractional anisotropy and T2W-FLAIR images were coregistered to the MNI atlas using a nonlinear procedure. A voxelwise one versus many t-Test ($p<0.01$; 100 voxel cluster size) was performed in each MS patient with comparison of FA and MD images to a group of 40 normal individuals. Lesion location was assessed by two CAQ certified neuroradiologists to determine the degree of concordance between abnormalities shown by T2W FLAIR, FA and MD.
Results
Hyperintensities were detected on T2W FLAIR images in callososeptal and periventricular regions and the brainstem, as expected in MS. Areas of both abnormally low and abnormally high FA were detected in all patients in these areas and in the corticospinal tracts (posterior limb of the internal capsule, corona radiata), corpus callosum and cerebellum. Many of the hyperintensities were concordant with areas of abnormal FA. However, overlap was generally only partial, with areas of abnormal FA generally exceeding the size of colocated hyperintensities. Additional areas of abnormal FA were detected in regions that appeared normal on T2W FLAIR images. Some areas of hyperintensity were present in the absence of colocated diffusion abnormalities. Abnormally high MD was detected in the posterior limb of the internal capsule, brainstem, cerebellum, fornices and the peripheral cerebral white matter.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

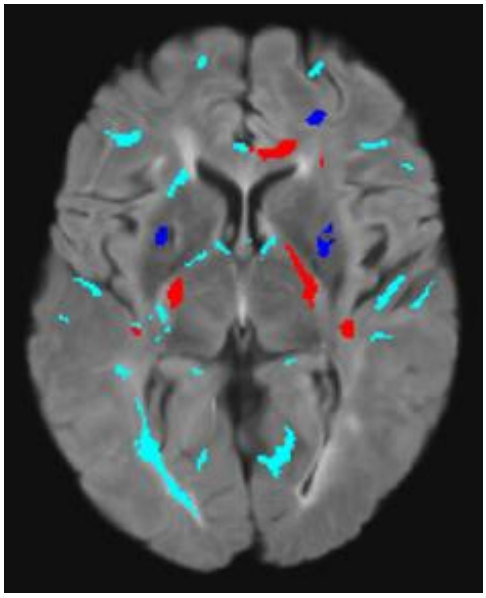

Figure 1. T2W FLAIR image of an MS patient showing hyperintensities in the periventricular white matter and multiple areas of abnormally low FA (red), high FA (blue) and high MD (aqua).

Conclusion

Abnormal white matter anisotropy is detectable in individual MS patients and provides both complementary information colocated with typical hyperintensities as well as abnormalities in normal-appearing white matter.

Head and Neck Paragangliomas in the Setting of SDHx Germline Mutations: A Distinct Radiologic and Clinical Entity

Cloran, F. J.·Fishbein, L.·Nathanson, K.·Seol, J.·Pryma, D.·Loevner, L.
University of Pennsylvania
Philadelphia, PA.

Purpose

A subset of head and neck paragangliomas (HNPGLs) harbor a germline mutation in one of the *Succinate Dehydrogenase* (*SDH*) subunit genes. While the imaging characteristics of sporadic head and neck paragangliomas (HNPGLs) have been well described, their behavior in the setting of *SDHx* germline mutations is not well understood and may be associated with different imaging characteristics. The aim of this study is to assess the imaging manifestations of HNPGLs in patients with germline mutations in an *SDHx* gene.

Materials & Methods

Medical records of 140 patients were reviewed who had paragangliomas (PGLs) and underwent genetic testing at our institution from January 2004 through December 2012. Thirty-eight of the 140 patients (27%) had HNPGLs. Pathologic confirmation of HNPGLs was available in 31 of these patients; the remaining 7 patients had either characteristic imaging findings for PGL and/or had tissue sampling from other sites consistent with synchronous or metastatic disease. CT and MR data as well as molecular imaging (In-111 Octreoscan, I-123 MIBG and PET-CT) data were reviewed in this cohort.

Results

SDHx germline mutations were found in 24 of 38 (63%) patients with HNPGLs (*SDHD* n=15; *SDHB* n=8; *SDHC* n=1). Of the 24 patients with *SDHx* mutations, there were a total of 38 HNPGLs. Eleven patients (46%) with *SDHx* mutations had multiple HNPGLs, while patients without a mutation did not have multiple HNPGLs. Of the 24 patients with HNPGLs and *SDHx* mutations, five (21%) had metastatic disease (nodal n=2, distant n=3), which was similar to the presence of metastatic disease in patients without a mutation (3/14 patients, 21%). Of patients with mutations and head and neck tumors, nine (38%) had thoracic and/or abdominal paragangliomas, compared to only one patient without a mutation. Morphologically, the CT and MR appearance of individual HNPGLs in patients with *SDHx* mutations was similar to sporadic HNPGLs without a mutation. Of 18 patients in our cohort who underwent molecular imaging, 8/18 HNPGLs (44%) showed uptake on I-123 MIBG imaging, and 7/9 HNPGLs (77%) showed uptake on In-111 Octreoscan. Two patients had both In-111 Octreoscan and I-123 MIBG imaging which showed their HNPGLs were avid on In-111 but not on I-123 imaging.

Conclusion

Our results suggest that *SDHx* mutations may be present in greater than 60% of patients with HNPGLs. The presence of multiple HNPGLs is indicative of an *SDHx* mutation. Over one-third of patients with HNPGL and a *SDHx* mutation harbor a synchronous thoracic or abdominal tumor, while this appears rare in patients without a mutation. Our data on patients with HNPGLs suggest that the incidence of metastatic disease related to their HNPGL is not clearly different from their sporadic (non-*SDHx* mutation) counterparts. Given the prevalence of *SDHx* mutations with HNPGLs, genetic counseling may be indicated in patients and their first degree relatives when a mutation exists. Furthermore, our results suggest that patients with

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

the mutation and HNPGLs have a greater than 33% chance of thoracic and abdominal PGL and should have dedicated imaging of these regions.

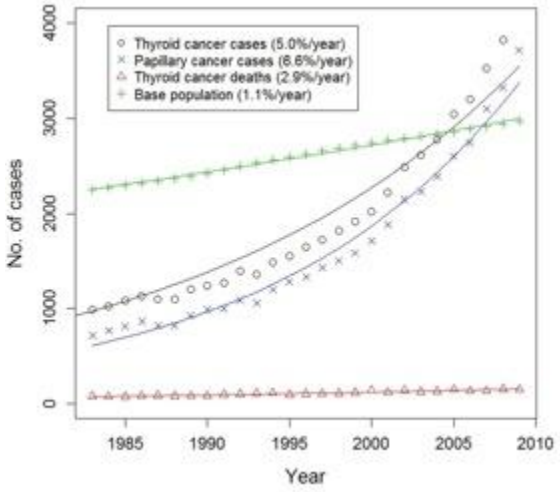
Exponential Growth in Thyroid Cancer: Trends in Incidence and Association with CT Imaging

Hoang, J. K.[1]·Roy Choudhury, K.[1]·Lyman, G.[1]·Eastwood, J.[1]·Wnuk, N.[1]·Esclamado, R.[1]·Nguyen, X.[2]
[1]Duke University Medical Center, Durham, NC, [2]The Ohio State University Medical Center, Columbus, OH.

Purpose
The incidence of thyroid cancer has increased in the United States since the 1980s. The trend is due to an "*apparent*" increase in incidence from increased diagnostic scrutiny, resulting in increased diagnosis of small clinically insignificant cancers. The aim of this study is to determine the recent trends in incidence of thyroid cancer, and to evaluate the relationship between CT scans volume and thyroid cancer incidence.
Materials & Methods
This retrospective cohort study utilized national databases for thyroid cancer and CT imaging volume. Thyroid cancer data for 1983 to 2009 were obtained from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database. Data on inpatient and outpatient CT imaging volume for 1993 to 2006 in the United States were obtained from the National Council of Radiation Protection and Measurements Report No. 16. Trends in thyroid cancer incidence were modeled for overall incidence and mortality and as a function of patient age and gender as well as tumor histology, size and stage. Simple regression analysis was performed to evaluate the relative impact of annual CT scans on thyroid cancer incidence.
Results
In 2009 the incidence of thyroid cancer was 14 per 100,000, and was almost double the incidence in 2000. The growth in incidence is exponential without significant change in mortality from thyroid cancer(Figure). The subgroup with the highest growth in incidence was subcentimeter papillary carcinoma with 11.8% growth per year resulting in doubling in incidence every 6.2 years. There was a very strong linear relationship between annual CT scan volume and incidence of subcentimeter papillary carcinoma ($r = 0.987$, $p<0.0001$). This is particularly significant given that growth in incidence of subcentimeter papillary carcinoma is not linear, but is exponential. We evaluated other tumor sizes and histologies for their relationship with annual CT volume and found high correlation coefficients, but the slopes of the regression line were smaller compared to subcentimeter papillary carcinoma.



Conclusion
The incidence of small nonpalpable thyroid cancer is growing at an exponential rate without a significant change in mortality rate. This supports the theory of apparent increase in incidence due to increased diagnostic scrutiny. There is a strong relationship between the incidence of subcentimeter papillary carcinomas and CT imaging volume over time. Since CT imaging may be a major source for detection of incidental thyroid cancers, future work should focus on establishing evidence-based and cost-effective guidelines for workup of thyroid nodules seen on CT.

Estimates of Clinical Cost Savings for New, Better Performing Criteria for Diagnosis of Persistent Nodal Metastases after Treatment for Oropharyngeal Carcinoma

Ahmed, S.·Jones, J.·Steele, J.·Sandulache, V. C.·Ow, T. J.·Skinner, H. D.·Rao, A.·Ginsberg, L. E.·Kumar, A. J.·Myers, J. N.·Hamilton, J. D.
M. D. Anderson Cancer Center
Houston, TX.

Purpose
A recent publication (Hamilton, et al.) demonstrated how new CT diagnostic criteria ("NECk REaD") improved the accuracy of best radiologic practice for diagnosing persistent nodal metastases after definitive treatment for oropharyngeal carcinoma. The economic ramifications of reducing the number of nodal dissections in this previously studied patient group are assessed.
Materials & Methods
One hundred thirty-eight patients who had 1) a diagnosis of oropharyngeal carcinoma between 2002 and 2008, 2) who received definitive radiation therapy +/- chemotherapy, and 3) had pre- and post-therapy CT

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

imaging were assessed retrospectively. The cost of all care (surgery, radiation therapy, chemotherapy, hospitalization, etc.) was gathered from a database for patients beginning from the start of radiation therapy through 90 days after nodal dissection. Inflation estimates derived from U.S. Department of Labor statistics adjusted the line item costs to the current standards. The cost of nodal dissection was estimated as all the costs associated with the day of surgery +/- one day. The thirty patients placed at lowest risk (score of 0 or 1; all found to be pathologically negative) by the "NECk REaD" criteria (1 point for necrosis, new calcification, ring enhancement, extranodal disease on pre-therapy CT, and diameter decrease of <50%, with two additional points for new necrosis) had the nodal dissection cost subtracted from the total as an estimate of the economic impact of improved diagnostic accuracy. Records were assessed to see if the new criteria changed the imaging diagnosis compared to the radiologist report.
Results
The average patient cost was ~$64,000. The average cost of the nodal dissection for the 30 patients with the lowest scores was ~$12,000. Of the 30 patients with the lowest scores, 21 had radiology reports that were positive or equivocal for persistent nodal metastases contrary to the NECk REaD Criteria, while nine had negative reports and received planned neck dissections. If the 21 patients' neck dissection costs are subtracted there is an average clinical cost savings of $1,836 per patient and if all 30 patients are used, the savings is $2,622. Interestingly, the five patients with the highest NECk REaD Criteria scores (score >5), all of whom had positive lymph nodes by pathology, had higher average costs (~$106,000) mainly due to three patients with additional chemotherapy or complications with care.
Conclusion
This study shows the economic savings resulting from incremental improvements in diagnostic accuracy. A minimal investment of radiologist time can have substantial impact on the cost of clinical care. Although the CT criteria improves the triaging of these patients with high-risk going straight to nodal dissection and low-risk to observation, there remains a large "intermediate-risk" group (105/137) where additional testing is warranted. The complimentary role of tests such as PET CT and image-guided needle biopsy in this "intermediate" group needs to be explored. Applying new CT diagnostic criteria to evaluate for persistent nodal metastases following definitive radiation +/- chemotherapy results in average clinical cost savings of up to $2600 per patient.

Comparison of PET/CECT with CECT or PET/CT Alone for Detection of Recurrent Laryngeal Cancer after Radiation Treatment

Lloyd Baugnon, K.·Chokshi, F. H.·Karagulle Kendi, A. T.·Viamonte, C. A.·Harrison, C. E.·Hudgins, P. A.
Emory University School of Medicine
Atlanta, GA.

Purpose
Positron emission tomography (PET) with computed tomography (PET/CT) has shown promise detecting recurrent laryngeal carcinoma, with improved sensitivity over contrast-enhanced CT (CECT) alone. Our hypothesis is that PET/CECT improves the diagnosis of recurrent or persistent laryngeal cancer, and reader confidence, particularly for less experienced readers.
Materials & Methods
Data warehouse query for patients undergoing PET/CECT for laryngeal cancer was performed with IRB approval. Inclusion criteria included: 1. PET/CT with CECT at our tertiary care facility. 2. History of laryngeal or hypopharyngeal malignancy, treated with radiation therapy, with or without chemotherapy. 3. Either > 6 months of clinical/imaging followup, or pathologic diagnosis to confirm positive or negative imaging study. Each combined PET/CECT yielded three separate studies: Contrast-enhanced CT of the neck, PET/CT, and PET/CECT. For each, the primary site and nodal disease were assessed on a 1-4 scale (1 = no disease, 4 = definite recurrent/residual tumor). The CECT was interpreted independently, blinded to PET results, by two neuroradiologists (NR), at different stages of training. The PET/CT was interpreted independently by two nuclear medicine (NM) physicians, blinded initially to CECT result, also at different levels of training. A final interpretation using both studies was made to determine if the impression was altered or reader confidence was improved. Score of 1 or 2 was considered a negative test, and 3 or 4 was considered a positive test. Sensitivity, specificity, PPV, NPV, and accuracy of each imaging modality, each reader, and the percent of cases with altered interpretations per reader were calculated.
Results
Twenty-five patients were included, ranging from T1 to T4b laryngeal or hypopharyngeal tumors. Imaging was performed at two to 240 months (median of 7 months) after completion of radiation therapy. Fifteen of 25 cases were positive for recurrence at the primary site, proven by biopsy in 13/15. Four of 25 patients had recurrent lymphadenopathy. When PET/CT was combined with CECT, the diagnostic accuracy for recurrent disease improved from 60% to 76% for NR reader 1 (with less experience), and from 76% to 84% for NR reader 2 (the more experienced reader). Staging for primary site and/or nodal disease on CECT changed 56% and 48% of the time with the PET information. When adding CECT information

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

to the PET/CT, the accuracy improved from 80 to 84% and 84 to 88% for the two NM readers. There was only one case when CECT prompted the NM physician to completely change the interpretation. Overall, combined CECT and PET/CT interpretation improved confidence in 82% of the cases in the NR group and in 70% of the cases in the NM group. False negative and false positive interpretations on the combined PET/CT interpretations were uncommon and were more common in the inexperienced readers.
Conclusion
Combined PET/CECT is the most accurate imaging modality to assess for recurrence of laryngeal or hypopharyngeal cancer in the post-treatment setting, particularly when compared to CECT alone in the hands of a less experienced radiologist.

Extra-Capsular Spread: Accuracy of Preoperative CT and MR Imaging Prediction of Extra-Capsular Spread in Oral Cavity Squamous Cell Carcinoma Lymph Node Metastases

Poliashenko, S. M.·Aiken, A.·Chen, A.·Baugnon, K.·Corey, A.·Hudgins, P.
Emory University School of Medicine
Atlanta, GA.

Purpose
Extra-capsular spread (ECS) is a poor prognostic indicator for patients with head and neck squamous cell carcinoma (SCC). The accepted gold standard for confirmation of ECS is pathology. However, the imaging diagnosis alone may be used to determine treatment in oropharyngeal SCC (OPSCC), as presence of pathologic ECS is an indication for postoperative chemoradiation rather than radiation alone. In addition, the imaging diagnosis of ECS is important in the consideration of primary surgical management for T1 or T2 OPSCC. Radiologic evidence of ECS may sway the decision from primary surgical therapy to primary concurrent chemoradiation. The impact of pretreatment ECS radiologic findings highlights the need to re-evaluate the accuracy of the imaging diagnosis of ECS as previous reports range from 62.5% - 80.9% sensitivity and 60% - 72.7% specificity. Imaging features such as nodal necrosis and large lymph node size have been reported to increase in chance of ECS. Nodal dissection is considered standard treatment for patients with oral cavity SCC, and therefore pathologic confirmation of ECS is available. This study aims to (1) evaluate the accuracy of computed tomographic (CT) and magnetic resonance (MR) imaging to diagnose ECS in oral cavity SCC as a proxy for OPSCC, and (2) to assess the correlation of radiographic lymph node necrosis and size with histopathologic ECS.
Materials & Methods
Our retrospective project had IRB approval. Inclusion criteria were: 1. CT or MR imaging at our tertiary referral Cancer Institute or adequate available outside imaging. 2. Neck dissection with pathology comment on ECS. 3. Re-review for ECS by 2 CAQ neuroradiologists if not documented in report. 4. Radiographic N0-N3 staged necks. An electronic search of the imaging data warehouse for ICD-9 codes for oral cavity cancer between 2007-2012, yielded 137 patients who met these inclusion criteria. Radiology reports were used to document lymph node size and necrosis. Two experienced head and neck radiologists blindly reviewed the cases for evidence of ECS based upon irregular borders, adjacent fat stranding and invasion of adjacent structures. The histopathology reports were reviewed as the gold standard for ECS.
Results
Radiographic evaluation of these 137 patients identified 18/137 thought to be positive for ECS. Pathologic analysis of the 137 patients showed 27 (19.7%) were positive for ECS and 110/137 (80.3%) were negative for ECS. The sensitivity and specificity of CT and MR imaging for ECS was 51.9% and 96.4% respectively. Radiologic nodal necrosis was present in 64% of cases with histopathologic positive ECS, and in only 7% of ECS negative cases with a strong association between the two(P=<.001). There was no significant association between lymph node size and ECS (P = .20).
Conclusion
Although CT and MR imaging specificity for predicting ECS is high, the sensitivity is low. If radiographic ECS is present, there is a high likelihood that ECS will be confirmed histopathologically. Lymph node necrosis is a predictive indicator of histopathologic ECS. CT and MR imaging for the determination of ECS preoperatively may lack the sensitivity for use in determining nonsurgical management decisions in OPSCC.

Volume CT Perfusion in Squamous Cell Carcinoma of the Head and Neck: Does Added Locoregional Lymph Node Perfusion Information Aid in Predicting Therapy Response?

Amrhein, T. J.[1]·Massari, F.[1]·Kolić, K.[2]·Canstein, C.[1]·Rumboldt, Z.[1]
[1]Medical University of South Carolina, Charleston, SC, [2]KBC Split, Split, CROATIA.

Purpose
To investigate the utility of volume CT perfusion (VCTP) in predicting the response of squamous cell carcinoma (SCC) of the head and neck to chemoradiation therapy.
Materials & Methods
CT perfusion (CTP) in SCC of the head and neck has been shown to have predictive value for response to chemoradiation therapy. However, traditional CTP methods have been limited in their craniocaudal coverage precluding evaluation of both the primary neoplasm and

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

nodal disease during the same acquisition. Volume CT perfusion provides a much larger area of perfusion coverage in the z-axis, which allows for assessment of both the primary lesion as well as locoregional nodal disease. In this prospective single institution study, 23 treatment-naïve patients with pathology proven SCC underwent VCTP of the neck on a 128-slice MDCT scanner using a continuous periodic table motion technique that provided 14 cm of craniocaudal coverage. Single separate regions of interest (ROI) were placed on the primary neoplasm as well as on areas of prominent locoregional nodal disease. Regions of interest were placed in areas of clear enhancement that were associated with solid tissue and did not contain a major vessel. The following perfusion parameters were calculated using a deconvolution algorithm: blood volume (BV), blood flow (BF), mean transit time (MTT), and capillary permeability (CP).
Results
Two patients had SCC of unknown primary precluding comparison between the primary lesion and nodal perfusion values. The remaining 21 patients had nine oral cavity, six oropharyngeal and three laryngeal cancers, with four primary lesions in other locations. The mean values for BF, BV, and CP were on average lower in lymph nodes than in primary lesions (73 versus 102.4, 10.9 versus 15, 29.6 versus 30.3, respectively). Blood flow, BV, and CP were highest in oral cavity cancers, both for the primary site and lymph nodes. Nine scans demonstrated perfusion values within locoregional lymph nodes that were similar to those found within the primary malignancy. The remaining 12 scans demonstrated lymph node perfusion values different from those of the primary neoplasm: nodal BF was more than 50% higher in four cases, while it was over 50% lower in eight patients, all of which had oropharyngeal or oral cavity neoplasms.
Conclusion
There are prominent differences in metastatic nodal CT perfusion values compared to the primary tumor in some patients. Continued patient followup over the duration of the study with attention to relationships between perfusion values and treatment responses will help to elucidate the potential prognostic role of VPCT in SCC of the head and neck. Concomitant nodal perfusion information may provide further insight into subtypes of disease and aid in future patient management and therapeutic decision making.

Pretreatment Perfusion-Weighted MR Imaging and Diffusion-Weighted MR Imaging in Local Failure Prediction in Oropharyngeal or Hypopharyngeal Squamous Cell Carcinoma Treated with Chemoradiotherapy

Ng, S. H.·Toh, C. H.·Wong, H. F.
Chang Gung Memorial Hospital
Taiwan, TAIWAN.

Purpose
To determine the utility of dynamic contrast-enhanced perfusion-weighted MRI (DCE PWI) and diffusion-weighted MRI (DWI) in predicting local failure of oropharyngeal or hypopharyngeal squamous cell carcinoma (OHSCC) treated with chemoradiotherapy.
Materials & Methods
Between July 2008 and December 2010, patients with newly diagnosed OHSCC scheduled for chemoradiotherapy with curative intent were eligible in this prospective study. Dynamic contrast-enhanced PWI was acquired using a 3D spoiled gradient-echo sequence while DWI was acquired using a modified Stejskal-Tanner diffusion gradient pulsing scheme. Regions of interest were drawn on the primary tumor by the experienced head and neck radiologist with the aid of the T2-weighted and T1-weighted postcontrast MR images. The visible necrosis regions were excluded for the evaluation. The relationship of local failure with clinical and imaging data, including age, hemoglobin level, T-stage, N-stage as well as tumor location, gross tumor volume (GTV), transfer constant (Ktrans), volume of blood plasma (Vp) and volume of extracellular extravascular space (Ve) of PWI, and apparent diffusion coefficient (ADC) of DWI of the primary tumor was analyzed using logistic regression analyses. The patients also were categorized into two groups: local control and local failure. Age, Ktrans, Ve, Vp, ADC, and GTV were compared between local control and local failure using the t-test. The T stage, N stage, and tumor location were analyzed for association with local failure using Fisher's exact test. Receiver operating characteristic (ROC) curve analysis was performed to determine the value that best predicted local failure.
Results
Seventy-eight OHSCC patients were enrolled, in whom 20 were excluded for the analysis because of small or unevaluable lesion, artifact on DWI/PWI images, or death before the definite diagnosis of treatment failure could be determined. Therefore, there were 58 patients (29 oropharynx, 29 hypopharynx; 4 women and 54 men, 48.5 ± 9.7 years of age) with successful pretreatment PWI and DWI available for analysis. With the median follow-up time of 18.2 months, 17 of the 58 patients had local failure while the other 41 patients achieved local control. In the univariate analysis, only pretreatment tumor Ktrans were significantly associated with local failure ($p = 0.03$). Similarly, only the pretreatment tumor Ktrans value of the local control group (0.68 minutes-1) was significantly

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

higher (P = .01) than that of the local failure group (0.45 minutes-1). The ROC analysis resulted in a threshold Ktrans value of 0.46 minutes-1 that attained 70.6% sensitivity and 82.9% specificity for the prediction of local failure.
Conclusion
Our results suggest that pretreatment tumor Ktrans of PWI could be a potential noninvasive indicator of local failure in OHSCC treated with chemoradiotherapy. Pretreatment Ve, Vp, ADC, and GTV measurements did not predict treatment response.

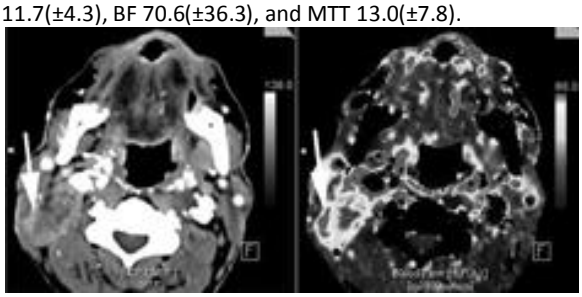
Feasibility of Volume CT Perfusion in Squamous Cell Carcinoma of the Head and Neck

Massari, F.[1]·Amrhein, T. J.[1]·Canstein, C.[1]·Vavro, H.[2]·Rumboldt, Z.[1]
[1]Medical University of South Carolina, Charleston, SC, [2]KB Dubrava, Zagreb, CROATIA.

Purpose
To investigate the feasibility of volume perfusion CT (VP CT) in the assessment of both primary and locoregional nodal disease in squamous cell carcinoma (SCC) of the head and neck.
Materials & Methods
Twenty-three treatment-naïve patients with proven SCC underwent VP CT. Images were acquired on a 128-slice multidetector CT with the following parameters: 80 kVp, 150 mAs, 54 seconds, scan delay of six seconds following intravenous administration of 40 mL of iohexol (350 mgI/mL) at 4mL/sec followed by a saline chaser of 50 mL at 4 mL/sec. A total of 35 scans were acquired per patient using a continuous periodic table motion technique providing z-axis coverage of 14 cm. Completed scans were reviewed for the inclusion of the primary lesion and locoregional nodal disease, and for the presence of artifacts. Perfusion maps were created using a deconvolution algorithm with placement of regions of interest (ROI) over the primary neoplasm as well as lymph nodes concerning for metastatic involvement. Region of interest placement was chosen in areas devoid of imaging findings of necrosis or blood vessels. Capillary permeability (CP), blood volume (BV), blood flow (BF), and mean transit time (MTT) perfusion parameters were recorded.
Results
All patients successfully completed the exam, without adverse events or substantial patient discomfort. Fourteen scans demonstrated streak artifact from dental amalgam. This was significant in one case precluding perfusion assessment of a known oral cavity primary lesion. Only one scan demonstrated considerable motion artifact despite automatic motion correction during postprocessing. Sixteen out of 22 scans had z-axis coverage extending from the paranasal sinuses to below the laryngeal cartilage. Of the six scans remaining scans, five terminated at the mid-aspect of the arytenoid cartilage and one at the level of the hyoid. Perfusion data from additional locoregional nodal disease was acquired in 22 of 22 scans. Mean values (±SD) obtained for the primary lesions were as follows: CP 30.0(±23.3), BV 14.9(±7.4), BF 102.4(±48.6), and MTT 10.4(±6.2). Mean values obtained for lymph nodes: CP 28.1(±11.6), BV 11.7(±4.3), BF 70.6(±36.3), and MTT 13.0(±7.8).



Conclusion
Volume perfusion CT in the head and neck is feasible and, due to the large volume of coverage, it is capable of providing perfusion information for both the primary lesion and locoregional nodal disease during a single acquisition.

Does Extrinsic Tongue Muscle Involvement Carry a Higher Risk of Local Failure Regardless of Size?: A Preliminary Report

Poliashenko, S.·Aiken, A.·Chen, A.·Baugnon, K.·Corey, A.·Hudgins, P.
Emory University School of Medicine
Atlanta, GA.

Purpose
The American Joint Committee on Cancer (AJCC) staging system for oral cavity (OC) squamous cell carcinoma (SCC) upstages a tumor, regardless of size, to T4a if there is cortical bone invasion or extrinsic tongue muscles (ETM). Extrinsic tongue muscle invasion was added to stage T4 classification of OC tumors in 1988, and is now included in T4a stage in the current 7th edition. Little has been published on the association of ETM invasion with surgical outcomes and prognosis. Our aim was to evaluate the significance of T4a stage due to either cortical bone or ETM invasion, and ETM invasion alone as factors on prognosis.
Materials & Methods
Our project had Institutional Review Board approval. Inclusion criteria for this project were: 1. T4a OC SCC. 2. Computed tomographic (CT) or magnetic resonance (MR) imaging interpretation at our tertiary referral Cancer Institute or available outside imaging. 3. Surgical resection

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

at our institution. 4. Minimum of six months of clinical or radiographic followup (for recurrence analysis). An electronic search of our imaging data warehouse for ICD-9 codes for OC SCC between 2007 and 2012 yielded 59 T4a patients who met the above inclusion criteria. Fifty T1-T3 tumors from the same database were used as size-matched controls. Two CAQ neuroradiologists blindly reviewed the images for T stage, presence of ETM and cortical bone invasion. Status of surgical margins and local recurrences were noted from radiology, clinical, and pathology reports for the duration of the patients' followup.

Results

Eighty-eight percent (52/59) T4a patients versus 92% (46/50) T1-T3 control patients had negative surgical margins. Thirty-nine of 52 T4a patients and 34/46 controls had six months or greater follow-up time**.** Sixteen of 39 T4a patients were positive for ETM invasion alone, Nineteen of 39 were positive for cortical bone invasion alone and 4/37 were positive for both. Fifty-three percent of T1-3 and 82% of T4a patients were treated with adjuvant radiation therapy. Overall, 11/39 (28.2%) of T4a patients versus 5/34 (14.7%) of T1-3 patients had local recurrence (P =.164). T4a patients did not have a significantly different local recurrence rate as compared to size-matched controls at 0-2 cm (2/6 versus 0/7), 2-4 cm (6/21 versus 5/19), and 4 cm or greater (3/12 versus 0/8), (P=.192)(P=.873)(P=.242). Overall, 5/16 (31.3%) of T4a patients with ETM invasion alone versus 5/34 (14.7%) of T1-3 controls had local recurrence (P=.256). Extrinsic tongue muscle invasion alone did not have a significantly different local recurrence rate as compared to size-matched controls at 0-2 cm (0/2 versus 0/7), 2-4 cm (4/8 versus 5/19), and 4 cm or greater (1/6 versus 0/8), (P=.99)(P=.375)(P=.429).

Conclusion

This preliminary study suggests that T4a cases have similar successful resection rates with negative margins compared to control T1-3 patients. Overall, patients staged with T4a based on the presence of ETM involvement alone had a higher rate of local recurrence than controls; however this difference was not statistically significant. Further investigation with a larger sample size would be needed to confirm this trend.

Apparent Diffusion Coefficient Histogram Analysis of Salivary Gland Tumors

Saito, N.[1]·Nakahira, M.[1]·Obara, M.[2]·Chang, Y.[3]·Uchino, A.[1]·Kimura, F.[1]·Sakai, O.[3]

[1]Saitama International Medical Center, Saitama, JAPAN, [2]Philips Electronics Japan, Tokyo, JAPAN, [3]Boston Medical Center, Boston University School of Medicine, Boston, MA.

Purpose

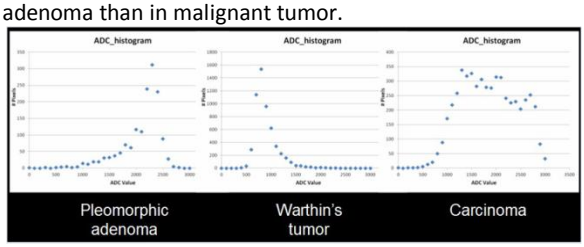
Histogram parameters such as skewness and kurtosis represent nongausian measures of differences in tissue heterogeneity. In evaluating pathologic types of salivary gland tumors, mean apparent diffusion coefficient (ADC) value has been used most commonly. However ADC histogram analysis could provide a better assessment of tumors by quantifying tissue heterogeneity characteristics caused by cyst, hemorrhage, and necrosis. The purpose of this study is to assess whether ADC histogram analysis can help identify pathologic types and differentiate between benign and malignant tumors in salivary gland.

Materials & Methods

Clinical history and imaging data of 27 patients with 28 salivary gland tumors (15 females, 12 males: 11 pleomorphic adenomas, 11 Warthin's tumors, 6 primary malignant salivary gland tumors) who underwent MR imaging prior to biopsy or surgical resection between April 2011 and November 2012 were evaluated retrospectively. MR imaging including diffusion-weighted imaging performed using a 3T MR scanner. The regions of interest were drawn manually along the entire tumor on each slice to generate ADC histogram. Peak ADC value, skewness, and kurtosis were extracted from the histograms. The differences in the parameters among tumor types were evaluated by Kruskal-Wallis test.

Results

Apparent diffusion coefficient histograms of the representative cases are demonstrated in the Figure. Significant differences were noted among three lesion types (pleomorphic adenoma, Warthin's tumor, and malignancy) in terms of skewness (p = 0.02) and peak ADC value (p = 0.01). There were no significant differences among the lesion types in kurtosis; however they tended to be higher in Warthin's tumor and pleomorphic adenoma than in malignant tumor.



Conclusion

Pleomorphic adenoma, Warthin's tumor, and primary malignant salivary gland neoplasms could be differentiated

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

based on skewness and peak ADC values. Apparent diffusion coefficient histogram analysis may be useful in determining lesion pathologic types in patients with salivary gland tumors.

Palliative Cryoablation of Metastatic Tumors Involving the Face

Morris, J. M.·Callstrom, M. R.
Mayo Clinic
Rochester, MN.

Purpose
To demonstrate the feasibility and technique of treating metastatic lesions to the face with percutaneous CT-guided cryoablation. Additionally to share techniques we have learned in avoiding critical structures such as nerves, uninvolved mucosa, and skin.
Materials & Methods
Palliative CT-guided cryoablation of metastatic lesions involving the face were reviewed retrospectively. The lesions were treated with 2-5 Endocare cryoprobes using a standard freeze, passive thaw, and freeze cycle. Patients then were evaluated for palliative relief of symptoms. Specifically we reviewed clinical outcomes, equipment used, techniques to avoid critical structures, and hospital stay length.
Results
Two patients underwent cryoablation of the face both for local control of tumor burden and palliative relief of symptoms. Patient one is a 77-year-old female with metastatic lung adenocarcinoma with direct extension into the liver and a lesion in the left buccal space refractive to radiation and chemotherapy. She developed sever pain and trismus and could not open her mouth to eat. Cryoablation of the lesion was performed under general anesthesia and CT guidance using 2 perc 15 Endocare cryoprobes. A small catheter was placed beneath the dermis and warm saline instilled to displace the overlying skin preventing frostbite injury. Patient had no complications, near immediate improvement in her pain and trismus and was discharged home on postprocedure day three. She was able to continue oral intake while undergoing the remaining chemotherapy treatments. Patient two is a 42-year-old female diagnosed with metastatic clear cell renal cell cancer. While undergoing radiation treatment to the brain, hip, and shoulder she developed a rapidly enlarging lesion involving the right mandible growing into the oral cavity with perineural tumor spread along the inferior alveolar nerve. Patient wished to undergo treatment but was not a surgical candidate. Cryoablation of the lesion was performed under general anesthesia and CT guidance using 5 perc 24 Endocare cryoprobes. A bite block and gauze were used to displace the uninvolved maxilla and spare all gingival surfaces not involved. Postprocedurally patient had complete paresthesia in the distribution of the inferior alveolar nerve but was able to open her mouth with decreased pain and decreased trismus allowing oral nutrition. She was discharged from the hospital on postprocedure day.
Conclusion
Cryoablation is used at our institution as part of a multidisciplinary approach in patients with metastatic and primary cancer in various organ systems for both local control and palliative treatment. We present two patients treated by our service to demonstrate the feasibility and techniques used in percutaneous CT-guided cryoablation of the jaw and of the masticator/buccal space. These cases demonstrate the ability of cryoablation to palliatively treat metastatic facial lesions safely. In both cases oral nutritional requirements while on chemotherapy were of concern and surgical options were not feasible. The primary goal was local tumor control but secondary goals of reducing trismus, reducing pain, and increasing ability to eat were of vital importance in these patients. Future studies will be required to determine the potential of cryoablation in the head and neck.

Metabolic Reserve and Stroke Risk in Patients with Carotid Stenosis or Occlusion: A Systematic Review and Meta-Analysis of the Predictive Role of Increased Brain Oxygen Extraction Fraction – Dyke Award Winner

Baradaran, H.·Gupta, A.·Schweitzer, A. D.·Hurtado Rua, S. M.·Delgado, D.·Wright, D.·Sanelli, P. C.
Weill Cornell Medical College
New York, NY.

Purpose
Impaired metabolic reserve defined by increased oxygen extraction fraction (OEF) on positron emission tomography (PET) is considered a risk factor for stroke in patients with internal carotid artery (ICA) steno-occlusive disease. However, the predictive ability of OEF has been questioned since the early termination of the Carotid

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

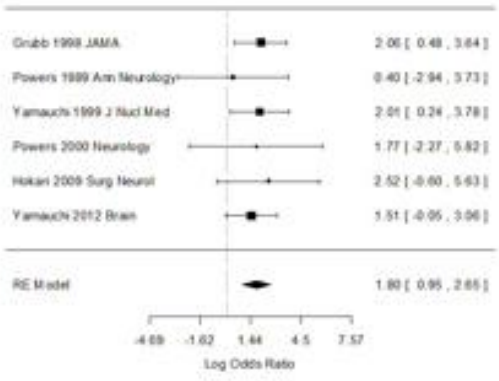
Occlusion Surgery Study (COSS) which used abnormal OEF hemispheric ratios as a key inclusion criterion. We need to re-evaluate OEF's association with stroke outcomes and solidify our understanding of PET-based OEF testing as a possible metric by which newer MRI measures of oxygen metabolism may be compared. To accomplish this, we performed a systematic review and meta-analysis to summarize the association between increased OEF and stroke risk in patients with ICA steno-occlusive disease.

Materials & Methods

We performed a comprehensive literature search evaluating the association of increased OEF to future stroke in patients with high-grade ICA stenosis or occlusion. We included studies with baseline PET-based OEF testing measures and at least one-year followup with ipsilateral stroke as the primary outcome. We performed subset analyses based on OEF testing method (absolute versus hemispheric ratio), disease site (ICA versus ICA plus middle cerebral artery), and presence of symptoms (all symptomatic versus all asymptomatic). A meta-analysis with assessment of study heterogeneity and publication bias was performed. Results were presented in a forest plot and summarized using a random-effects model.

Results

Seven studies with 430 patients met the inclusion criteria for systematic review after screening 2,158 studies. Six of seven studies with a total of 331 unique patients with mean followup of 31.1 months were amenable to meta-analysis. We found a significant positive relationship between abnormal OEF and future ipsilateral stroke with a pooled random effects odds ratio (OR) of 6.04 (95% CI, 2.58-14.12) (Figure, OR on logarithmic scale). There was no statistically significant difference in the OR in the subset analyses divided by testing method, disease site, and presence of symptoms. Measures of heterogeneity showed mild heterogeneity between studies (I-squared statistic=0, 95% CI, 0 to 38.34) and no statistically significant publication bias (Begg-Mazumdar, p-value=1.00).



Conclusion

Abnormal OEF remains a powerful predictor of stroke in carotid stenosis or occlusion. These results indicate there is insufficient evidence that the failure of the COSS trial is due to a failure of OEF methodology. Furthermore, our results suggest that PET-based OEF testing is a valuable gold standard by which studies of MRI surrogates of oxygen metabolism can be compared.

Carotid Intraplaque Hemorrhage: Increased Stroke Risk in Stenotic and Ulcerated Plaque

McNally, J. S.·Kim, S.·Roberts, J.·Parker, D.·Treiman, G. S.
University of Utah
Salt Lake City, UT.

Purpose

Carotid atherosclerosis accounts for 20-30% of the >690,000 strokes occurring annually in the United States, according to the American Heart Association 2012 update. Stroke risk stratification based primarily on carotid stenosis and plaque morphology results in many unnecessary surgeries on asymptomatic patients each year. Lumen evaluation does not detect unstable plaque components such as carotid intraplaque hemorrhage (IPH), which may account for the disconnect between carotid stroke risk estimates and treatment recommendations. The purpose of this study was to determine if carotid IPH modifies stroke risk with traditional markers of plaque vulnerability.

Materials & Methods

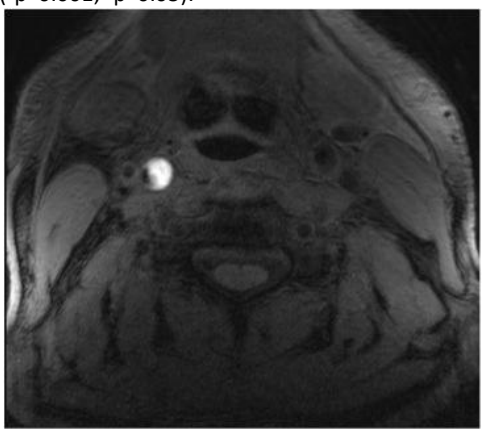
Over two years, 159 patients with suspected acute stroke were imaged with MR brain and MRA neck. Carotid MRA was used to measure traditional markers of vulnerable plaque including stenosis, ulceration and intraluminal thrombus. As shown in the figure, IPH was detected with the magnetization prepared rapid acquisition gradient-recalled echo (MPRAGE) sequence. Nonlacunar ipsilateral ischemic strokes were detected with brain diffusion tensor imaging (DTI). This provided 318 carotid artery and ipsilateral brain images for analysis. Forty-eight arteries were excluded due to extracarotid sources of brain ischemia and four were excluded due to carotid occlusion. Two hundred sixty-six arteries were eligible for data analysis.

Results

Carotid IPH was associated with acute territorial ischemic events [relative risk(RR)=6.4*, 95% confidence interval (CI)=4.3-8.7]. This was similar to the risk associated with >70% stenosis (RR=4.4*, CI=2.8-5.9), ulceration (RR=3.8*, CI=2.4-5.6), and intraluminal thrombus (RR=5.7*, CI=3.6-5.7). Carotid IPH was associated with ulceration (RR=7.2*, 4.5-13.8) and >70% stenosis (6.0*, CI=2.6-13.8). There was a trend toward association with intraluminal thrombus, but this did not reach significance (RR=2.7, CI=0.9-5.6, p=0.056). In addition, the presence of IPH further modified the risk of stroke in >70% stenosis (RR=2.2$^{\#}$, CI=1.1-2.2) and ulceration (RR=2.3$^{\#}$, CI=1.1-6.1). Interestingly, IPH did not modify the stroke risk in the setting of intraluminal

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

thrombus (RR=1.0), since all patients with intraluminal thrombus had acute ischemic events (PPV=100%). (*p<0.001, $^{\#}$p<0.05).



Conclusion

In this retrospective study, carotid IPH was found to be an independent risk factor for ischemic stroke. This risk was on par with historic markers of plaque vulnerability including high-grade stenosis, ulceration, and intraluminal thrombus. Importantly, IPH modified stroke risk in the presence of >70% stenosis and ulceration. These results strongly argue against using plaque stenosis and morphology as sole determinates of stroke risk. By detecting IPH and refining stroke risk, carotid MRI will play an important role optimizing treatment and eliminating unneeded operations.

Can CT Angiography Plaque Segmentation Predict *Recurrent* Events in Patients Presenting Initially with Stroke and TIA?: Evaluation in Moderate 50-70% Stenosis

Lum, C.·Perry, J.·Duan, S.·Sharma, M.·Ottawa Hospital Research Institute
University of Ottawa
Ottawa, ON, CANADA.

Purpose

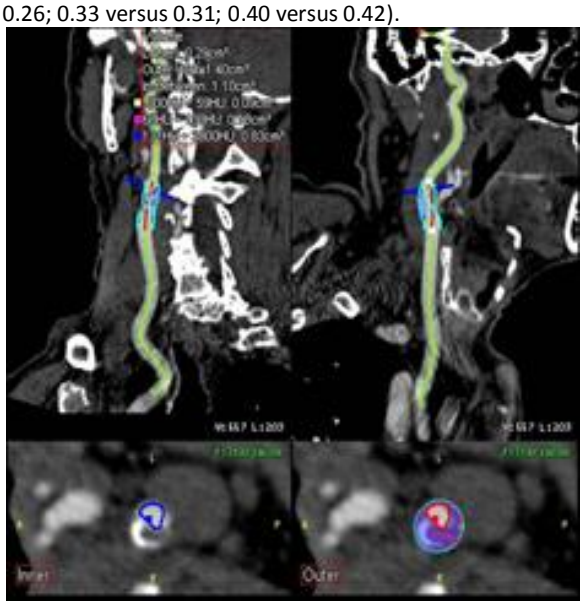
CT angiography plaque segmentation techniques now are readily available via thin-client software and recently have been used to categorize carotid plaque volumetrically into lipid, fibrous and calcific components. Lipid-rich plaques are considered more vulnerable than calcified plaques and may be a target for revascularization techniques. In our centre, CTA is the preferred vascular imaging technique in acute stroke or TIA. Plaque component analysis has not been performed in patients presenting initially with TIA or stroke and moderate 50-70% stenosis. Plaque volume has been suggested to be a better predictor than stenosis measurements. Our objective was to determine if individual plaque components or plaque volumes in symptomatic patients with moderate stenosis can predict future recurrent ischemic events.

Materials & Methods

Between Nov 2006-Aug 2011, 2612 consecutive patients with TIA or minor stroke assessed in the emergency department at two large tertiary care hospitals were evaluated in a specialized stroke clinic. These patients were enrolled prospectively and assessed for subsequent TIA or stroke at 90 days by a blinded adjudication committee. All patients received a screening Doppler and a CTA was performed on those with stenosis. Patients with moderate stenosis on CTA were included in the current analysis. We segmented the carotid plaque in a semi-automated fashion (Terarecon) by a radiologist blinded to clinical outcome. The volume and percentage composition of plaques were calculated using the following HU thresholds: lipid<60, fibrous≤130, calcium>130.

Results

There were 102 patients with moderate stenosis: 28 patients had recurrent TIA/stroke versus 74 without. Mean plaque volume was greater in patients with recurrent stroke versus those without (1.66 versus 1.03 cm^3; p = 0.0007). Recurrent strokes had larger plaque volumes than recurrent TIAs (1.66 versus 1.06 cm^3; p = 0.0055). Receiver operating charcteristic analysis using an optimal threshold plaque volume of 1.1 cm^3 had a sensitivity = 87.5%, specificity = 66.3%, AUC = 0.78(p = 0.0004) for distinguishing recurrent strokes at followup from asymptomatics. There was no significant difference in proportion of lipid, fibrous and calcium in patients with versus those without recurrent symptoms (0.28 versus 0.26; 0.33 versus 0.31; 0.40 versus 0.42).



Conclusion

Patients presenting with TIA/stroke and moderate stenosis do not have a CTA plaque composition signature that predicts risk of future events. However, plaque volume is larger in patients who develop recurrent stroke. A

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

threshold of > 1.1 cm^3 may be helpful for predicting recurrent stroke in a prospective study.

KEYWORDS: CT angiogram, Plaque imaging, recurrent stroke or TIA

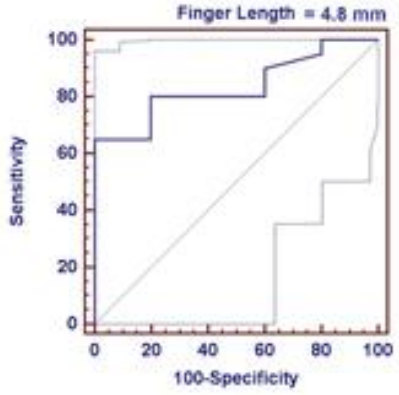
How to Manage Proximal Internal Carotid Artery Thrombus Identified on CT Angiography and MR Angiography in the Workup of Acute Stroke or Transient Ischemic Attack

Lum, C.·Jaberi, A.·Thornhill, R.·Stefanski, P.·Petrcich, W.·Momoli, F.·Iancu, D.·Dowlatshahi, D.·Ottawa Stroke Research Group
University of Ottawa/Ottawa Hospital Research Institute
Ottawa, ON, CANADA.

Purpose
Luminal filling defects at the ICA origin imaged in the workup of stroke/TIA may be due to an ulcerated plaque or rarely, free-floating thrombus (FFT). Accurate identification of FFT is critical because of the potential for distal embolization. There is a paucity of CTA/MRA imaging literature on FFT and its evolution, mostly described in single case reports. Controversy exists regarding its acute management: urgent endarterectomy versus medication. At our institution, we treat suspected FFT with antiplatelets or anticoagulation and perform imaging to evaluate its evolution. We have collected a large series of patients with suspected FFT. The purpose of our study was to describe the imaging appearance at presentation, evolution with therapy, clinical variables and mimics of FFT.
Materials & Methods
Twenty-five consecutive patients with suspected FFT, defined as proximal ICA filling defects in the axial plane surrounded by contrast, were identified at the ICA origin on CTA and MRA. Cases were collected prospectively between Feb 2008-May 2012 at an academic stroke center. Patient demographics, imaging features and clinical data were analyzed using univariate statistics. Free-floating thrombus was measured in the cranial-caudal dimension(finger length) by a vascular neuroradiologist blinded to clinical outcome. Filling defects resolving on follow-up imaging were defined as true+ FFT. Recursive partitioning analysis was performed to identify potential predictors for FFT. ROC analysis was performed to determine a threshold measurement for FFT.
Results
There were 24 cases imaged with CTA, one with MRA. Median follow-up CTA was at five days. Patients were managed medically with antiplatelets(28%), full anticoagulation(48%) or both(24%). In 20 patients(80%), the suspected FFT resolved or significantly improved; in five(20%) there was no change. There was no clinical deterioration on medical therapy. True+ FFT filling defects extended more cranially than false+ cases[7.25 mm(4.47-17.00 IQR) versus 4.30 mm(2.10-4.42 IQR), p=0.023]. Ipsilateral underlying stenosis was seen in 60%, the majority(83%) of stenoses measuring <50%. Using recursive partitioning, we found the presence of filling defects had a sensitivity of 85%, but low specificity=24%. ROC analysis using a threshold of 4.8 mm(finger length) improved performance with a sensitivity of 65%, specificity of 100% and AUC of 0.84(p<0.0001) for distinguishing FFT+ from FFT-(underlying plaque) cases.



Conclusion
Suspected FFT on CTA resolves with antiplatelet and/or anticoagulant therapy without associated morbidity. A filling defect in the proximal ICA that extends cranially for >4.8mm is more likely to be FFT rather than ulcerated plaque. A prospective trial evaluating this threshold is warranted.

Association between Cervical Spine or Skull Base Fracture and Blunt Cerebrovascular Injury

Buch, K.·Nguyen, T.·Mahoney, E.·Libby, B.·Calner, P.·Burke, P.·Mian, A.
Boston Medical Center
Boston, MA.

Purpose
Blunt cerebrovascular injuries (BCVI) are associated with high morbidity and mortality and can lead to neurologic deficits. Prompt diagnosis and treatment of BCVI can limit the associated morbidity and mortality. While digital subtraction angiography has been the gold standard for diagnosing these injuries, computed tomographic angiography (CTA) is employed increasingly for evaluation in blunt trauma patients. The established criteria for recommending patients receiving CTA for evaluation of possible injury are broad, potentially exposing patients to unneeded radiation. The goal of this study was to examine the prevalence of vascular injury in patients with blunt trauma on CTA examination and to determine which

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

presentations have the highest rates of vascular injury.
Materials & Methods
From 2007-2010, we instituted prospectively a protocol to screen trauma patients for blunt cerebrovascular injury following a predefined set of criteria at a Level I Trauma University Hospital. CT angiography studies were helically acquired at 1.25 mm slice thickness on 64 detector row CT scanners. The corresponding electronic medical records were reviewed on all subjects, including the initial patient presentation and hospital course. Statistical analysis of imaging and clinical data were performed using a Fisher test. The study was approved by the IRB.
Results
Four hundred thirty-nine patients were reviewed retrospectively for the presence of vascular injury. A positive CTA was defined as presence of vasospasm (n = 10) and dissection (n = 38) and found in 48/439 (10.9%) patients. Cervical spine or skull base fractures were present in 40/48 (83.3%) positive CTAs compared to 267/391 (68.2%) negative CTAs (p = 0.02). Three patients had a dissection in more than one artery. Thirty-eight of 48 patients (79.2%) had a diagnosis of dissection and 10/48 patients (20.8%) had a diagnosis of vasospasm. Thirty-two of 38 (84.2%) patients had both dissection and fractures compared to 6/38 patients (15.8%) with dissection without fracture. There was a significant correlation between dissection and fracture (p = 0.0016). Twenty-two of 439 patients (5%) presented with neurologic deficits attributed to cerebral contusion (10 patients), cerebral injury (six patients), cervical spine hematomas (two patients), and cervical spine cord injury (one patient). In three patients there was no obvious cerebrospinal injury to account for neurologic deficit. Thirteen of 22 patients (59%) with neurologic deficits had fractures. All 13 of these patients with neurologic deficits and fractures had positive CTAs. There was a significant correlation between neurologic deficits and positive CTA (p = 0.0001). No statistically significant correlation between neurologic deficits and underlying fractures (p = 0.66).
Conclusion
The presence of a blunt cerebrovascular injury is correlated with the presence of a cervical and/or skullbase fracture. There is also a correlation between blunt trauma with neurologic deficits and underlying vascular injuries with or without fractures. Patients with blunt trauma presenting with cervical spine and skull base fractures or focal neurologic deficits should have rapid CTA evaluation for suspected underlying vascular injury.

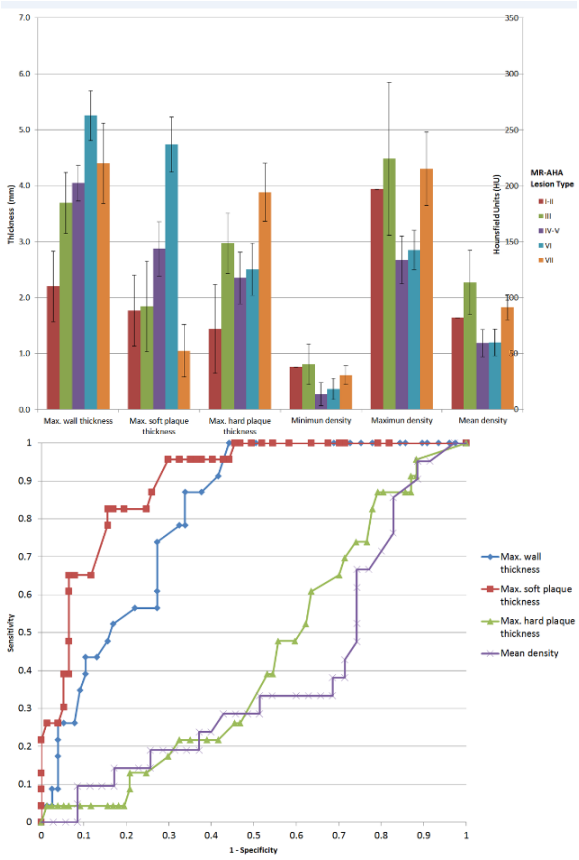
CT Angiography for Screening of Complicated Atherosclerotic Carotid Plaque: American Heart Association Type VI Lesions as Defined by MR Imaging

Trelles, M.[1]·Buchholz, M.[2]·Schindler, A.[2]·Bayer-Karpinska, A.[2]·Dichgans, M.[2]·Reiser, M. F.[2]·Nikolaou, K.[2]·Saam, T.[2]
[1]University of Texas Medical Branch at Galveston, Galveston, TX, [2]Ludwig-Maximilians-University Hospital, Munich, GERMANY.

Purpose
High-resolution carotid MRI can accurately identify complicated American Heart Association lesion type VI (AHA-LT6) plaques, which are characterized by thrombus, hemorrhage or a ruptured fibrous cap. The purpose of this study is to evaluate whether CTA can be used as screening tool to predict the presence or absence of AHA-LT6 as defined by high-resolution MRI.
Materials & Methods
Fifty-one patients with suspected ischemic stroke or TIA with carotid CTA and high-resolution carotid MRI performed within 14 days of the event or admission from April 2008 to December 2010 were reviewed. Vessels with stents or occlusion were excluded (n=2). Each carotid artery was classified according to the MRI-based AHA lesion type classification. The maximum wall thickness, maximum soft plaque component thickness, maximum calcified component thickness and plaque density (if thickness of the soft plaque component >2 mm) was obtained from the CTA.
Results
Twenty-three out of 100 vessels had a complicated AHA-LT6 plaque by MRI representing presence of intraplaque hemorrhage, thrombus and/or a ruptured fibrous cap. The average maximum wall thickness and the maximum thickness of the soft plaque component of complicated plaques was significantly higher compared to noncomplicated plaques (5.3±0.4 versus 3.9±0.3 mm; P<0.001 and 4.7±0.5 versus 2.2±0.3 mm, P<0.001, respectively). The mean soft plaque component density did not differ significantly between complicated and noncomplicated plaques (60±12 HU versus 72±12 HU; P=0.12). The maximum soft plaque component thickness proved the best discriminating factor to predict a complicated plaque by MRI with a relative operating characteristics area under the curve (ROC-AUC) of 0.897 ± 0.063. Maximum wall thickness performed less adequately with ROC-AUC of 0.81 ± 0.084. Hard plaque component thickness and HU measurements did not prove to be of diagnostic help. Utilization of maximum, minimum and average HU value made no difference in the discriminatory power. The optimal sensitivity and specificity for detection of complicated plaque by MRI was achieved with a soft plaque component thickness threshold of 4.4mm (sensitivity:0.65, specificity:0.94, PPV:0.75 and NPP:0.9). No complicated plaque had a soft tissue plaque thickness lower than 2.2 mm (NPV:1) and no simple

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

(noncomplicated) plaque had a thickness greater than 5.6 mm (PPV:1).



Conclusion

This study demonstrates that CTA can be used as a screening tool to predict the presence/absence of complicated AHA-LT6. Maximum soft plaque component thickness has the best discriminatory power with a threshold of 2.2 mm representing little to no probability of a complicated AHA-LT6 plaque.

Stenosis Asymmetry Index between Symptomatic and Asymptomatic Patients in the Analysis of Carotid Arteries with Severe Stenosis

Saba, L.[1]·Montisci, R.[1]·Raz, E.[2]·Porcu, M.[1]·Fatterpekar, G.[2]·Piga, M.[1]
[1]AOU Cagliari, Cagliari, ITALY, [2]University of New York, New York, NY.

Purpose

Extracranial carotid artery stenosis is accepted as a significant risk factor for cerebrovascular events. The purpose of this work was to compare the stenosis asymmetry index (SAI) in symptomatic and asymptomatic patients with a severe stenosis of carotid arteries.

Materials & Methods

Eighty-five consecutive symptomatic patients (males 52; median age 67 years) and 85 consecutive nonsymptomatic patients matched for gender and age, were analyzed by using a 40 detector-row CT angiography. Stenosis degree of 340 carotids was calculated according to NASCET method. Only patients with at least one carotid stenosis > 70% NASCET were included. For each patient, the ratio between the most severe stenosis and the contralateral was calculated to obtain the SAI. Wilcoxon test was applied to evaluate difference between asymmetry index in symptomatic and asymptomatic group. Receiver operating characteristic (ROC) curve also was calculated.

Results

Fourteen patients were excluded because of a stenosis < 70% NASCET. Results of our study indicate a mean SAI of 1.44 (95% CI 1.34 -1.53) in asymptomatic group and a mean SAI of 1.88 (95% CI 1.72 - 1.92) in the symptomatic group with a statistically significant difference (p value = 0.0018). The ROC curve analysis indicated that an SAI value of 1.8 has a specificity of 87% for the presence of cerebral symptoms whereas to have a sensitivity of 90% we should use a 1.5 SAI.

Conclusion

Our results indicate that the SAI can be used as further parameter to stratify the stroke risk related to carotid artery in those patients with a NASCET stenosis > 70%.

Is There an Association between Carotid Artery Dissection and Vessel Tortuosity?

Saba, L.[1]·Raz, E.[2]·Argiolas, G. M.[3]·Fatterpekar, G.[2]·Suri, J. S.[4]·Siotto, P.[3]·Piga, M.[1]
[1]AOU Cagliari, Cagliari, ITALY, [2]University of New York, New York, NY, [3]Ospdale Brotzu, Cagliari, ITALY, [4]Biomedical Technologies, Pocatello, ID.

Purpose

Carotid artery dissection is an important cause of ischemic stroke in all age groups, in particular young subjects. The purpose of this work was to assess whether there is an association between the presence of carotid artery dissection (CAD) and vessel tortuosity.

Materials & Methods

In this multicentric analysis, one hundred three patients (males 62; median age 58 years) with CT/MR diagnosis of CAD of internal carotid artery were analyzed retrospectively. The vessel tortuosity was evaluated and when present was categorized as tortuous, kinking, coiling. For each patient both right and left side were considered for a total number of 206 in order to have a similar number of case control. Fisher's exact test was applied to test the association between tortuosity, kinking, coiling, dissection and the side affected by CAD.

Results

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

No patients were excluded and Fisher's test showed that there was a statistically significant association between the CAD and kinking (p = 0.009) and coiling (p = 0.046) whereas no statistically significant difference was found with the vessel tortuosity (p = 0.304). We found that the side (left or right) plays a statistically significant role in the risk of CAD (p = 0.0001).
Conclusion
The presence of kinking and coiling are statistically significantly associated with an increased risk to CAD. The underlying causes that determine the increased risk of CAD may therefore be genetic predisposition or geometrical ones. The CADs show a statistically significant association with the left side.

Localized Gray Matter Changes in Acute Stroke

Gupta, J.·Young, B.·La, C.·Reiter, P.·Jensen, M.·Chacon, M.·Sattin, J.·Nair, V. A.·Prabhakaran, V.
University of Wisconsin
Madison, WI.

Purpose
Global gray matter volume decreases linearly with age.There is evidence that changes in subcortical gray matter volume is associated with cognitive impairment after ischemic stroke (3-6 months). We investigated 1) gray matter differences between acute noncortical stroke patients, patients with risk factors for stroke, and healthy controls and 2) gray matter changes associated with behavioral performance after a stroke.
Materials & Methods
Patients with acute stroke (N = 11, noncortical ischemic stroke within seven days of stroke onset, mean age 58 years, six M), patients with risk factors for stroke (N = 5, mean age 69 years, three M) and age-matched healthy controls (N = 17, mean age = 56 years, 10 M) were scanned on a GE 3T MRI scanner. High-resolution 3D T1-weighted whole brain BRAVO FSPGR images were collected with: repetition time TR = 8.13 ms, echo time TE = 3.18 ms, flip angle = 12,156 slices, voxel resolution 1 mm isotropic. The subjects also performed a letter fluency task (word generation-FAS task) which was collected outside the scanner and corrected for age and education. Gray matter changes were assessed using VBM8 toolbox and SPM8 in Matlab. Further groupwise gray matter volume changes and cortical thickness in areas of interest also were analyzed using Freesurfer in a subset of five noncortical stroke (average age 56 years, three M) and 13 healthy controls (average age 56 years, seven M).
Results
There was a significant group difference between acute noncortical stroke patients and healthy controls on the verbal task (p<.05) with patients scoring less (mean score = 35) than healthy controls (mean score = 49). Two sample t tests indicated significant group differences between strokes and controls in gray matter volume in regions of bilateral inferior temporal, bilateral middle temporal, right post central, and right lingual gyrus (p<.001 (uncorrected), extent threshold 20 voxels). Analysis with verbal fluency score as covariate identified differences in the left inferior temporal and left middle temporal regions (p<.001 (unc), extent threshold 20 voxels).There were no significant differences between healthy controls and patients with risk factors for stroke. In a subset of patients, Freesurfer analysis of cortical thickness and volume showed a significant difference in left inferior temporal cortical thickness at p<.007 (unc) and Lt transverse temporal volume at p<.02 (unc).
Conclusion
There are localized cortical gray matter changes notably in the temporal lobe in acute periods of noncortical stroke patients showing significant association with verbal fluency deficits in these patients. This suggests that acute noncortical stroke may induce cortical regional changes in gray matter volume. This could be attributed to remote effects of stroke as well as chronic changes due to risk factors for stroke. Further studies will test this and compare stroke patients with patients with risk factors for stroke.

Penumbra Imaging in Patients with Acute Stroke Using Susceptibility-Weighted MR Imaging

Radbruch, A.[1]·Mucke, J.[1]·Graf, M.[2]·Floca, R.[2]·Schlemmer, H.[2]·Heiland, S.[1]·Bendszus, M.[1]·Rohde, S.[1]
[1]University of Heidelberg, Heidelberg, GERMANY, [2]German Cancer Research Center (DKFZ), Heidelberg, GERMANY.

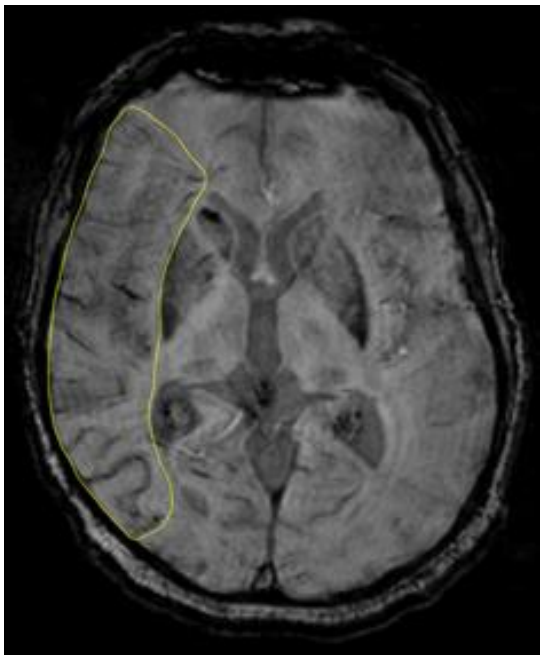
Purpose
Although increasingly used for the clinical management of patients with acute ischemic stroke the mismatch concept, based on MR perfusion and diffusion imaging, has come under debate, since it is reported that time to peak (TTP) maps, generated from PWI, tend to overestimate the tissue at risk. Susceptibility-weighted imaging (SWI) has been reported to enable the identification of the tissue at risk in patients with acute ischemic stroke due to the visualization of hypointense vessels within the hypoxic area. The aim of this study was to assess size of the penumbra determined by either SWI or TTP perfusion maps and calculate their intersection.
Materials & Methods
Seventy patients with ischemic infarction proved by clinical symptoms (NIHSS>2) and a reduced perfusion on the TTP perfusion map determined by dynamic susceptibility contrast perfusion images (TE 35, TR 1920, FoV 240, 75 dynamic scans, injection of 0.1 mmol/kg DOTAREM with bolus technique after the third frame followed by 20 ml of NaCl solution) were included. Alterations of SWI were

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

defined as a conglomeration of vessels presenting a higher diameter than vessels on the contralateral, nonischemic hemisphere (Figure). Regions of altered SWI, restricted diffusion on diffusion-weighted images (DWI) and reduced perfusion on PWI were delineated manually on SWI, apparent diffusion coefficient (ADC) DWI and TTP maps. Subsequently, the maps were coregistered automatically and intersections of the determined regions were calculated and visualized using in-house developed software.

Results

In all patients the area of SWI alterations could be delineated. Mean size of the delineated SWI region (2994.8 mm^2±1097.3) was significantly smaller than size of the delineated TTP maps (3626.6 mm^2±1315.5) ($p>0.0001$) but significantly larger than areas on ADC diffusion maps (1396.6 mm^2±1102.0) ($p>0.0001$). Median intersection of TTP and SWI was 73.6%±28.6% of the delineated TTP area, SWI and ADC intersected on 34.0%±32.1% of the size of SWI area.



Conclusion

Since the identified region on SWI was significantly smaller than on the TTP map, that supposedly overestimates the tissue at risk, SWI may determine the size of the penumbra more accurately. Further studies are required to clarify the pathomechanism of SWI alterations and verify our findings considering follow-up images and patient outcome. Until then SWI provides a valuable tool in addition to PWI for penumbra estimation and treatment decision. Since SWI does not require contrast agent injection, it can be used in patients with contraindications to contrast agents.

High Baseline CT ASPECTS Correlates with Perfusion-Based Patient Selection, but May Be Poor Discriminator of Functional Outcomes

Honarmand, A. R.·Soltanolkotabi, M.·Prabhakaran, S.·Hurley, M. C.·Shaibani, A.·Rahman, O.·Ansari, S. A.
Northwestern University Feinberg School of Medicine
Chicago, IL.

Purpose

Appropriate patient selection in acute ischemic stroke (AIS) is central for improving patient outcomes following intra-arterial (IA) reperfusion therapy (thrombolysis/mechanical thrombectomy). Perfusion imaging with CTP/MR DWI-PWI has been utilized increasingly to identify subpopulations with acceptable risk-benefit profiles for reperfusion, avoiding futile or harmful recanalization. Earlier studies reported to have prognostic value of baseline Alberta Stroke Program Early CT Score (ASPECTS) of >7 in determining good functional outcomes following IA reperfusion. We investigated baseline CT ASPECTS in AIS patients selected for IA reperfusion therapy based on perfusion mismatch profiles. Furthermore, we studied the predictive value of CT ASPECTS for clinical outcomes following recanalization.

Materials & Methods

In a multicenter review, all AIS patients that underwent IA thrombolysis/thrombectomy between January 2010 and September 2012 were studied retrospectively for the following inclusion criteria: baseline NIHSS >8, presentation <8 hours from symptom onset, CTA/MRA verified M1-M2 MCA occlusion, and favorable perfusion (CTP/MR DWI-PWI) mismatch profile. Patient demographics, medical comorbidities, time from symptom onset to recanalization, final recanalization (TICI scale), and clinical outcomes (90 day modified Rankin Scale) were obtained. One neuroradiologist conducted blinded scoring of ASPECTS for all baseline noncontrast CT scans. For evaluation of inter-rater reliability, scores by another neuroradiologist were used and analyzed using Intraclass Correlation Coefficient (ICC) and Bland and Altman method. ASPECTS scores were dichotomized into >7 and ≤7 for primary analysis. Chi-square, Mann-Whitney U and student *t* tests were used for univariate analyses as appropriate. To obtain the optimal cut-off ASPECTS for discriminating patients with favorable outcomes, receiver operating characteristic (ROC) curve analysis was performed.

Results

Fifty-six consecutive patients (29 male/27 female patients with mean age of 71±16 years) met inclusion criteria for analysis. Successful recanalization (TICI > 2b/3) was achieved in 34 patients (60.7%), highly correlating with good functional outcomes (mRS 0-2) in 36 patients (64.3%) ($P < 0.005$). No significant difference was observed between ASPECTS reading ($P=0.6$) with good inter-rater reliability (ICC=0.80, 95% confidence interval: 0.63 to

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

0.87). No significant differences were observed in baseline characteristics between groups with ASPECTS >7 (37 patients) and ≤7 (19 patients) (age, P=0.9; sex, P=0.9; baseline NIHSS score, P=0.3; diabetes, P=1.0; atrial fibrillation, P=0.5; hyperlipidemia, P=1.0; hypertension, P=0.5; time from symptom onset to recanalization, P=0.1). Relatively high ASPECTS correlated with perfusion-based patient selection with mean and median baseline ASPECTS of eight. However, no significant correlation was observed between baseline ASPECTS and final clinical outcomes (P=0.6). Additionally, baseline ASPECTS score >7 did not correlate with final outcome in patients with successful recanalization (P=0.4). The ROC curve analysis demonstrated a cut-off point of eight for discrimination of final outcome, but with poor predictive value (sensitivity=47.1%; specificity=68.7%; P=0.7, AUC=0.52).
Conclusion
Our results indicate favorable baseline CT ASPECTS correlate with favorable perfusion mismatch profiles and may represent an equivalent surrogate for primary patient selection in IA reperfusion therapy. However, CT ASPECTS did not clearly predict good functional outcomes independent of recanalization, suggesting other confounding variables such as core infarct volume versus eloquence may impact clinical outcomes and have to be elucidated.

Structural Connectivity Alterations in Brain Networks in Pediatric Hydrocephalus: A Pilot Study

Jones, B. V.[1]·Shimony, J. S.[2]·McKinstry, R. C.[2]·Mangano, F. T.[1]·Limbrisk, D. D.[2]·Nash, T.[1]·Simpson, S.[1]·Rajagopal, A.[1]·Holland, S. K.[1]·Phillips, J. M.[1]·Powell, S. K.[2]·Mercer, D.[2]·Altaye, M.[1]·Yuan, W.[1]
[1]Cincinnati Children's Hospital, Cincinnati, OH,
[2]Washington University School of Medicine, St. Louis, MO.

Purpose
This study seeks to investigate the impact of brain injury as reflected in the topological features of brain networks in children with hydrocephalus (HCP). Increased intracranial pressure and ventriculomegaly in HCP can lead to white matter structural displacement and distortion. Resulting damage has been found in multiple areas in the brain, especially in major white matter tracts that connect and transfer information among functional brain regions. The goal of this study was to investigate structural network connectivity in children with HCP using graph theoretical analysis. It was hypothesized that both global and regional topological connectivity features of brain networks in children with HCP are abnormal compared to controls.
Materials & Methods
Three groups of children were included in the study. (Group 1: controls, n = 10, age 1.1-6 years; Group 2: HCP patients before CSF diversion surgery, n = 4, age 2.1-16.2 years; Group 3: HCP patients 3-12 months after CSF diversion surgery, n = 5, age = 1.6-16.3 years). Informed consents or assent were obtained during the enrollment. Diffusion tensor imaging (DTI) data were acquired on 1.5T scanners using a single-shot EPI sequence (TR/TE = 9400/93.2 msec; resolution = 2.5 mm iso, 15 directions, b = 1000). The structural connectivity data processing and analysis pipeline followed the methodology described by Ferreira et al. Five global connectivity measures (global coefficient, characteristic path length, clustering coefficient, small-worldness, modularity) and four regional connectivity measures (degree, betweeness centrality, nodal clustering coefficient, regional coefficient) were calculated. Group comparisons were made between Group 1 with Groups 2 and 3 separately, using Mann-Whitney U-test at significance level of $p<0.05$.
Results
Global network measures - Compared to the controls, no significant change was found for the Group 2 in any of the global network measures. There was statistically significant decrease in the normalized clustering coefficient ($p = 0.02$), modularity ($p = 0.007$), and a trend of decrease in the small-worldness ($p = 0.07$) in Group 3. Regional network Measures - Extensive brain network regions were found to have significant changes in the regional network measures. In both Group 2 and Group 3, cingulate gyrus and the middle occipital lobe gyrus were found to have significant changes (or at least at trend level) in all the four regional network measures examined. Initial results also showed that the change in the measure of nodal degree was region specific: the cingulate gyrus in both patient groups had a significantly higher nodal degree than the controls, while the mid-occipital lobe gyrus in both patient groups had significantly lower nodal degree than the controls.
Conclusion
Our data showed that graph theoretical analysis using DTI data is sensitive in the detection of abnormalities of brain network connectivity at both global and regional levels, providing a new avenue in quantifying brain damage in children with hydrocephalus.

Reorganization of the Remaining Brain after Hemispherectomy: A Diffusion Tensor Imaging Study

Meoded, A.·Faria, A. V.·Bastian, A. J.·Jallo, G.·Hartman, A. L.·Mori, S.·Huisman, T. A. G. M.·Poretti, A.
Johns Hopkins Hospital
Baltimore, MD.

Purpose
Hemispherectomy should reduce the burden of seizures and the general dysfunction in children with severe or progressive unilateral cortical epilepsy. Etiologies of intractable seizures requiring hemispherectomy include congenital (e.g., hemimegalencephaly) and postnatally acquired (e.g., Rasmussen encephalitis) causes. In a large cohort of patients after hemispherectomy, we aimed to evaluate the architecture of 1) projection (e.g., corona radiate), association [e.g., cingulum, supero-fronto-occipital fasciculus (SFO)], and commissural (e.g., corpus callosum) white matter fibers and 2) cortical and deep gray matter structures of the remaining, nonaffected cerebral hemisphere.
Materials & Methods
The inclusion criteria were: 1) Status posthemispherectomy and 2) availability of postsurgical DTI data. Diffusion tensor imaging data were acquired using 1.5/3T MR scanner. Age- and gender-matched controls were selected from our pediatric DTI database. Diffusion tensor imaging postprocessing including atlas (ABA)- and voxel (VBA)-based analysis was performed using MRI Studio software. With ABA we measured fractional anisotropy (FA), mean (MD), axial (AD), and radial (RD) diffusivity of the projection, association and commissural white matter fibers and FA of the cortical and deep gray matter of the remaining hemisphere. One-way ANOVA and Tukey's significant difference test were used to access differences between patients and controls. With VBA we assessed DTI metrics' differences between patients and healthy controls using a two-sample *t*-test.
Results
Nineteen patients (mean age 13.3 years) and 21 age- and gender-matched healthy controls (mean age 12.5 years) were included in the study. Mean age at surgery and time since surgery were 4.15 and 7.12 years, respectively. Eleven patients had a congenital, eight patients a postnatally acquired pathology requiring hemispherectomy. Compared to controls, in patients the ABA revealed 1) lower FA values in the anterior (ACR) and posterior corona radiata (congenital), cingulum (congenital<acquired), and callosal genu, body and splenium (congenital), 2) higher MD values in the cingulum and callosal genu and splenium (congenital and acquired), SFO, congenital) and callosal corpus (acquired), 3) lower AD values in the callosal genu and splenium (congenital) and cingulum (acquired), and 4) higher RD values in the callosal genu, corpus, and splenium (congenital and acquired), SFO and ACR (congenital), and cingulum (acquired). ABA of the gray matter structures showed reduced FA values in the superior frontal, temporal, parietal, occipital, pre and postcentral, and cingulate gyri in patients compared to controls. Compared to ABA, VBA showed similar FA and more pronounced MD and RD changes for the studied structures.
Conclusion
Using DTI, we were able to quantifiy brain reorganization within the remaining cerebral hemisphere after hemispherectomy. A decrease in FA and AD and increase in RD and MD of the white matter fibers reflects secondary Wallerian degeneration. Wallerian degeneration appears to be more severe in commissural and association, than projection fibers. A decrease in FA values in gray matter structures most likely is explained by increased unoccupied interecellular space. This might be due to a change in neuronal cell density and/or be the result of reduced cortical neuropil.

Reorganization of the Infratentorial White Matter Tracts after Hemispherectomy: A Diffusion Tensor Imaging Study

Meoded, A.[1]·Faria, A. V.[1]·Bastian, A. J.[2]·Jallo, G.[1]·Hartman, A. L.[1]·Mori, S.[1]·Huisman, T. A. G. M.[1]·Poretti, A.[1]
[1]Johns Hopkins Hospital, Baltimore, MD, [2]The Kennedy Krieger Institute, Baltimore, MD.

Purpose
Hemispherectomy aims to reduce the burden of seizures and the general dysfunction in children with severe or progressive unilateral cortical epilepsy. Etiologies of intractable seizures requiring hemispherectomy include congenital (e.g., hemimegalencephaly) and postnatally acquired (e.g., Rasmussen encephalitis) causes. Little is known about the reorganization of the infratentorial white matter tracts after hemispherectomy. In a large cohort of patients after hemispherectomy, we aimed 1) To evaluate differences in DTI metrics and volume between the ipsi-/contra-lesional corticospinal tract (CST), medial lemniscus (ML), middle cerebellar peduncle (MCP), and cerebellar hemisphere and 2) To correlate the values of the studied parameters with the age at and time since surgery.
Materials & Methods
The inclusion criteria were: 1) Status posthemispherectomy and 2) availability of postsurgical diffusion tensor imaging (DTI) data. DTI data were acquired using 1.5/3T MR scanner. Different acquisition protocols were used. DTI postprocessing included atlas (ABA)- and voxel (VBA)-based analysis and was performed using MRI Studio software. With ABA we measured the volume, fractional anisotropy (FA), mean (MD), axial (AD), and radial (RD) of the bilateral CST, ML, and MCP and the size of the cerebellar hemispheres. Symmetry between

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

ipsi-/contra-lesional structures was determined with the laterality index, LI = (ipsi-contra)/(ipsi+contra). One-way ANOVA and Tukey's significant difference test were used to analyze data obtained from ABA. Spearman's rank correlation test was used to correlate age at/time since surgery with DTI metrics/volume of the studied structures. With VBA we assessed DTI metrics' differences between patients and healthy controls using a two-sample *t*-test.
Results
Nineteen patients (mean age 13.3 years) and 21 age- and gender-matched healthy controls (mean age 12.5 years) were included in the study. Mean age at surgery and time since surgery were 4.15 and 7.12 years, respectively. Eleven patients had a congenital, eight patients a postnatally acquired etiology for hemispherectomy. For the CST, ABA showed a significantly negative LI for volume, FA, and AD (=smaller volume and lower values ipsi-lesionally) and positive LI for MD and RD (=higher values ipsi-lesionally) for patients (acquired>congenital) compared to controls. A significantly positive LI of the cerebellar volume (=smaller size contra-lesionally) and negative LI for MD and RD (=higher values contra-lesionally) of the MCP was found for patients (congenital) compared to controls. An older age at surgery correlated significantly with a smaller volume and positive LI for MD and RD values of the contra-lesional cerebellar hemisphere and MCP, respectively. VBA confirmed the results of atlas-based analysis.
Conclusion
Our findings demonstrate the ability of DTI to quantify brain reorganization after hemispherectomy. A decrease in volume, FA, and AD and increase in RD of the ipsi-lesional CST reflects secondary Wallerian degeneration. Wallerian degeneration seems to be more severe in acquired than congenital etiologies for hemispherectomy. A smaller volume of the contra-lesional cerebellar hemisphere represents crossed cerebro-cerebellar diaschisis (CCCD). CCCD is secondary to Wallerian degeneration involving the main contra-lesional afferent cerebellar pathway (MCP) and is shown by increased MD and RD values. CCCD seems to be more severe in older patients at surgery reflecting higher reorganization in younger patients.

7T MR Spectroscopy in Healthy Children: Relationship between Neuropsychologic Performance, N-Acetylaspartate and Glutamate Concentrations

Horska, A.[1]·Wang, X.[1]·Ryan, M.[2]·Denckla, M.[2]·Barker, P.[1]·Mahone, E. M.[2]
[1]Johns Hopkins University, Baltimore, MD, [2]Kennedy Krieger Institute, Baltimore, MD.

Purpose
Maturation of the prefrontal and frontal-striatal systems in children is paralleled by development of higher-order cognitive functions. As disruption of neural circuits involving the frontal cortex and its striatal-thalamic-cerebellar connections may contribute to development of neuropsychiatric disorders, studies in healthy children may help to interpret findings in patients. The goal of this ^{1}H MRS study was to evaluate the relationship between frontal, premotor, and striatal concentrations of the neuronal marker N-acetylaspartate (NAA) and the neurotransmitter glutamate (Glu) and neurobehavioral assessment in healthy children.
Materials & Methods
A group of 20 healthy children 5-10 years old (mean age 7.3 ± 1.6 years, eight boys) participated in this IRB-approved study. The neuropsychologic evaluation included tests of IQ, language, reading, neuromotor function, attention, working memory (verbal, spatial), and visual perception. MR imaging (3D-MPRAGE) and single voxel ^{1}H MRS (STEAM, TR/TE/TM = 3000/14/26 ms, SW = 3000 Hz, 2048 data points, NS = 96 and NS = 4 for water-unsuppressed spectra, voxel volume = 5-9 ml) were performed at 7T using a 32-channel volume head coil. Spectra were acquired in the left hemisphere in the anterior cingulate (ACC), dorsolateral prefrontal cortex (DLPFC), premotor cortex (PMC), and the striatum (STR). Metabolite concentrations were evaluated using the LCModel and were corrected for CSF. General linear model ANOVA was applied to examine the relationship between neuropsychologic performance and concentrations of NAA and Glu and the concentration ratios Glu/creatine (Cr) and NAA/Cr, controlling for age.
Results
On the test of auditory working memory, the performance improved with increasing NAA in the DLPFC and STR (both $p<0.05$), but was not associated with Glu concentration, Glu/Cr and NAA/Cr ratios. There was a significant correlation between motor performance (PANESS) and Glu, such that children with poorer performance on the measures of motor speed and response inhibition had higher Glu and NAA concentrations in the PMC and in the striatum, respectively (all $p<0.05$). No significant associations between motor performance and Glu/Cr or NAA/Cr ratios were detected. We also tested for a correlation between NAA and Glu concentrations; in all regions, a strong positive correlation was found (all $p<0.0001$).
Conclusion
In typically developing children, the hypothesized relationship between NAA concentration and cognitive performance followed the anticipated direction on the test of auditory working memory but not on the test of motor performance. In studies including adult patients, higher Glu levels were reported with better cognitive performance, while lower Glu concentration with improving performance was detected in our study. More data thus are needed to explain this apparent discrepancy, which may be due in part to examination of only healthy children in our study, although the positive correlation

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

between gray matter Glu and NAA concentrations is in agreement with results in healthy adults (hippocampal region). Future plans include comparisons between healthy children and patients with neuropsychologic disorders (e.g., ADHD).

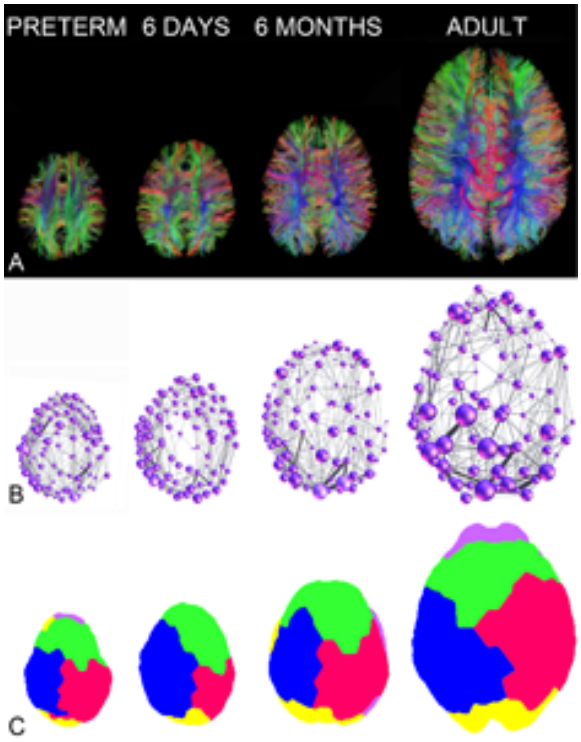
Development of Structural Brain Networks and Network-Driven Cortical Modules

Tymofiyeva, O.·Hess, C. P.·Ziv, E.·Lee, P. N.·Glass, H. C.·Ferriero, D. M.·Barkovich, A. J.·Xu, D.
University of California San Francisco
San Francisco, CA.

Purpose
Perinatal disease and premature birth affect more than one in 10 of all babies born around the world and put infants at risk of adverse neurodevelopmental outcome. Application of effective therapies in a timely and targeted manner depends on our ability to detect and monitor individual deviations from anticipated normal developmental trajectories. MR imaging connectomics enables noninvasive mapping of brain networks. However, mapping the developing newborn brain networks poses challenges, since atlases commonly used for brain parcellation might not match with function and anatomy during early brain development. The purpose of this study was to examine the maturational changes of the cortical connectome using a template-free network-driven analysis of white matter connectivity.
Materials & Methods
Diffusion MRI was performed in eight prematurely born neonates (gestational age at birth 27-30 weeks, at scan 31-40 weeks), eight term-born neonates, and 10 six-month-old infants; the two latter groups had transient encephalopathy at birth but no clinical or imaging evidence of brain injury. Seven healthy adults (age 24-31 years) were included to represent the mature brain. The subjects were scanned on a 3T MR scanner using SE EPI with a FOV=24-25.6cm, 128×128, slice thickness 1.8-2mm, 30 directions, b=600s/mm2 for preterm babies, b=700s/mm2 for term and six-month-olds, and b=1000s/mm2 for adults. To assess structural networks, the “baby connectome” framework was employed, which included data quality assurance, deterministic whole-brain fiber tractography (Figure A), and template-free parcellation of the brain surface into 100 nodes based on equal area sphere partitioning. The resulting networks (Figure B) were assessed using the Brain Connectivity Toolbox. To identify modules, the spectral community detection algorithm was applied.
Results
The optimal number of modules was relatively consistent in all groups: 5-6 modules in the preterm group, 5-7 modules in the term-born neonates, 5-8 modules in the six-month-old infants, and 5-7 modules in the adults. In Figure C, we selectively show the obtained network-driven segmentation of the cortex into five modules for subjects from all age groups that showed a similar pattern. We also observed increasing brain network integration and decreasing segregation with age in term-born subjects, consistent with previous findings in the late developing human brain.



Conclusion
In this study, we explored how the structural brain network nodes can be grouped into modules without any prior anatomical information and observed a basic modular network topology that is present in the brain from the first days of life.

Myelination Age: Establishing Normal Ranges for Myelination Status during Development Using a Histogram-Based Fractional Anisotropy Metric

Chin, E. M.[1]·Choudhri, A. F.[1,2]
[1]University of Tennessee Health Science Center, Memphis, TN, [2]Le Bonheur Children's Hospital, Memphis, TN.

Purpose
Conventional MR imaging typically shows near complete myelin maturation by approximately three years of age; however, it is known that myelin maturation progresses into adolescence. Research studies have shown changes in

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

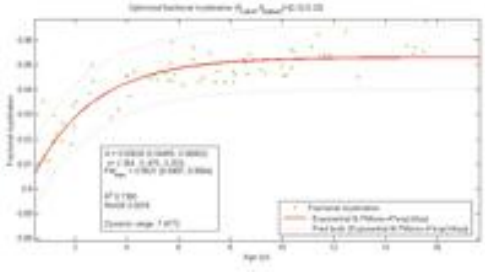
myelination, as determined by diffusion tensor imaging (DTI); however, measures such as mean fractional anisotropy (FA) have shown high variance making quantitative determination of age-appropriateness of myelination status difficult. We have applied a newly developed algorithm to measure fractional myelination (FM), a scanner-independent reproducible measure resistant to partial volume effects to a population of children with normal MRI scans to establish normal ranges throughout development.

Materials & Methods

This HIPAA compliant retrospective study was performed after IRB approval. Five hundred consecutive MRI scans on children under 18 years of age were evaluated. Studies were excluded if there was any definable structural abnormality as determined by neuroradiologist review. All studies has a volumetric T1-weighted sequence, as well as DTI with 15 noncollinear directions of encoding, a b-value of 1000 msec and a single b-0 acquisition. Registration and segmentation were performed within SPM. Fractional anisotropy was analyzed for intracranial white matter as a whole. Fractional myelination with optimized parameters then was calculated based on the FA histograms of each patient. A nomogram of FM over age then was calculated based on an exponential model FM(FA,t)=FM_max - A*exp(-t/tau) with 5th and 95th percentile bounds based on a Student's t-distribution.

Results

Two hundred seventy-five datasets met inclusion criteria and were able to be analyzed successfully. Fractional anisotropy shows exponential convergence to adult values with age, in agreement with previous studies. Similarly, fractional myelination, or the ratio of maturely myelinated white matter as a percentage of total white matter volume also increases throughout childhood before asymptotically approaching adult values. Using FM, we have created a nomogram for assessment of myelination status.



Conclusion

Statistical analysis of DTI metrics confirms the ability to follow myelin maturation from birth through adolescence. Reference values based on statistical analysis of DTI metrics may allow identification of myelination anomalies in a clinical setting. Difffusion tensor imaigng appears to be a more sensitive and reproducible method of assessing myelination than conventional T1- and T2-weighted sequences, and this may serve as the foundation for automated myelination age determination.

Brain Diffusion Tensor Imaging and Volumetric Analysis in Young Children with Autism Spectrum Disorder

Pichiecchio, A.[1]·Carigi, T.[1,2]·Bergsland, N.[1,2]·Palesi, F.[2]·Di Perri, C.[1]·Lucignani, G.[3]·Rossi, G.[1]·Balottin, U.[1,2]·Bastianello, S.[1,2]

[1]Neurological National Institute I.R.C.C.S., Pavia, ITALY, [2]University of Pavia, Pavia, ITALY, [3]University La Sapienza, Rome, ITALY.

Purpose

Since the hypothesis of autism as a disconnection syndrome has been proposed, advanced MRI techniques have taken a great part in its research. Nevertheless, although autism is considered a very early onset disorder, few diffusion tensor imaging (DTI) and volumetric studies focused on the first years of life. We aimed to investigate whether DTI metrics and volumetric analysis could detect regional abnormalities in young autism spectrum disorder (ASD) children.

Materials & Methods

A sample of 22 pre-school ASD children (mean age 44.45 months ± 10.6) and 10 age-matched controls were selected and underwent a conventional and advanced MRI protocol (1.5T), including DTI with 15 directions and 3D T1-weighted imaging. The Diffusion Trackvis Toolkit was used to compute fractional anisotropy (FA) and mean diffusivity (MD) from DTI images, for each voxel in the brain. A region-specific DTI analysis also was performed in the following brain regions: both frontal, parietal, temporal and occipital lobes, cerebellum, amygdale, hippocampi and corpus callosum. Whole brain tissue (BT), white matter (WM) and gray matter (GM) FA and MD histograms also were extracted. Cortical reconstruction and volumetric segmentation was performed with the FreeSurfer image analysis suite. Considering the small sample size, we considered more appropriate to perform a group comparison with the nonparametric Mann-Whitney test. Due to the exploratory nature of the study, a nominal p value of less than 0.05 was considered significant.

Results

No significant differences between ASD and controls were found neither in mean BT, WM and GM volumes nor in the region-specific volumetric analysis. Group comparison of FA and MD mean values and other histogram metrics for both WM and GM only showed significant differences in GM FA (FA mean: p = 0.026; peak height: p = 0.020; skewness: p = 0.041; kurtosis: p = 0.029). Diffusion tensor imaging region-specific group comparison showed significant reduced values in the following regions in ASD children with respect to controls: GM FA in all supratentorial regions analyzed, namely left and right frontal lobe (p = 0.006 and 0.001), left and right parietal lobe (p = 0.010 and 0.003), left and right temporal lobe (p

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

= 0.008 and 0.009), left and right occipital lobe (p = 0.001), left and right hippocampi (p = 0.033 and p = 0.016), right amygdale (p = 0.037) and cerebellar hemispheres (p = 0.004); WM FA in the occipital lobes (p = 0.029 and 0.041) and cerebellum (p = 0.001 and 0.003); MD only in the right cerebellum, both for WM (p = 0.016) and GM (p = 0.041).
Conclusion
Volumetric analysis revealed no significant differences between ASD children and controls, while our DTI results suggest an early involvement of both cerebellum and supratentorial GM in young ASD children, with FA being the most sensitive parameter. Further investigation on a larger sample is warranted in order to confirm a potential primary role of GM changes to white matter ones in the complex etiopathogenesis of ASD and to correlate radiologic data to clinical findings.

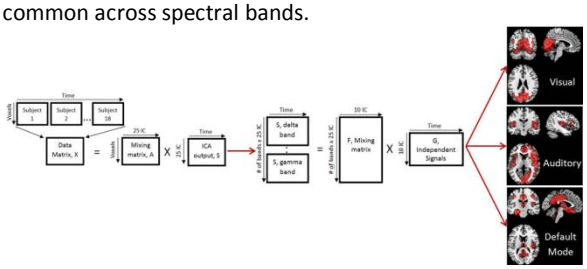
Investigation of Pediatric Magnetoencephalographic Networks Using Meta-Independent Component Analysis

Davenport, E. M.[1]·Whitlow, C. T.[1]·Powers, A.[1]·Thompson, M. M.[2]·Rawley, J.[2]·McGowin, I.[2]·Alberto, G.[2]·Bungo, T.[2]·Godwin, D.[2]·Urban, J. E.[2]·Stitzel, J.[2]·Maldjian, J. A.[1]
[1]Wake Forest University School of Medicine, Winston-Salem, NC, [2]Wake Forest University, Winston-Salem, NC.

Purpose
Magnetoencephalography (MEG) is a noninvasive form of functional brain imaging that can be used to further understand brain function. Independent component analysis (ICA) can be used to decompose the mixture of signals from recorded MEG data into multiple independent components representing networks. Meta-ICA is a newly described method to extract networks common across all spectral bands. The purpose of this study is to use Meta-ICA to identify common MEG networks across spectral bands in a group of pediatric subjects.
Materials & Methods
An institutional ethics committee approved this study. Eighteen normal male subjects aged 16-18 years were scanned using a 3T Siemens Skyra scanner using a 32 channel head coil for collection of structural anatomical MRI data. Eight minutes of, eyes open, resting-state MEG data were acquired for each subject using a 275 channel CTF whole-head system. Using an in-house automated pipeline, all data were baseline corrected, filtered for 60Hz line noise, down-sampled to 100Hz, and band-pass filtered into five frequency bands (δ: 0-4Hz, θ: 4-8Hz, α: 8-13hz, β: 13-30Hz, γ: 30-50Hz). Artifacts from head motion, and muscles also were removed. Magnetoencephalography data then were projected into source space at 5 mm resolution using a scalar beamformer with leadfield correction for noise normalization. The Hilbert envelope was computed, and data were down-sampled to 1Hz. These data then were used as the input for Meta-ICA. For each frequency band, the data from each subject was concatenated into a matrix, X, where each row represented a timecourse for a single voxel across all subjects. Twenty-five independent components, S, for each frequency range were estimated from this matrix using FastICA. The 25 estimated components for each frequency range then were concatenated into a matrix where each column represented a single timepoint across all bands and components. Finally, 10 independent components, G, were estimated from this matrix using FastICA.
Results
Figure 1 demonstrates the spatial representation of three of these 10 components, which are representative of all subjects across all bands and time. The components appear to represent portions of the visual, auditory, and default mode networks, in addition to other regions common across spectral bands.



Conclusion
The application of Meta-ICA analysis to MEG data from pediatric subjects revealed specific networks bearing similarity with those found in other studies of network connectivity. The data demonstrates the utility of Meta-ICA when analyzing MEG data to compare networks in pediatric subjects across spectral bands.

Retrospective Study of the Impact of a Perception-Based Anisotropic Diffusion Filter on Image Quality in Low-Dose Pediatric Head CT

Tang, E. R.·Li, B.·Sakai, O.·Barest, G.·Setty, B.·Mian, A.
Boston University/Medical Center
Boston, MA.

Purpose
To retrospectively study the impact of a unique perception-based anisotropic diffusion filter (pADF), which uses a structural similarity measure based on visual components (luminance, contrast, structure), on noise and reader-assessed image quality in low-dose pediatric head CT.
Materials & Methods
Ten pediatric patients (ages: 1 to14 years), who underwent brain CT and MRI within one month, were selected after IRB approval. Brain CT images were

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

obtained with axial 5mm (brain kernel) and 1.25mm (bone kernel) sections using a 64-multidetector CT. CT dose index, dose-length product, and major CT brain findings (confirmed when possible by MRI) were recorded for each patient. pADF processing (Imsonic Corp.) was applied to images for each patient. The nonprocessed paired brain/bone series and the pADF-processed series were anonymized and randomized. Three neuroradiologists graded the each series on a 5-point scale for noise, contrast, resolution, and overall image quality (1=nondiagnostic to 5=exceptional). Standard deviations (SDs) for noise also were recorded (based on Hounsfield units) in 6x6mm regions of interest at the lenticular nucleus and periventricular white matter.

Results

Quantitative noise SDs of the pADF-processed images for the brain and bone kernel reconstructions were significantly lower than in the nonprocessed images, measured at the lenticular nucleus (brain: 2.44 versus 3.94, p<0.01; bone: 28.42 versus 38.55, p<0.01) and at the periventricular white matter (brain: 2.14 versus 3.65, p<0.01; bone: 25.73 versus 36.26, p<0.01). For bone reconstructions, the pADF-processed series resulted in a slight but statistically significant improvement in reader-assessed scores for resolution (4.52±0.59 versus 4.17±0.75, p=0.02), particularly for low-dose CT (score improvement by average of 0.28 when compared to standard-dose CT, p=0.03). There also were slightly improved scores in contrast (4.39±0.58 versus 4.20±0.71, p=0.58) and overall image quality (4.26±0.62 versus 4.00±0.64, p=0.07) for pADF-processed bone images, though not statistically significant (p>0.05). For brain reconstructions, the pADF-processed series resulted in a slight but statistically significant decrease in reader-assessed scores for overall image quality (3.22±0.74 versus 3.73±0.66, p=0.08). Slightly decreased scores for contrast (3.39±0.84 versus 3.73±0.78, p=0.09) and resolution (3.57±0.59 versus 3.80±0.66, p=0.08) for pADF-processed brain images were not statistically significant (p>0.05). Aside from the bone resolution scores, the other qualitative reader-assessed changes were less pronounced at low-dose CT than standard-dose CT, though differences were not statistically significant (see table below).

Reader-assessed image score changes for pADF- versus nonprocessed CT, in standard- versus low-dose CT.

Reader-assessed image factor (kernel)	Standard-dose CT score change (pADF-processed - nonprocessed)	Low-dose CT score change (pADF-processed - nonprocessed)	Difference in score change by dose (Standard-dose CT - low-dose CT)
Resolution (bone)	0.143 (p=0.409)	0.286 (p=0.032)	-0.143 (p=0.498)
Contrast (bone)	0.143 (p=0.456)	0.143 (p=0.297)	0 (p=1)
Overall image quality (bone)	0.429 (p=0.095)	0.143 (p=0.409)	0.286 (p=0.343)
Resolution (brain)	-0.431 (p=0.156)	-0.287 (p=0.179)	-0.144 (p=0.687)
Contrast (brain)	-0.445 (p=0.236)	-0.297 (p=0.262)	-0.148 (p=0.740)
Overall image quality (brain)	-0.877 (p=0.058)	-0.364 (p=0.242)	-0.513 (p=0.337)

Conclusion

pADF-processing shows statistically significant quantitative reduction in CT noise for both brain and bone reconstructions. pADF-processing demonstrates particular promise for bone-kernel CT images, resulting in a statistically significant improvement in reader-assessed resolution, especially in the low-dose CT group. There is, however, a slight decrease in reader-assessed overall image quality for the pADF processed brain kernel CT imaging. Ongoing studies are underway to confirm these findings, as well as the impact of pADF-processing on CT imaging of other structures.

Adaptive Statistical Iterative Reconstruction: Reducing Dose while Preserving Image Quality in the Pediatric Head CT Examination

McKnight, C. D.·Ibrahim, M.·Watcharotone, K.·Baer, A.·Wright, R.·Parmar, H.
University of Michigan
Ann Arbor, MI.

Purpose

Over the last decade there has been escalating concern regarding the increasing radiation exposure stemming from computed tomography, particularly in children. Adaptive statistical iterative reconstruction (ASIR) is a relatively newer and promising tool to reduce radiation dose while preserving image quality. While encouraging results have been found in adult head and chest and body imaging, validation of this technique in pediatric population is limited due to very small sample size in the previous study. The purpose of our study was to retrospectively compare the image quality and radiation dose of pediatric head CT examinations obtained with ASIR compared to pediatric head CT examinations without ASIR in a large patient population.

Materials & Methods

Retrospective analysis was performed on 82 pediatric head CT examinations. This group included 33 pediatric

head CT examinations obtained with ASIR and 49 pediatric head CT examinations without ASIR. Qualitative analysis consisted of independent assessment by two radiologists in a blinded manner of gray-white differentiation, sharpness and overall diagnostic quality. Quantitative analysis consisted of standardized measurement of attenuation and the standard deviation at the bilateral centrum semiovale and cerebellar white matter. Dose length product (DLP) was recorded on all examinations.
Results
The average DLP value of the ASIR group was 352.0 mGy-cm while the average DLP for the non-ASIR group was 545.5 mGy-cm, representing a statistically significant 35% reduction in DLP in the ASIR group ($p < 0.01$). Radiologist assessment of gray-white differentiation, sharpness and overall diagnostic quality in ASIR examinations was not significantly different compared to non-ASIR examinations. Quantitative analysis revealed a slightly increased average attenuation in the bilateral cerebellar white matter on ASIR examinations (Right 28.1 HU, Left 27.7 HU) as compared to non-ASIR examinations (Right 26.1 HU, Left 25.7 HU) ($p < 0.01$), though no corresponding significant difference was seen in the centrum semiovale.
Conclusion
The use of ASIR in pediatric head CT examinations allows for a 35% reduction in radiation dose without significantly affecting image quality.

Value of Transcranial-Enhanced Ultrasound in Newborns: Initial Experience

Kastler, A.[1,2]·Manzoni, P.[3]·Chapuy, S.[3]·Cattin, F.[3]·Biondi, A.[3]·Kastler, B.[3,2]
[1]University Hospital, Clermont ferrand, FRANCE, [2]I4S Laboratory EA 4268, Franche Comte University, FRANCE, [3]University Hospital, Besançon, FRANCE.

Purpose
To assess the feasibility and value of transcranial-enhanced ultrasound (TCEUS) in various neurologic conditions in newborns.
Materials & Methods
Local Institutional Review Board approval was obtained and written informed consent was waived. Sixteen newborns who underwent a total of 20 TCEUS were included in this retrospective study from June 2009 to February 2012. All TCEUS were performed by one trained operator on an Acuson Sequoia ® U.S. ™ system. Second generation contrast material (SonoVue, Bracco ®) was used. Transcranial-enhanced ultrasound imaging findings were compared with those of conventional transcranial ultrasound and CT/MRI findings when available.
Results
Mean gestational age was 32.6 weeks (range 25 to 41 weeks). Ten out of the 16 included new borns (66%) were premature. Eleven of 18 ETFC were performed within 10 days of life. In 18 out the 20 performed examinations, TCEUS showed brain perfusion abnormalities which were not depicted on nonenhanced TCUS (ischemic: nine cases, hypoperfusion: eight cases, CDR: one case). Two newborns had negative TCEUS findings. MR imaging or CT scans were available for comparison in 12 of 16 patients. A good correlation between TCEUS and either MRI or CT findings was found in 10 out of 12 initial TCEUS (correlation with MRI: three cases, CT: one case, CT and MRI: six cases).
Conclusion
Transcranial-enhanced ultrasound appears as a potential bedside accessible nonionizing alternative imaging modality in the assessment of emergency neonatal brain injury. It provides additional information compared to nonenhanced TCUS, especially in the field of brain perfusion assessment.

Visualization of the Medial and Lateral Geniculate Nucleus with Phase Difference Enhanced Imaging

Kitajima, M.·Hirai, T.·Shigematsu, Y.·Yoneda, T.·Komi, M.·Azuma, M.·Iryou, Y.·Nishimura, S.·Yamashita, Y.
Kumamoto University
Kumamoto, JAPAN.

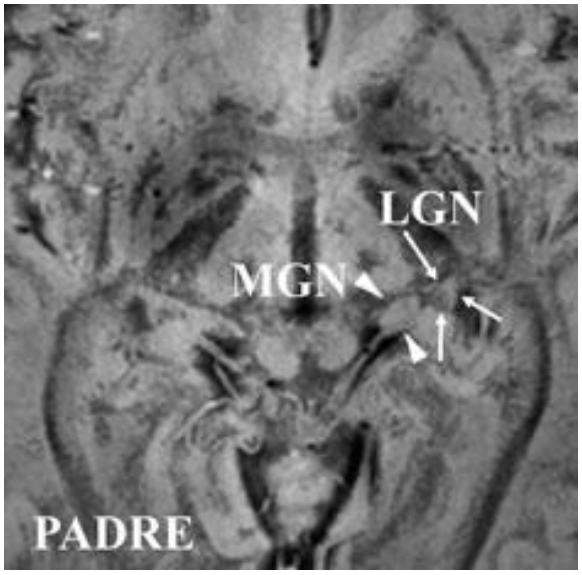
Purpose
The medial geniculate nucleus (MGN) and lateral geniculate nucleus (LGN) are the specific nuclei that relay hearing and vision, respectively. Although there is increasing interest in the morphometry of the MGN and LGN, imaging methods for precisely identifying the two nuclei have not been sufficiently developed. The purpose of this study was to compare the delineation of the MGN and LGN among phase difference enhanced (PADRE) imaging on which the phase difference between the target and surrounding tissue was selected in order to enhance the contrast of the target tissue, 2D T2-weighted image (T2WI), short TI inversion recovery (STIR), proton density-weighted image (PD) and diffusion tensor imaging (DTI).
Materials & Methods
We recruited 10 healthy volunteers (six men, four women; ages, 28 - 47 years, mean, 36.8 ± 6.7 years) for this study. Phase difference enhanced images created from 3D high-

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

resolution T1 FFE images, 2D T2WI, STIR, PD and DTI were obtained. To elucidate the visibility of the boundary of MGN and LGN, two neuroradiologists consensually assessed PADRE, 2D T2WI, STIR, PD and DTI by referring to Schltenbrand-Wahren atlas. They used a 4-point scale as follows: grade 0, no visible boundary of MGN and LGN; grade 1, vaguely visible boundary; grade 2, mostly obvious boundary; and grade 3, obvious boundary with clear delineation of MGN and LGN. We compared the visibility of MGN and LGN among five sequences statistically.

Results

The visibility of MGN and LGN was grade 3 in all volunteers on PADRE. There were statistically significant differences for visibility of the MGN and LGN between PADRE and the other four sequences ($p<0.01$). Boundary structures of the MGN and LGN consisted of low intensity white matter tracts including the zona lateralis, cerebral peduncle, lateral lemniscus and brachium colliculi superioris. The MGN was found dorsal to the lateral lemniscus, while the LGN existed medial to the zona lateralis and dorsal to the cerebral peduncle. The brachium colliculi superioris was found between the MGN and LGN. The MGN and LGN were identified in 30% and 60% for STIR, and 25% and 55% on PD, respectively. They were not identified on T2WI and DTI in all volunteers.



Conclusion

The delineation of MGN and LGN on PADRE was superior to that on STIR, PD, DTI or T2WI.

Observing the Cerebral Autoregulation of Cerebral Blood Flow in Simulated Normotensive Hypovolemia Using Incremental Increases of Lower Body Negative Pressure and Phase-Contrast MR Imaging

Cain, J. R.·Brodie, S.·Sinha, R.·Stivaros, S.·Jackson, A.
University of Manchester
Manchester, UNITED KINGDOM.

Purpose

Classical cerebrovascular autoregulation maintains cerebral blood flow (CBF) during fluctuations in cerebral perfusion pressure. Stimuli which cause a decrease in blood volume while blood pressure is maintained are normotensive hypovolemic challenges. An equivalent stimulus to a tilt-table test can be reproduced by lower body negative pressure (LBNP) of -20mmHg, applying an external vacuum to the lower limbs and torso. Higher levels of negative pressure hypovolemic states also can be simulated eventually resulting in syncope. Understanding the relationship between cardiac output and CBF in normotensive hypovolemic patients has implications for the management of trauma patients.

Materials & Methods

Eleven healthy male volunteers (21-24 years) underwent imaging with a 3T MR scanner with their legs and lower torso within the Manchester MRI compatible LBNP chamber. Quantitative phase-contrast angiography (PCA) acquisitions were used to measuring total blood inflow from internal carotid and basilar arteries middle cerebral arteries(MCA) and flow in both the ascending and descending aorta. Data were acquired at 10mmHg increments from baseline to -50 mmHg. Heart rate (continuous) and blood pressure(intermittent) was measured during the experiment.

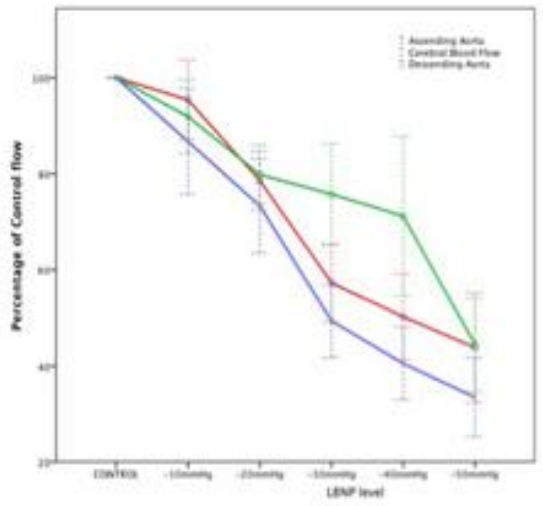
Results

Increases in heart rate were seen from -20mmHg LBNP, mean arterial pressure did not decrease until -50mmHg, two of the 11 subjects had pre-syncope episodes at -50 mmHg. A 65.5% decrease ($P<0.01$) in CBF and a 63.6% ($P<0.01$) decrease in cardiac output were observed at -50mmHg LBNP. The decrease in CBF was proportional to the cardiac output up to LBNP of -20mmHg. At pressures between -20mmHg and -40mmHg there was a relative preservation of CBF in relation to cardiac output. MCA flow was maintained until -50mmHg LBNP.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

All values are mean ±S.E.M *P<0.05, ** P<0.01

LBNP level (mmHg)	0 (Control)	-10	-20	-30	-40	-50
Heart rate (bpm)	56±3	57±4	60±4**	62±4**	69±5**	80±5**
Systolic BP (mm Hg)	115±2	114+2	112±2	110±2**	110±2**	110±3**
Diastolic BP (mm Hg)	63±3	63±2	63±2	63±2	63±3	64±3
Ascending aorta flow (l/min)	6.87±.70	6.53±0.69	5.43±0.62*	4.22±0.66*	3.52±0.50*	2.50±0.35*
Descending aorta flow (l/min)	4.51±0.61	4.19±0.71	3.56±0.63*	2.63±0.52*	2.10±0.39*	1.43±0.25*
MCA flow (l/min)	0.15±0.03	0.15±0.02	0.15±0.02	0.13±0.02	0.13±0.03	0.07±0.01*
CBF (l/min)	0.87±0.09	0.83±0.10	0.72±0.08*	0.67±0.10*	0.61±0.10*	0.30±0.06*



Conclusion

These results add to the classic autoregulation model by describing normotensive autoregulation. They suggest an increase in cerebral vascular resistance comparable to the resistance increase seen peripherally up to -20mmHg. At higher levels of LBNP (-20mmHg to -40mmHg) relative sparing of the cerebral circulation is noted in association with early small changes in systolic blood pressure suggesting that “classic” pressure-based autoregulatory mechanisms are active. While mean arterial pressure remain constant, decompensation seen at -50mmHg LBNP suggests failure of pressure-based autoregulation at this level of hypovolemia.

Enhanced Detection of Cerebral Venous Anatomy with Susceptibility-Weighted Imaging at 7T

Ge, Y.[1]·Zaman, O.[2]·Lu, H.[3]·Haacke, E.[2]·Grossman, R. I.[1]
[1]New York University Langone Medical Center, New York City, NY, [2]Wayne State University School of Medicine, Detroit, MI, [3]University of Texas Southwestern Medical Center, Dallas, TX.

Purpose

The cerebral venous system consists of superficial and deep venous systems which drain blood following oxygenation of tissues into internal jugular veins. Compared to the well studied cerebral arterial system on MR angiography, the complex venous system is still largely under-investigated with in vivo imaging. This study was to describe the cerebral venous anatomy using susceptibility-weighted imaging (SWI) at 7T MR with enhanced visualization of small venules and their draining courses on SWI venography.

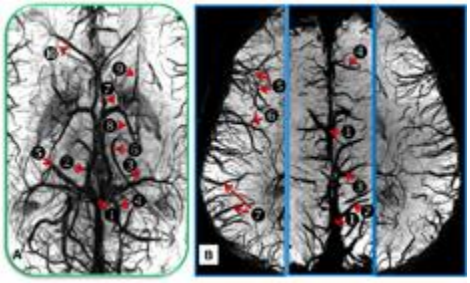
Materials & Methods

Five healthy volunteers (age: 22~40 years old) underwent 7T MR imaging with the use of a 24-element head coil array. High-resolution SWI (a 3D gradient-echo imaging with all-direction flow compensation) MR venography with in-plane resolution of 0.21mm was performed. The slice thickness is 2mm. Susceptibility-weighted imaging minimal intensity projection (mIP) images over variable slice numbers (8~32) were created with phase multiplication algorithm to enhance venous structure contrast. The images were acquired in both transverse and sagittal planes. Using a schematic diagram as a template, we systematically reviewed the resulting venograms in each plane for detection of cerebral veins from both superficial and deep systems.

Results

In addition to the major dural venous sinuses (i.e., superior/inferior sagittal sinuses, straight sinus, occipital sinus and transverse sinuses), the optimized 7T SWI (TR/TE/FA = 40ms/16ms/25°) venography also distinguished nicely the superficial and deep systems with enhanced detection of small branches of veins and their draining courses. Figure 1 showed deep (A) and superficial (B) venous systems. The deep system (A) contains three major veins - great vein of Galen (1), internal cerebral vein (2), and basal veins (3); and the basal vein is formed with small veins (not marked) collecting deep cerebral regions. The internal cerebral vein is formed from the merger of the atrial veins (4), choroid (5), thalamostriate veins (6-9) and septal veins (10). The superficial system (B) contains superior sagittal sinus (1) that drains blood of cerebral hemisphere and is formed by parietal (2,3,7), frontal (4,5), and occipital veins (8) as well as the vein of trolard, vein of Labbe, and pre/post central and central veins (shown on separate saggital views).

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Conclusion
7T SWI venography has great potential to produce a superior venous anatomy (i.e., from venous to collecting veins to sinuses) images to systematically study cerebral venous vasculature in vivo. This may aid in improved detection, visualization, and localization of brain diseases of venous malformations, venous thrombosis, and/or abnormalities.

Correlation of Arcuate Fasciculus Dominance with Hand Dominance: Does Right-Handed Group Have Left Arcuate Fasciculus Dominance?

Chung, G.·Kwak, H.·Hwang, S.
Chonbuk National University
Jeonju, KOREA, REPUBLIC OF.

Purpose
Arcuate fasciculus (AF) is a direct white matter connection that runs medially between Braca's and Wernicke's area. For more than a century, neurologists have hypothesized that the AF carries signals that are essential for language function; however, the exact function and anatomical pathway is highly controversial. It is known in right-handed patient group, almost 99% of them have left hemispheric dominance, but in contrast, the left-handed patient group has only 50-60% of right hemispheric dominance. We hypothesized there will be a relationship between AF and hemispheric dominance, and in this study, we want to evaluate it by using diffusion tensor imaging (DTI).
Materials & Methods
Twenty-two healthy volunteers (11 right-handed, 11 left-handed, mean ages were 28.3 and 24.6 years, respectively, 12 women, 10 men) were studied with conventional MR imaging and DTI. Dominant hand was confirmed by Edinburgh handedness inventory. Using 3T MRI and DTIStudio program, AF fiber tracking was performed in ExploreDTI (A. Leemans, Antwerp, Belgium), using a deterministic streamline method. Fractional anisotropy (FA) and fiber number (FN) of both (right and left) AF fibers of each group were measured by DTIstudio program and then after, we measured LI [lateralization index = (left-right)/(left+right)] to compare right and left AF fiber.
Results
1. Right-handed group: Ten of 11 of right-handed group has positive LI, that means 91% of right-handed group has left dominant AF. Only one has negative LI. So the average of LI was 0.47 and 0.016 in fiber's number and fiber's FA respectively. We compared the number of both fibers and it was significantly left side dominant (p =0.039), but FA of both fibers was insignificantly different (p = 0.0537). 2. Left-handed group: Four of 11 of left-handed group has negative LI, that means only 36% of left-handed group has right dominant AF. Other 64% of left-handed group has positive LI, left dominant AF. So the average of LI was 0.12 and 0.006 in fiber's number and fiber's FA respectively. We compared number of both AF and it was not significantly dominant in any side (p = 0.453), but FA of both fibers was insignificantly different (p = 0.2696).
Conclusion
We demonstrated right-handed group significantly has left dominant AF, in number. But FA was not significant, and this means the number of fibers express well about dominance. Also left-handed group has no dominant AF, and it was well correlated with Edinburgh test.

Lesion Mimic: Dilated Anterior Temporal Lobe Virchow Robin Spaces on 3T MR Imaging

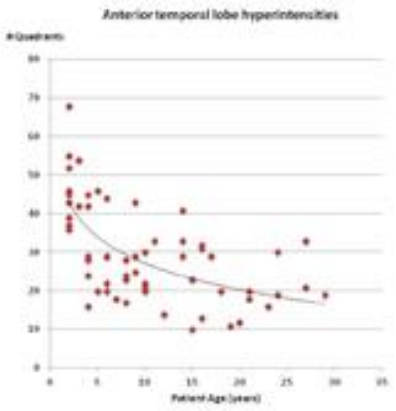
Weisman, N. J.·Thakur, M.·Bronen, R.
Yale New Haven Hospital
New Haven, CT.

Purpose
As imaging of seizure patient has evolved with the introduction of 3T MRI, high-resolution coronal imaging sometimes reveals prominent subcortical T2-weighted hyperintensities in the anterior temporal lobes, particularly in young children. While most of these findings are suspected to be secondary to perivascular (Virchow-Robin) spaces, this study sought to determine the significance and frequency of these findings.
Materials & Methods
Coronal T2-weighted and FLAIR images performed on 3.0T scanners were reviewed retrospectively to determine the frequency and distribution of anterior temporal lobe subcortical hyperintensities. High-resolution thin section MR images from 60 seizure patients (mean age = 10.5 years, range 2 -29 years) were compared to 20 control subjects imaged for pituitary conditions (mean age = 20.4 years, range 9-35 years) by three CAQ certified/eligible neuroradiologists using a consensus interpretation method. For each subject, coronal images of each temporal lobe from the anterior pole to the uncal recess were divided into four quadrants. The number of positive quadrant slices then was tallied to determine the prominence and extent of these findings; these were assessed using Student's *t*-test and Pearson correlation statistics.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Results

T2 hyperintensities at the gray-white matter junction were common in both seizure and control groups, with a prevalence of 99% (79/80 patients) and 95% (19/20 controls). There was no significant difference in the number of positive quadrant slices between seizure patients and controls (29.6 versus 28.6, p = 0.84). A moderately strong inverse relationship between the number of positive quadrant slices and age was found, with Pearson correlation of -0.54 for seizure patients and -0.71 for controls (Graph). There was also a significant difference in prominence of hyperintensities when separated into groups above and below 16 years of age, with an increased number of positive quadrant slices noted in the younger age group ($p<0.01$ for patients and $p<0.0001$ for controls). Confluent T2 hyperintensities, mimicking a pathologic lesion, were encountered in 8.3% (5/60) of seizure patients and 5% (1/20) of control subjects.



Conclusion

Anterior temporal lobe subcortical hyperintensities are almost universally present on high-resolution 3T coronal imaging in both seizure and control subjects, particularly in younger children. These findings likely represent dilated perivascular spaces. One should be aware that prominent hyperintensities may occur in young children and should not be confused with a pathologic abnormality. Location, signal intensity and adjacent findings should help distinguish confluent perivascular spaces from true abnormalities.

Shrinkage of the Petrous Carotid Canal following Application of Selverstone Clamps

Bag, A. K.·Chapman, P.·Cure, J.·Fisher, W.·Zaza, A.
University of Alabama at Birmingham
Birmingham, AL.

Purpose

Narrowing of the petrous carotid canal is believed to be of developmental origin due to a congenitally small internal carotid artery. We have observed gradual narrowing of the ipsilateral carotid canal after Selverstone clamping of the common carotid artery to treat giant cavernous carotid aneurysms. The purpose of this study was to confirm the hypothesis that the carotid canal shrinks compared to the control side in response to iatrogenic narrowing of the common carotid artery with Selverstone clamps. We also hypothesized that iatrogenic narrowing of the carotid would be accompanied by compensatory enlargement of the contralateral ICA.

Materials & Methods

We retrospectively reviewed imaging studies from 21 patients who had clamping of the common carotid artery to treat giant cavernous aneurysm. We measured the pre- and post-therapy (2-6 years after the initial scan) petrous carotid canal diameter as well as anterior-posterior (AP) and transverse diameter of the opening of the entrance of the carotid canal in 21 patients with Selverstone clamping. We also measured (using the same technique) petrous carotid canal diameter as well as anterior-posterior and transverse diameter of the opening of the entrance of the carotid canal at the time of diagnosis and at the latest followup (2-6 years after the first scan) in another 21 patients who were followed up for untreated small MCA bifurcation aneurysm. The diameter of the contralateral cervical ICA was measured just proximal to its entry into the carotid canal.

Results

There was no statistically significant difference between the pre- and post-treatment carotid canal diameters in the control group. However, the pre- and post-treatment measurements were significantly different in the Selverstone group. The rate of change of diameters also was significantly different between the cases and control. There was no statistically significant change in the diameter of the contralateral ICA after Selverstone clamp application.

Conclusion

Narrowing of the carotid canal can be acquired. Canal diameter shrinks over time in response to iatrogenic narrowing/occlusion of ipsilateral common carotid artery. This suggests that a small carotid canal diameter may not in isolation reliably distinguish a congenitally hypoplastic carotid from acquired carotid stenosis.

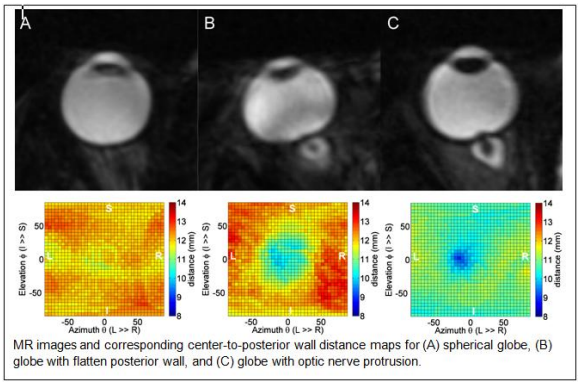
Automated Quantitation of Globe Flattening by MR Imaging in Idiopathic Intracranial Hypertension

Alperin, N.·Bagci, A.·Lam, B. B.·Sklar, E.
University of Miami
Miami, FL.

Purpose
To develop a fully automated method for assessing globe flattening and nerve protrusion by MRI, and to determine association with papilledema grade and intraocular pressure in patients with idiopathic intracranial hypertension (IIH).
Materials & Methods
Seven women with newly diagnosed untreated IIH and six healthy women of similar age, and BMI were studied by MRI. The diagnosis of IIH was made using the modified Dandy criteria. The mean and SD of papilledema grade (using the Frisen scale) in the seven IIH patients were 2.0 ± 0.96 with a range of 1-4. The MR images were acquired with 1.5 and 3T scanners (Symphony and Trio; Siemens, Erlangen, Germany). MRIs were performed before the diagnostic spinal tap and at one week after the spinal tap. All of the patients were treated with acetazolamide after the spinal tap. The MRI exam included heavily T2-weighted 3D volumetric MRI scan covering both eye globes with 0.6 mm isotropic resolution. The automated quantitative 3D method provides two objective measures: 1) "globe flatness measure (GFM)" depicting overall flatness of the posterior wall of the eye, and 2) "nerve protrusion measure (NPM)"- depicting degree of optic nerve protrusion. Globe flatness measure value of one represents a perfectly spherical posterior globe wall and a lower number represents a higher degree of globe flattening.
Results
Mean and SD values of the GFMs and NPMs in the healthy controls were 0.947 ± 0.015, and 0.986 ± 0.009, respectively. These measures in IIH patients were significantly lower 0.897 ± 0.028 and 0.961 ± 0.017, (p = 0.0001 and 0.00012), respectively. Nerve protrusion measure but not GFM correlated significantly with the degree of papilledema (contingency coefficient of 0.757, p = 0.0033). On the other hand, intraocular pressure was more strongly associated with GFM. Following treatment with acetazolamide, significant improvement was found in the GFM (0.900 ± 0.031 versus 0.930 ± 0.020, p = 0.04). The improvement in NPM did not reach statistical significance (0.961 ± 0.020 versus 0.976 ± 0.002, p = 0.09).



MR images and corresponding center-to-posterior wall distance maps for (A) spherical globe, (B) globe with flatten posterior wall, and (C) globe with optic nerve protrusion.

Conclusion
Automated MRI-derived globe flattening and optic nerve protrusion measures provide reliable and objective quantitative measures of anatomical changes associated with papilledema and increased intracranial pressure. Globe flatness measure and NPM provide complementing information related to the influence of elevated ICP on visual alterations.

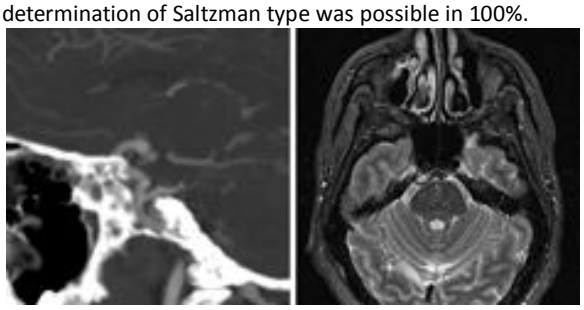
Persistent Trigeminal Artery: Modern Characterization Using High-Resolution MR Imaging, MR Angiography and CT Angiography

Lensing, F. D.·Fourgas, E.·McNally, S.·Schabel, A.·Shah, L.·Wiggins, R.·Quiqley, E.
University of Utah Health Sciences Center
Salt Lake City, UT.

Purpose
The persistent trigeminal artery (PTA) is the most common carotid-basilar anastamosis. Persistent trigeminal artery usually is discovered incidentally on MRI and CT angiography (CTA) studies. Persistent trigeminal artery, however, becomes critically relevant in neurovascular intervention. We will review the imaging anatomy of the PTA and demonstrate the value of high-resolution MRA and CTA in characterizing this anomalous vessel.
Materials & Methods
We performed a search of the Radiology Information System (RIS) for the term "trigeminal artery" over a 10-year period (2002-2012). We retrospectively reviewed the imaging studies in 12 patients with incidental persistent trigeminal artery at our institution over the past 10 years. These imaging studies included MRI, MRA, CTA and cerebral angiograms. Special attention was directed to defining the relationship of the PTA and the posterior communicating artery to determine the Saltzman type.
Results
All cases of persistent trigeminal artery were associated with hypoplastic intracranial vertebral arteries and basilar artery proximal to the anastamosis. Of the 12 patients,

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

seven were female and five were male. The age range was 39-77 years and the mean age was 60 years. Persistent trigeminal arteries were distributed evenly between left and right. Seven of the cases had Saltzman type I, and five of the cases had Saltzman type II PTAs. Eleven of 12 patients had lateral PTAs and one of 12 had a medial PTA. One of the patients had a dural arteriovenous fistula on the contralateral side and one of the patients had a left posterior communicating aneurysm on the ipsilateral side. Two of 12 of the patients presented with vertiginous or stroke-like symptoms. Thin section CTA was performed in 6/12 (Figure). High-resolution MR imaging [defined as three-dimensional T1 or T2 (Figure) weighted imaging, time of flight magnetic resonance angiography or thin section T2-weighted imaging] was obtained in 8/12. The PTA was adequately characterized in 12/12 cases. The determination of Saltzman type was possible in 100%.



Conclusion

When a hypoplastic posterior circulation is encountered, a persistent carotid-basilar anastamosis should be suspected. The most common persistent carotid-basilar anastamosis is the PTA. High-resolution CT angiography and MRI/MRA provide useful adjuncts in characterizing the relationship of the PTA to the PCA and determining the Saltzman type. If small vertebral and proximal basilar arteries are detected on routine imaging, an abnormal vessel at the level of the persistent trigeminal artery should prompt a high resolution CT or MR evaluation to better characterize this anomalous vessel.

MR-Based Measurement of Spinal Cord Motion during Flexion of the Spine: Implications for Intradural Spinal Cord Stimulator Systems

Smittkamp, C. A.[1]·Viljoen, S.[1]·Dalm, B. D.[1]·Wilson, S.[1]·Reddy, C. G.[1]·Gillies, G. T.[2]·Howard, M. A.[1]
[1]University of Iowa, Iowa City, IA, [2]University of Virginia, Charlottesville, VA.

Purpose

We are developing the Human Spinal Cord Modulation System (HSCMS) as a new means of delivering electrical stimuli directly to the pial surface of the spinal cord for treatment of intractable pain via neuromodulation of targeted dorsal column pathways. To optimize device performance and avoid risk of injury to the spinal cord, the HSCMS implant must remain in gentle yet direct contact with the spinal cord even as it moves within the spinal canal. Functional anatomical knowledge of the spinal cord movement within the spinal canal therefore is needed to inform design requirements for the HSCMS. We have conducted an experiment to assess this movement at the anticipated lower thoracic location of the HSCMS.

Materials & Methods

The lower thoracic cord in healthy volunteers was imaged in both supine neutral and supine maximal spinal flexion positions. A bariatric MR was utilized as its larger bore size could accommodate volunteers while in the flexed position. CISS pulse sequences were selected for their high spatial frequency, allowing for the most accurate measurements. The distance between the T10 dorsal nerve root entry zone (DREZ) and T11 DREZ on the cord surface was measured in flexed and neutral positions and used as an assessment of spinal cord compression/expansion along the cranial-caudal axis. Next, the distance from the T10 DREZ to the inferior aspect of the T10 pedicle was measured. The difference in this measurement between flexed and neutral position is a measurement of cranial-caudal movement of the cord within the canal. Finally, a similar measurement was made on the conus tip to assess cranial-caudal movement at the distal-most cord.

Results

The inter-DREZ distance across all patients between the neutral and flexion positions ranged from -2.0 mm to +6.7 mm, with a mean and standard deviation of 3.5 ± 2.6 mm. The measured change in the pedicle-to-DREZ distance across all patients between the neutral and flexion positions ranged from 1.9 mm to 18.0 mm, with a mean and standard deviation of 8.5 ± 6.0 mm. The mean and standard deviation for the rostral-caudal conus movement was found to be 6.4 ± 4.1 mm within an overall range of 1.1 to 11.4 mm.

Conclusion

Although mean values for cranial-caudal movement and compression/expansion are calculated and reported as intended, much more interesting results are seen when evaluating the ranges of measurements obtained. An unexpected result was immense intersubject variability in how the spinal cord accommodates maximal flexion. Some subjects have nearly two centimeters of cranial cord movement with very little stretching while others have almost no cord movement while stretching over 25% along the measured segment. Because the spinal cord's structure and anchoring elements vary somewhat over its length, some difference in degree of motion and stretch is expected. Our measurement data further suggests that the intersubject variance in these quantities can be quite large even over a localized segment of the cord. Our findings thus highlight the need for the HSCMS design to accommodate large patient-to-patient variations in spinal cord dynamic movement properties.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Postmortem Radiology-Pathology Correlation of Recurrent Tumor after Bevacizumab Treatment and Apparent Diffusion Coefficient

Weinstein, G.·Wu, J.·Mignano, J.·Linendoll, N.·Do-Dai, D.·Madan, N.
Tufts Medical Center
Boston, MA.

Purpose
After the introduction of bevacizumab (BV) in the treatment of glioblastome multiforme (GBM), it has become increasingly difficult to separate post-treatment changes from recurrent tumor. This is because BV, an anti-angiogenesis agent, often results in recurrent tumor which doesn't enhance on Gadolinium -enhanced MRI. This study sought to determine if apparent diffusion coefficient (ADC) correlated with residual tumor when compared to histologic evaluation in patients with GBM treated with bevacizumab.
Materials & Methods
Eleven patients with GBM treated with bevacizumab consented to postmortem autopsy and inclusion in the current study. The last in vivo MRI was co-registered with a postmortem MRI, and multiple histologic samples were selected based on the presence of FLAIR signal abnormality on the in vivo MRI. Regions of interest (ROI) correlating with the areas of histologic sampling were made on the ADC maps. Histologic analysis was made by a neuropathologist, who graded the amount of tumor present in the region of interest as either absent, low, medium or high-grade (utilizing similar criteria as used to distinguish Grade 2 through 4 astrocytomas). The association between tumor grade and ADC then was evaluated using a mixed linear model with a fixed tumor grade effect and a random subject effect to account for the correlated nature of the data (R software).
Results
An overall trend was identified such that ROIs in regions without tumor had the lowest ADC values (mean 945 x 10-6 mm2/s) compared to those with low (mean 984 x 10-6 mm2/s), medium (mean 1034 x 10-6 mm2/s) or high-grade (mean 1057 x 10-6 mm2/s). A significant association was found between tumor grade and ADC, with a statistically significant difference between regions where no tumor was observed and regions where high-grade tumor was observed ($p = 0.016$). Sensitivity to outliers analysis was performed leading to the same conclusions.
Conclusion
In the setting of GBM treated with BV, higher ADC values are more predictive of tumor recurrence. However, given the high degree of variability, while this is true on a statistical basis, great care must be taken in interpreting ADC images in an individual patient. While in and of itself, ADC is not able to predict tumor recurrence, it may prove to be a useful biomarker when combined with other laboratory, immunohistochemical, clinical and/or MRI data.

Novel Finding of Optic Nerve Central T2 Hypointensity Utilizing 3T MR Imaging

Heymann, J. C.·Hakimelahi, R.·Uribe Acosta, T. E.·Cotes, C. C.·Riascos, R.
University of Texas Medical Branch
Galveston, TX.

Purpose
The improved signal-to-noise ratio of 3T MRI creates opportunities to visualize detailed anatomical features within the optic nerve. We unexpectedly observed a central T2 hypointensity within the optic nerve on MR studies obtained as a part of the NASA Flight Medicine Visual Impairment/Intracranial Pressure Protocol, which had not been described previously.
Materials & Methods
Twenty-one astronauts (two females) who had undergone MRI of the orbits with direct coronal T2 sequences between 2010 and 2012 were included retrospectively. In total, 42 eyes were evaluated. Two astronauts were in training without previous missions to the International Space Station (ISS) and exposure to microgravity. Assessments were done on direct coronal T2 fat-saturated fast-spin-echo pulse sequences obtained by a 3T MR scanner.
Results
A central T2 hypointensity was observed in 100% of both right and left eyes. It was completely visualized throughout the nerve course in 15 right eyes (71.4%) and in 19 left eyes (90.5%). The two astronauts not yet exposed to microgravity also show the central T2 hypointensity throughout bilateral optic nerves. A cylindrical T2 hyperintensity also was present in bilateral eyes in all astronauts.
Conclusion
Previous literature describes a central T2 hyperintensity at the center of the optic nerve when imaged with 1.5T MRI. In our study, we describe a new finding seen in all study participants: a central T2 hypointensity in the epicenter of the previously described hyperintensity with the increased resolution made possible by 3T imaging. We speculate that this T2 hypointensity may represent flow voids caused by the central retinal vessels. Further research is necessary to determine if changes regarding this anatomical finding could potentially predict or be seen in certain disease states affecting the central nervous system. Although this finding was seen in the two astronauts not yet exposed to microgravity, further evaluation of a normal population is needed.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

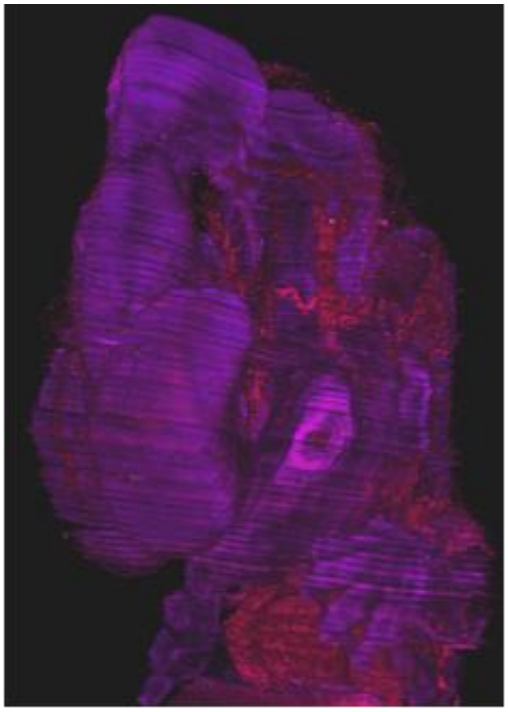
Human Embryonic Serial Anatomy: Bulbar and Pontine Venous System in Relation with the Lower Cranial Nerves

Tonnelet, R.[1]·Lhuaire, M.[2]·Labrousse, M.[2]·Braun, M.[1]
[1]Université de Lorraine, Nancy, FRANCE, [2]Université de Champagne, Reims, FRANCE.

Purpose
Since the mid 1950s, very little work has been done to contribute to a better understanding of venous vasculature development during embryogenesis. We present a new analysis method with multiplanar reformation process based on microscopic sections. This presentation focuses on the brain stem arachnoido-pial venous anastomoses evolutive morphology.
Materials & Methods
High resolution numerized microscopic continuous sections (10 to 20 µ) from Carnegie stage XIX to XXIII human embryo were used. Specific image treatment was the following : binarization- thresholding-labellization, rigid shifting, median filtration (cubic matrix) (resolution 10 µm/pixel) ; DICOM format images (1000 to 4000) are exported for post-treatment process depending on the embryonic stage and size. Angiographic rendering was obtained thanks to the eosine/hematoxylin red cell fixation within the vessels.
Results
At first step, we confirmed the embryonic status relatively to the Carnegie classification in assessing the cochlear canal orientation. The evolutive morphology of the brain stem primitive venous network is presented; at stage XIX, the initial longitudinal veins are separated from the caudal plexus. During the next stages, we demonstrate how they connected to transverse pial anastomoses. The next period (i.e., the early and late postembryonic period) show these intrinsic pial veins lying between the arteries and the brain surface leading to a progressive simplication pattern. During the stages XX to XXIII, we present the changing morphology of the trijeminal ganglion venous plexus and the relationships with CN XII, XI and X. The venous and arterial patterns are presented thanks to the possibilities of the computer program. These organizations are compared to the Padget and Streeter works.



Conclusion
We present the preliminary work of the bulbar and pontine venous embryogenesis using 3D and angiographic rendering at the early postembryonic stages and their relationships with the lower cranial nerves and ganglionic plexux and the vertebral arteries and collaterals.

Distinguishing Laryngeal Tuberculosis from Cancer by CT: A Practical Approach

Fourgas, E.[1]·Eid, M.[2]·Harnsberger, R.[1]·Wiggins, R.[1]
[1]University of Utah, Salt Lake City, UT, [2]Alexandria University, Alexandria, EGYPT.

Purpose
Tuberculosis (TB) of the larynx is a rare form of extra-pulmonary tuberculosis which can mimic laryngeal

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

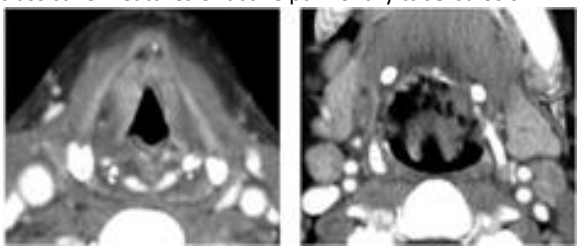
carcinoma. Because of the high infectivity of laryngeal TB, early diagnosis will alert the examining physician to the possibility of this entity, outline the extent of the disease and avoid unnecessary biopsies. The purpose of this presentation is to demonstrate the CT features of laryngeal tuberculosis and identify characteristics that help differentiate it from laryngeal carcinoma.

Materials & Methods

We retrospectively reviewed CT studies in 12 patients with laryngeal tuberculosis over a three-year period. Biopsy was performed on three patients on initial endoscopic examination. The diagnosis was established by sputum culture and complete resolution on imaging and endoscopic followup in the properly treated patients.

Results

The most common CT findings were diffuse edema and thickening of the aryepiglottic folds, vocal cords, paralaryngeal spaces and epiglottis without a focal mass (Figure). Destruction or sclerosis of the laryngeal cartilage was not present. Seven patients had associated lymphadenopathy in the mediastinum and neck including the deep cervical chain and retropharynx. In six of these patients the lymph nodes were necrotic. Three of the patients had asymmetric enhancement of the nasopharynx and one patient had abnormal enhancement and thickening of the soft palate. One patient had an associated cold abscess in the right palatine tonsil. Vocal cord mobility was not impaired in the properly treated cases. One key finding in all cases was the detection of classical CT features of active pulmonary tuberculosis.



Conclusion

The most important imaging features that aid in differentiating laryngeal tuberculosis from carcinoma are the bilateral and diffuse involvement of the anterior larynx without destruction of the laryngeal architecture and without a focal mass in the setting of pulmonary TB. The presence of associated necrotic lymph nodes, often at sites different from the expected lymphatic drainage of the larynx, also can differentiate it from laryngeal carcinoma. Additional involvement of the soft palate, nasopharyngeal mucosa and palatine tonsils provides other clues in supporting the diagnosis of tuberculosis and these structures should be evaluated carefully. Vocal cord mobility is spared in the properly treated cases of laryngeal TB whereas it often is compromised in laryngeal carcinoma.

KEYWORDS: Tuberculosis, Larynx

Yield of CT Examinations of the Neck in Patients with Globus Sensation

Alhilali, L. M.·Seo, S.·Branstetter, B.·Fakhran, S.
University of Pittsburgh
Pittsburgh, PA.

Purpose

To determine diagnostic and therapeutic efficacy of CT examinations of the neck in patients with isolated globus sensation.

Materials & Methods

We retrospectively identified patients presenting with globus sensation from January 2005 to December 2012 who underwent a CT examination of the neck. We excluded patients with a history of head and neck cancer or other known primary malignancy. We calculated the proportion of patients with abnormal findings on CT, tabulated the nature of the abnormality, and reviewed the medical records to determine whether imaging changed management.

Results

Seventy-five patients undergoing CT examinations of the neck were included (38 females, 37 males; mean age 53.3 years, range 12-91 years). Two patients demonstrated significant imaging findings that related to the history of globus sensation (2.7% diagnostic efficacy, 95% confidence interval 0.5-10.2%). One patient had prominent anterior cervical osteophytes and the second demonstrated an infected thyroglossal duct cyst. Of these, only the study with the infected thyroglossal duct cyst resulted in a change in clinical management (1.3% therapeutic efficacy, 95% confidence interval 0.1-8.2%). Incidental CT findings felt unrelated to globus sensation were six thyroid nodules, three thyroid goiters and a periapical dental abscess. On subsequent clinical followup 20 patients (26.7%) were found to have gastroesophageal reflux disease and three were found to have infectious pharyngitis (4.0%). The majority of the studies were ordered by otolaryngologists (36.0%) or primary care physicians (30.7%). Although emergency physicians only ordered 13 studies (17.3%), both of the studies with significant findings related to globus sensation were emergency department patients.

Conclusion

CT examinations of the neck in patients with isolated globus sensation are unlikely to identify clinically significant imaging findings and are very unlikely to result in a change in clinical management, with an overall therapeutic efficacy of 1.3%. Thus, the routine use of CT examinations of the neck in the evaluation of the patient with isolated globus sensation cannot be recommended.

Imaging Manifestations of Nasopharyngeal Carcinoma Subdivided by Histologic Subtype and Epstein Barr Virus Serology

Russell, D. P.·Baugnon, K. L.·Aiken, A. H.·Hudgins, P.·Muller, S.·Corey, A.
Emory University
Atlanta, GA.

Purpose
Nasopharyngeal carcinoma (NPC) has a distinct behavior compared to other head and neck cancers, particularly in regard to pathogenesis, risk factors, and treatment. Nonkeratinizing NPC has a known association with Epstein Barr virus (EBV) and often a better prognosis, while the keratinizing form, although a separate entity, is more akin to squamous cell carcinoma, with an association with alcohol and tobacco use. The purpose of this study is to review our experience with NPC, and assess for imaging trends based upon the histologic subtype and EBV serology.
Materials & Methods
Twenty-eight cases of biopsy-proven nasopharyngeal carcinoma (NPC) from 2002 through 2012 were reviewed retrospectively by two CAQ neuroradiologists. Inclusion criteria included: 1) Pathologic diagnosis of nasopharyngeal carcinoma, 2) Pretreatment CT and/or MR imaging available for review, 3) EBV serology results for cases of nonkeratinizing carcinoma. The patients were organized into three groups: keratinizing, Epstein Barr positive nonkeratinizing, and EBV negative nonkeratinizing. The pretreatment images were reviewed with regard to primary tumor volume, T stage, N status, lymph node size and number, and degree of intracranial extent. The size of the largest lymph node and number of nodes (0-3, or >3 = extensive) was recorded. Intracranial extent was further subdivided into perineural spread and frank involvement of the sella or prepontine cistern.
Results
Twenty-eight cases of NPC were subdivided into six cases of keratinizing subtype, and 22 nonkeratinizing, most of which (15) were EBV positive. The majority of cases were T4 (15/28, 53%), and N2 at diagnosis (17/28, 60%), and most (64%) had the number of lymph nodes classified as "extensive"; this was greatest in the keratinizing subtype (5/6, 83%). There was no statistically significant difference in the mean diameter of the largest lymph node amongst subtypes. The mean tumor volume was greatest in the keratinizing group, with a mean volume 36.3 cc, compared to EBV positive nonkeratinizing (29.2 cc) and EBV negative nonkeratinizing (16.4 cc). The degree of sphenoid sinus and nasal cavity involvement was greatest in the EBV positive nonkeratinizing subtype, at 50 and 53% respectively compared to EBV negative nonkeratinizing (14 and 0%) and keratinizing (20 and 0%). Similarly, while not statistically significant, there were greater numbers of cases of intracranial extension (including perineural spread and prepontine cistern/sellar extension) in the EBV positive nonkeratinizing subtype (60% and 27%), compared to EBV negative nonkeratinizing (43% and 14%) and keratinizing subtype (50% and 0%).
Conclusion
There were no statistically significant differences between the imaging appearances of the different histologic subtypes of NPC, possibly related to the power of the study, although trends were observed. The keratinizing subtype was more likely to have extensive lymphadenopathy. However, the degree of intracranial extent and local invasion (including sphenoid sinus and/or nasal cavity involvement) was greatest in the EBV positive nonkeratinizing subtype. No significant difference between the groups could be identified with regard to T stage, N status, or largest pathologic lymph node mean diameter.

Imaging Surrogates of Increased Intracranial Pressure Are Associated with Spontaneous Cerebrospinal Fluid Leaks

Espinoza, F. V.·Madan, G.·Cohn, E.·Zanation, A.·Senior, B.·Ebert, C.·Castillo, M.·Huang, B.
University of North Carolina
Chapel Hill, NC.

Purpose
The etiology of spontaneous cerebrospinal fluid (CSF) leak is poorly understood, but evidence suggests that intracranial hypertension (IH) plays a causative role. The purpose of this study was to determine whether imaging surrogates of IH are seen more commonly with spontaneous than nonspontaneous CSF leaks both overall and at specific leak sites.
Materials & Methods
A retrospective chart and imaging review of adult patients presenting to our institution with new CSF leaks between 2001 and 2012 was performed. Inclusion criteria included a previously untreated CSF leak or encephalocele confirmed either surgically or with a positive beta-2 transferrin assay and a dedicated maxillofacial CT performed at time of diagnosis. Ninety-eight patients meeting these criteria were identified, and were classified as having spontaneous (SL) or nonspontaneous leaks (NSL, postsurgical or postraumatic). The site of leak (sphenoid, cribriform/ethmoid, frontal), determined intraoperatively, also was recorded. CT images were reviewed by a single blinded neuroradiologist who estimated the midsagittal sellar area and the number (0, 1-5, 6-10, >10) and maximal size of arachnoid pits in the greater sphenoid wing and temporal bone. Seventy-five patients also underwent brain MRI which was evaluated for the presence of an empty or partially empty sella. Group comparisons were made using Student *t*-tests for continuous variables and 2-tailed Fisher exact tests for categorical variables, with $p<0.05$ indicating a statistically significant result.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Results
There were 62 SL and 36 NSL patients. Among SL patients, 41.9% of leaks were sphenoid, 51.6% cribriform/ethmoid, and 6.5% frontal. In the NSL group, 19.4% of leaks were sphenoid, 52.8% cribriform/ethmoid, and 16.7% frontal, while in four patients (11.1%) the site of leak was not identified surgically. Mean midsagittal sellar area was significantly higher overall in the SL group (131.7 mm^3 versus 95.8 mm^3, $p<0.001$). When the site of the leak was taken into account, the mean sellar area was higher in all locations in the SL group, but only significantly so in those with cribriform/ethmoid leaks (130.6 mm^3 versus 91.5 mm^3, $p=0.001$). Among those undergoing MRI, 60.8% of SL patients compared to only 33.3% of NSL patients were deemed to have an empty or partially empty sella ($p=0.046$), but significant differences were not seen at individual leak sites. Arachnoid pits were significantly more likely to be identified in SL patients than in NSL patients (72.6% versus 38.9%, $p=0.001$), and SL patients also tended to show more arachnoid pits. Arachnoid pits were more common among SL patients for all CSF leak sites, but significantly so only for those with sphenoid leaks (84.6% versus 28.6%, $p=0.009$). Among SL patients, arachnoid pits were significantly more common with sphenoid leaks than with cribriform/ethmoid leaks (84.6% versus 59.4%, $p=0.046$).
Conclusion
Three imaging parameters are more likely to be associated with SL than NSL. These include the appearance of an empty sella on MRI, the presence and number of arachnoid pits, and a larger sellar area. Interestingly, increased sella size is associated with leaks in the cribriform/ethmoid area, and the presence of arachnoid pits is associated with sphenoid leaks.

Temporal MR Imaging Evaluation of Endoscopic Multilayer Cranial Defect Reconstruction Utilizing Pedicled Nasoseptal Flap

Learned, K. O.·Adappa, N. D.·Lee, L. Y. K.·Palmer, J. N.·Newman, J. G.·Loevner, L. A.
University of Pennsylvania
Philadelphia, PA.

Purpose
Endoscopic endonasal approach (EEA) is evolving as the surgical approach of choice for resection of a spectrum of skull base pathology beyond sellar lesions. Successful endoscopic closure of the surgically created cranial defect routinely necessitates multilayer reconstruction utilizing inlay free grafts (fat packing, collagen matrix dural graft, and/or fascia lata) and mucosal onlay pedicled nasoseptal flap (NSF) based on the sphenopalatine artery. Kang et al described the characteristic enhancing C-shaped configuration of NSFs in the sphenoidectomy bed on immediate postoperative imaging following trans-sphenoidal hypophysectomy. However, the MR imaging features of the cranial defect reconstructions remain poorly understood and recognized, and frequently mistaken for neoplasm. This study aims to evaluate the normal imaging evolution of skull base reconstruction utilizing NSFs.
Materials & Methods
We retrospectively reviewed unenhanced and enhanced brain MRIs of patients following EEAs and multilayer skull base reconstructions utilizing NSFs. Nasoseptal flaps and free grafts were evaluated for temporal changes in signal intensity, enhancement, thickness, and configuration. Imaging findings were correlated with clinical followup.
Results
Eighteen patients with reconstructions utilizing 22 onlay NSFs with a combination of inlay free grafts had follow-up MRIs (2-41 months). All 18 reconstructions retracted into the skull base defects. All nine intracranial fat grafts showed progressive resorption with 50% reduction in the fat by six months and near complete resorption by 14 months. All six collagen matrix dural inlays remained $\leq$ 2 mm in size, similar to immediate postoperative exams. By 3-6 months, all six inlay fascia lata and 22 onlay NSFs demonstrated mature imaging features with little or no further change on subsequent imaging. The initial variable T2 signal and nonenhancing fascia lata became T2 hypointense, solidly enhanced and decreased in thickness by 50% (range 2-6 mm, mean 5 mm). The initial enhancement of viable NSFs persisted but the flap thickness decreased by 20-30% (range 2-7 mm, mean 5 mm). The distinct C-shaped arc and vascular pedicle leading toward the sphenopalatine foramen seen on immediate postoperative imaging were not defined as clearly due to incorporation of the flap into the denuded skull base, as well as evolving changes in signal characteristics in the sinus contents. The flap location remained unchanged. All four nonviable NSFs showed no enhancement and 1-5 mm enhancing granulation and mucosalization occurred by 2-3 months. In 25% of patients, the NSFs were misinterpreted for neoplasm.
Conclusion
Maturation and stability of multilayer endoscopic skull base reconstruction utilizing NSF appears to occur on MR imaging within 3-6 months after surgery. Identification and an understanding of the normal evolution and appearance of NSF reconstructions are essential for accurate image interpretation and to avoid its misinterpretation for neoplasm.

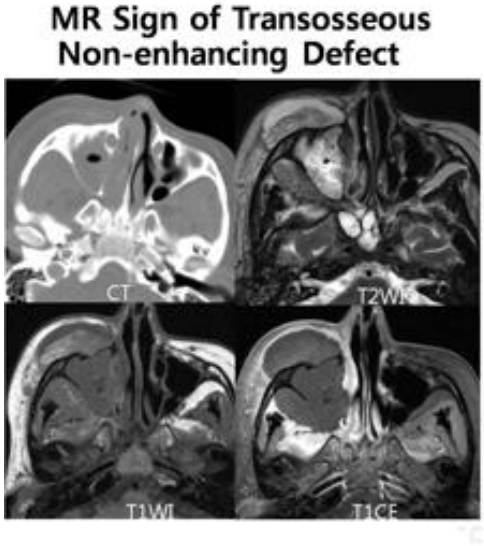
Prognostic Imaging Factor in Acute Invasive Fungal Infection of the Sinonasal Cavity: MR Sign of Transosseous Nonenhancing Defect

Kim, J.[1]·Choi, Y.[1]·Park, S.[2]·Yun, T.[1]·Choi, S.[1]·Sohn, C.[1]·Ryoo, I.[1]·Kim, S.[2]
[1]Seoul National University Hospital, Seoul, KOREA, REPUBLIC OF, [2]Seoul National University Boramae Hospital, Seoul, KOREA, REPUBLIC OF.

Purpose
Acute invasive fungal infection of the sinonasal cavity is a fatal disease that necessitates early diagnosis and treatment. However, its imaging characteristics have not been demonstrated clearly. The purpose of our study was to describe its imaging characteristics and to determine the prognostic imaging factors along with pathologic correlation.
Materials & Methods
CT and MR images of 22 consecutive patients (12 men and 10 women; age range, 2-75 years, mean age, 53 years) with acute invasive fungal infection of the sinonasal cavity were evaluated retrospectively, with particular attention to the location, bone destruction, periantral soft tissue infiltration, signal intensity and enhancement pattern on MR, with a review of the clinical records and pathologic slides. The patient age, underlying disease, immune status, performance of surgical debridement, fungus isolated, and imaging features were assessed to identify factors affecting survival by using Kaplan-Meier survival curves, the log-rank test, and the multivariate Cox proportional hazards model.
Results
Seventeen patients were immunocompromised and five patients were immunocompetent. All of them showed extrasinonasal involvement as follows; orbit (n = 10), cavernous sinus (n = 7), brain parenchyma (n = 7), masticator space (n = 3), and oral cavity (n = 1). There were bony destruction on CT in 12 (55%) patients and periantral soft tissue infiltration on CT or MR in all patients. MR showed homogeneous enhancement with low signal intensity on T2-weighted image in seven (32%) patients and transosseous nonenhancing defect in nine (41%) patients. MR sign of transosseous nonenhancing defect has not been reported and was characterized by nonenhancing round or ovoid lesion involving bony structure and periosseous soft tissue as well as primarily infected sinonasal cavity with preservation of bone integrity on CT and MR. It was correlated pathologically with coagulative necrosis by fungal angioinvasion. The MR sign was found to be an independent prognostic factor for mortality in patient with acute invasive fungal infection (hazard ratio = 4.481; 95% confidence interval (CI), 1.140-17.619). In addition, the group with the MR sign showed significantly lower survival rate than the group without the MR sign (P = 0.011).



Conclusion
Periantral soft tissue infiltration is a common imaging finding of the acute invasive fungal infection. MR sign of transosseous nonenhancing defect frequently is found and a unique prognostic imaging factor.

Trends and Safety of Endovascular Treatment of Epistaxis: A Study of the Nationwide Inpatient Sample 2003-2010

Brinjikji, W.·Kallmes, D. F.·Cloft, H. J.
Mayo Clinic
Rochester, MN.

Purpose
Patients presenting with epistaxis that is refractory to anterior and posterior packing of the nasal cavity often require more invasive measures to control their bleeding. Surgical ligation of culprit vessels has historically been the primary treatment modality in these cases; however, endovascular embolization has emerged as a viable alternative and adjunct. Using a large administrative database, we sought to determine trends in the surgical and endovascular management of epistaxis and to determine outcomes and complications associated with endovascular treatment of epistaxis.
Materials & Methods
Using the Nationwide Inpatient Sample from 2003-2010, patients with a primary diagnosis of epistaxis were selected using the *International Classification of Diseases 9th Revision* (ICD-9) diagnostic code 7847. Patients undergoing surgical ligation were identified using ICD-9 procedure codes 210.3-210.7 and patients undergoing endovascular embolization were identified using ICD-9 procedure codes 397.2 and 397.9. Trends in utilization of these procedures from 2003-2010 were examined.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Patients were stratified into three groups: 1) patients undergoing surgical ligation, 2) patients undergoing endovascular embolization and 3) patients undergoing both surgical ligation and endovascular embolization. Demographic variables and comorbidities were compared across groups. The following outcomes were assessed: in-hospital mortality, postoperative stroke, transient ischemic attack, hematoma and length of stay.
Results
A total of 69410 patients underwent surgical and/or endovascular treatment for epistaxis between 2003 and 2010. 64289 (92.6%) patients underwent surgical ligation alone for epistaxis during this time period compared to 4440 (6.4%) undergoing endovascular embolization alone and 681 (1.0%) undergoing both endovascular embolization and surgical ligation. Utilization of endovascular embolization for epistaxis increased from 2.8% of cases in 2003 to 10.7% of cases in 2010 (P<.0001). Patients undergoing endovascular embolization were significantly younger than those undergoing surgical ligation (59.1 ± 41.5 compared to 65.6 ± 42.9, P<.0001). Patients undergoing endovascular embolization were significantly more likely to have head and neck cancers (3.7%, 162/4440 compared to 0.8%, 498/64289, P<.0001) and hereditary hemorrhagic telangiectasia (2.2%, 96/4440 compared to 0.8%, 513/64289, P<.0001). Mortality rates between the two groups were similar (2.1%, 93/4440 compared to 2.1%, 1328/64289, P = 0.89). Patients undergoing endovascular embolization had significantly higher rates of stroke (0.9%, 41/4440 compared to 0.1%, 34/64289, P<.0001) and hematoma (1.9%, 83/4440 compared to 0.4%, 239/64289, P<.0001). Length of stay was similar between the two groups (5.5 ± 18.6 days compared to 5.4 ± 15.5 days, P = 0.68).
Conclusion
Utilization of endovascular embolization for treatment of epistaxis increased significantly between 2003 and 2010. Perioperative mortality rates and length of stay of endovascular embolization and surgical ligation patients are similar. However, stroke rates for patients treated with endovascular embolization are higher than those of patients with surgical ligation. More research is needed to determine which patients would benefit most from endovascular embolization compared to surgical ligation.

KEYWORDS: Endovascular therapy, ENT, Epistaxis

"Boomerang" Malleus-Incus Complex in Congenital Aural Atresia

Mukherjee, S.·Raghavan, P.·Kesser, B.
University of Virginia Health System
Charlottesville, VA.

Purpose
Patients with congenital aural atresia (CAA) have numerous associated external and middle ear abnormalities, many of which have critical implications for atresia repair and reconstructive surgery. The purpose of this study is to describe a specific fusion deformity of the malleus and incus, appearing as a “boomerang” on axial computed tomography (CT) scans, and to discuss the clinical and surgical relevance of this anomaly.
Materials & Methods
We retrospectively reviewed the charts of 18 CAA patients with the boomerang malleus-incus complex to characterize the radiographic features, to report the associated surgical findings, and to analyze postoperative hearing gains. The following imaging features were reviewed: presence of the malleus-incus fusion, the characteristic shape, attachment to stapes superstructure, and attachment to the tympanic fallopian canal.
Results
The "Boomerang” deformity always was associated with attachment of the dysplastic incus to the tympanic fallopian canal rather than to the stapes superstructure; the stapes capitulum was absent in all cases. These findings were confirmed at surgery. The ossicular deformity required removal of the boomerang malleus-incus complex with partial ossicular replacement prosthesis (PORP) reconstruction in all cases. Hearing improved significantly after surgery.

Axial (A and B) and coronal (C) CT images show the characteristic malleus incus “boomerang” fusion abnormality (A), the attachment of the incus to the fallopian canal (B) and the absent incudostapedial joint and stapes capitulum (C) at the oval window.
Conclusion
The “boomerang” malleus-incus deformity is an easily identifiable, important preoperative finding on CT imaging in patients with Congenital Aural Atresia and is associated consistently with absence of the stapes capitulum and attachment of the incus to the fallopian canal. The "boomerang" deformity requires a challenging reconstruction, one that invariably requires an ossicular prosthesis (PORP) given the lack of an incudostapedial joint. Previous work has shown that use of an ossicular prosthesis yields inferior hearing results when compared to using the patient's intact ossicular chain. Recognition of this entity preoperatively enables the surgeon to prepare for the PORP procedure.This important finding must be communicated to the referring surgeon for optimal clinical decision making, surgical planning, and patient counseling.

Identification of Endolymphatic Hydrops in Meniere's Disease Utilizing Delayed Postcontrast 3D FLAIR and Fused 3D FLAIR and CISS Color Maps

Hagiwara, M.[1]·McGorty, K.[2]·Wu, X.[1]·Nusbaum, A. O.[1]·Reaume, J.[1]·Roland, J. T.[1]·Schmit-Hoffman, J.[1]·Babb, J. S.[1]·Roehm, P. C.[1]·Fatterpekar, G. M.[1]
[1]New York University School of Medicine, New York, NY, [2]Columbia-Presbyterian Medical Center, New York, NY.

Purpose
Gadolinium contrast material has been shown to accumulate in the perilymphatic space four hours after intravenous administration. The preferential enhancement of the perilymphatic space allows for detection of the nonenhancing endolymphatic hydrops present in patients with Meniere's disease. The aim of this study was to evaluate the diagnostic utility of delayed postcontrast high-resolution FLAIR images as well as a color map of fused postcontrast FLAIR and CISS images in the identification of endolymphatic hydrops in patients with Meniere's disease.
Materials & Methods
Four hours after the intravenous administration of contrast, 3D FLAIR and CISS sequences of the inner ears were obtained on a 3T magnet in eight patients with Meniere's disease and five volunteer controls. Patients were asked to fill out a questionnaire regarding the side of involvement, symptomatology, date of initial presentation, and date of most recent episode. Color maps were generated upon fused 3D FLAIR and CISS images. Two neuroradiologists blinded to the clinical history independently reviewed the images of both inner ears (right and left) for test and control subjects; both the standard gray-scale FLAIR images and the fused color map images were reviewed independently. Agreement between readers was assessed using a kappa coefficient. Ordinal logistic regression statistical analysis was performed.
Results
Interevaluator reliability was excellent for the two independent and blinded radiologists who evaluated the scans (kappa = 0.69 for gray scale images, kappa = 0.796 for fused color map). There was no significant difference between the unaffected ears of patients with Meniere's disease and the inner ears of controls, and therefore, the two groups were combined into one unaffected ear category. According to ordinal logistic regression for correlated data, there was significant correlation between the gray scale images and color map images with the categorization of involvement ($p = 0.002$). The gray scale 3D FLAIR images demonstrated 60% sensitivity and 96.9% specificity, and the fused color map images demonstrated 78.6% sensitivity and 93.3% specificity. All patients with false negative results on the gray scale and/or color map images reported time of initial presentation to be within the past two years, whereas all of the true positive results were in patients with reported initial presentation of greater than three years prior (range 3-28 years).
Conclusion
3D FLAIR images of the inner ears obtained four hours after the administration of intravenous contrast is potentially a useful diagnostic tool in the evaluation of patients with Meniere's disease. The technique demonstrated good interobserver agreement, and the fused 3D FLAIR-CISS color map images increased diagnostic accuracy. The diagnostic accuracy proved greatest in patients with a longer history of symptomatology of greater than three years.

KEYWORDS: Meniere, FLAIR, color map

CT Findings for Diagnosis and Complications of Temporal Bone Osteoradionecrosis

Ahmed, S.[1]·Gupta, N.[2]·Hamilton, J.[1]·Garden, A.[1]·Gidley, P.[1]·Ginsberg, L.[1]
[1]University of Texas M. D. Anderson Cancer Center, Houston, TX, [2]University of Texas Houston Medical School, Houston, TX.

Purpose
The temporal bone (TB) is included in the radiation field when treating tumors of the nasopharynx, retromolar trigone, external ear, and parotid glands. Osteoradionecrosis (ORN) of the TB is a delayed, but serious complication that may arise in a small number of patients. Patients present with hearing loss, otalgia, otorrhea, and even gross tissue extrusion. Despite an incidence of 2-12% with irradiated parotid tumors, no large series of cases describing CT findings in patients with TB ORN exists in the radiology literature. The goal of this study is to describe CT findings in patients with clinical osteoradionecrosis.
Materials & Methods
Twenty patients with (1) radiation field that included the TB, (2) no evidence of tumor recurrence, and with (3) clinical diagnosis of TB ORN made between 9/10/2002 and 2/20/12 were included for review. High-resolution CT scans were evaluated by a neuroradiologist for bony, soft tissue, and intracranial abnormalities. Retrospective chart review of therapy administered was used to assign a clinical grade of mild (observation), moderate (antibiotics/hyperbaric oxygen), or severe (surgery). P values were calculated using Fisher's exact test (two-tailed).
Results
Radiation therapy had been administered for two SCCa of the skin, five primary parotid malignancies , four metastatic SCCa to the parotid, four nasopharyngeal carcinoma, two melanoma, one basal cell carcinoma, and two SCCa of the retromolar trigone. Radiation dose to the primary tumor ranged from 30 to 75.6 Gy. Time to onset of ORN from completion of RT was two years to 22 years

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

(median = 7 years). Clinical grade: mild = 7/20 patients, moderate = 8/20, and severe = 5/20. Please refer to Table 1 for description of CT findings. Of the 20 patients evaluated, 19 demonstrated exposed bone on clinical exam, 17 had otorrhea, 11 had hearing loss, and 10 complained of otalgia. Of the seven patients with clinically mild ORN, none demonstrated enhancing soft tissue or air within deep spaces, while each of these findings was present in six of 13 patients with a clinical grade of moderate or severe ORN. Three patients developed an abscess; one infratemporal fossa abscess, one Bezold's abscess, and one intracranial (temporal lobe) abscess.

Table 1. CT Findings

Clinical grade	External auditory canal erosion	Mastoid effusion	Mastoid bony Coalescence	Enhancing soft-tissue	Air within deep spaces	TMJ-condylar erosion
Mild (7)	6	6	1	0	0	0
Moderate (8)	6	7	1	3	3	2
Severe (5)	5	5	3	3	3	1
TOTAL (20)	17	18	5	6	6	3

Conclusion

Mastoid effusion and EAC erosions commonly are seen with TB ORN. Enhancing soft tissue (p = 0.05) and air within deep spaces (p = 0.05) are more likely to be seen with clinically moderate or severe TB ORN. TMJ-condylar erosion and mastoid bony coalescence also can be seen with TB ORN. Intracranial and soft tissue abscesses are serious complications that can arise. Knowledge of the CT findings and potential complications associated with temporal bone osteoradionecrosis is important for the neuroradiologist who must differentiate from tumor recurrence, with which ORN may be confused.

Persistent Craniopharyngeal Canal and Its Spectrum of Pathology

Abele, T. A.[1]·Salzman, K. L.[1]·Harnsberger, H. R.[1]·Glastonbury, C. M.[2]
[1]University of Utah, Salt Lake City, UT, [2]University of California San Francisco, San Francisco, CA.

Purpose

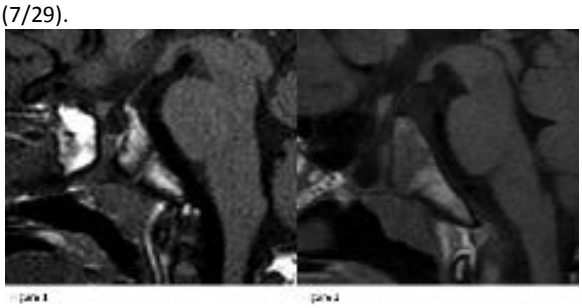
The craniopharyngeal canal is an embryonic remnant extending from the sella turcica floor to the anterosuperior roof of the nasopharynx. While formation of the canal is disputed, evidence supports its origin from incomplete closure of Rathke's pouch, the precursor of the anterior pituitary gland. Lesions related to the persistent craniopharyngeal canal are varied, ranging from small incidental canals to ectopic tumors of the adenohypophysis and associated embryonic tissues. We reviewed a series of persistent craniopharyngeal canals in an effort to improve diagnosis of this embryonic remnant and highlight the range of associated pathologic lesions. In addition, we examine the embryology and relevant literature of the craniopharyngeal canal to refine understanding of this rare entity.

Materials & Methods

Two neuroradiologists reviewed available clinical and imaging data of a series of persistent craniopharyngeal canals from multiple institutions. All cases had cross-sectional imaging studies, either CT, MRI, or both. The length and diameter at the midpoint of the canal were recorded when available. Imaging evaluation also was directed to position and morphology of the pituitary gland and associated cephalocele or neoplasm. Clinical data including presenting symptom and presence of pituitary dysfunction or other congenital malformations were reviewed.

Results

Twenty-nine patients aged 1 day - 66 years were included. Small (AP diameter range: 0.7-1.0 mm) incidental canals were observed in 31% (9/29) of patients. Medium (3.5-4.4 mm) sized canals with inferiorly displaced pituitary tissue (Figure 1) were seen in 24% (7/29) of patients. Seventeen percent (5/29) of patients had large (7.7-13.5 mm) canals associated with cephaloceles (Figure 2) while 28% (8/29) had associated tumors, including pituitary adenoma, craniopharyngioma, dermoid, teratoma, and glioma. The medium sized canals and large canals with cephaloceles all contained identifiable anterior pituitary tissue. Persistent craniopharyngeal canals are associated with pituitary dysfunction (6/29) and other congenital malformations (7/29).



Conclusion

Persistent craniopharyngeal canal is an important entity to consider in the differential diagnosis of nasopharyngeal or midline skull base lesions. Persistent craniopharyngeal canals can be divided into four types: (1) small incidental canals (2) medium sized canals with displaced or ectopic pituitary tissue, (3) large canals with associated cephaloceles, and (4) canals containing epithelial tumors of the adenohypophysis and associated embryonic tissues. Accurate diagnosis can distinguish lesions requiring surgery from those that do not. In our series the medium and large craniopharyngeal canals invariably contained pituitary tissue, which is important in surgical management of these lesions to avoid iatrogenic hypopituitarism.

Imaging Genomics: Correlation of Invasive Genomic Composition and Patient Survival Using Qualitative and Quantitative MR Imaging Parameters: A TCGA Glioma Phenotype Research Group Project

Colen, R. R.[1]·Abrol, T.[1]·Gutman, D. A.[2]·Hwang, S. N.[2]·Wintermark, M.[3]·Jain, R.[4]·Jilwan-Nicolas, M.[3]·Chen, J. Y.[5,6]·Raghavan, P.[3]·Holder, C. A.[2]·Rubin, D.[7]·Huang, E.[8]·Kirby, J.[8]·Freymann, J.[8]·Jaffe, C. C.[9]·Flanders, A.[10]·TCGA Glioma Phenotype Research Group·Zinn, P. O.[1]
[1]M. D. Anderson Cancer Center, Houston, TX, [2]Emory University, Atlanta, GA, [3]University of Virginia, Charlottesville, VA, [4]Henry Ford, Detroit, MI, [5]University of California San Diego Health System, San Diego, CA, [6]San Diego Medical Center, San Diego, CA, [7]Stanford University, Stanford, CA, [8]NCI/NIH, Bethesda, MD, [9]NCI/NIH, Rockville, MD, [10]Thomas Jefferson University Hospital, Philadelphia, PA.

Purpose
To identify the invasive MRI characteristics in GBM and the implicated genes and microRNAs associated with these invasive features. Preoperative qualitative imaging data reflective of invasive tumor grown patterns have been documented. These include the presence of either T1 contrast enhancement or increase T2/FLAIR hyperintensity involving the basal ganglia, corpus callosum (unilateral, bilateral, or contralateral,) or brainstem; the presence of subependymal enhancement; the presence of pial enhancement; and a peritumoral nonenhancing FLAIR hyperintensity. Tumor volumetry of the nonenhancing FLAIR hyperintensity also has been validated to reflect increase tumor invasion.
Materials & Methods
A total of 78 treatment-naïve GBM patients whom had both gene- and microRNA expression profiles and pretreatment MR neuroimaging were analyzed. Each image (T1 axial image both before and after gadolinium contrast administration, and axial T2/FLAIR image) was qualitatively assessed by at least three independent neuroradiologists. The standardized VASARI feature set criteria was used for qualitatively visual assessment of key features of invasion (presence of either T1 contrast enhancement of increase T2/FLAIR hyperintensity involving the basal ganglia, corpus callosum (unilateral, bilateral, or contralateral) or brainstem; the presence of subependymal enhancement; and the presence of pial enhancement; and a peritumoral nonenhancing FLAIR hyperintensity). For quantitative assessment, we performed volumetric analysis using the 3D Slicer platform to quantitatively measure actual volumes of each individual region. The flair-volume, contrast-enhancing region, and necrotic core were segmented independently and verified by a trained neuroradiologist experienced in tumor volumetry.
Results
Quantitative tumor volumetry was the strongest predictor of tumor invasive genomic targets such as POSTN ($p<.001$), a known invasive gene implicated in GBM. Qualitative features did not demonstrate similar correlations. Both qualitative and quantitative invasive signatures were predictive of patient survival. This was strongest using the qualitative parameter of involvement of the corpus callosum.
Conclusion
Invasive features of MRI as determined by both qualitative and quantitative assessment reflect tumor compositions which have genes involved in invasion. However, quantitative tumor volumetry of nonenhancing FLAIR hyperintensity continues to be the strongest predictor of highly invasive tumors and genes involved in invasion.

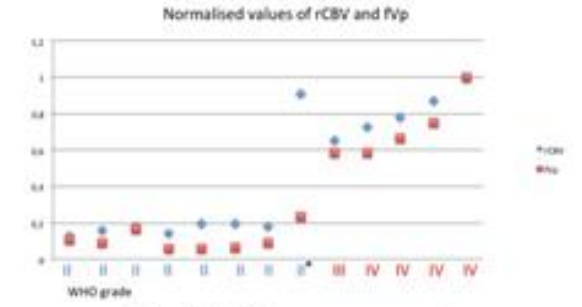
Evaluation of T2* Dynamic Susceptibility-Based Contrast-Enhanced and T1 Dynamic Contrast-Enhanced Perfusion Imaging in Glioma Grading: Comparison between Two Estimates of Vessel Compartment Volume, T2* DSC-rCBV and T1 DCE-fVp

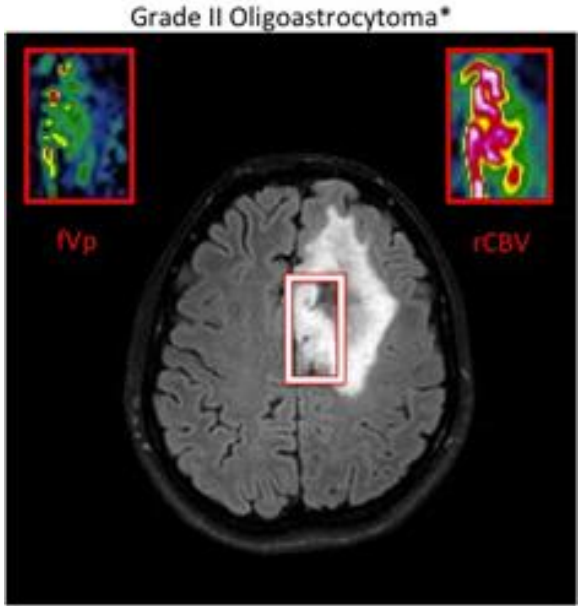
Santarosa, C.·Castellano, A.·Politi, L. S.·Terreni, M. R.·Leoncini, G.·Falini, A.·Anzalone, N.
Ospedale San Raffaele
Milano, ITALY.

Purpose
The role of relative cerebral blood volume (rCBV) from T2*-weighted dynamic susceptibility-based contrast-enhanced (DSC) MR perfusion imaging in glioma grading is established. Nevertheless limitations of DSC technique due to high sensitivity to susceptibility effects are well known. Our aim was to evaluate an alternative parameter, named fractional plasma volume (fVp), derived from a T1-weighted perfusion technique, dynamic contrast-enhanced (DCE) MR perfusion imaging. We compared estimations of vessel compartment volume given by rCBV and fVp and determined their correlation with histologic

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

WHO grade.
Materials & Methods
Thirteen patients with untreated brain gliomas (including both astrocytic and oligodendroglial histotypes) underwent DSC and DCE perfusion MR imaging with a 3.0T MRI scanner (Achieva, Philips). NordicIce software (NordicImagingLab) was used for postprocessing. Measurements of both parameters were obtained, through hotspot method, from ROI of the maximal abnormality within the lesion. Estimations of rCBVmax and fVpmax were reciprocally compared after normalization for their respective highest value in our sample. Spearman rank correlation measured associations between both parameters and histologic WHO grade.
Results
Mean values of both parameters were significantly different between low-grade gliomas (LGG) and high-grade gliomas (HGG) (LGG rCBVmax mean: 1.45; HGG rCBVmax mean: 4.44) (LGG fVpmax mean: 1.3; HGG fVpmax mean: 8.6). Normalized rCBVmax and Vpmax values were very close to each other in all cases, except for a low-grade fronto-mesial oligoastrocytoma (normalized-rCBVmax: 0.9, rCBVmax: 5; normalized-Vpmax: 0.23, Vpmax: 2.8). Correlation beetween Vpmax and WHO grade was more significant (p: 0.000) than that between rCBVmax and WHO grade (p:0.011).





Conclusion
Our preliminary results suggest that fVp is as reliable as rCBV in glioma noninvasive grading. Benefit of fVp seems to emerge when superficial brain lesions, affected by macrovessels-associated susceptibility effects, are evaluated.

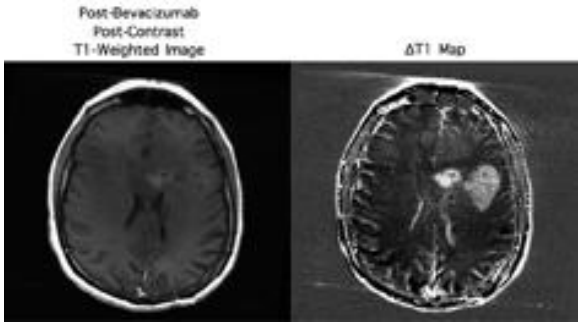
Intensity-Normalized T1 Subtraction Maps Improve Quantification of Contrast-Enhancing Tumor Burden and Predict Survival in Recurrent Glioblastoma Treated with Bevacizumab: Evaluation in a Single Institution and a Multicenter Clinical Trial

Woodworth, D. C.·Cloughesy, T. F.·Kim, H. J.·Cloughesy, J. N.·Harris, R. J.·Lai, A.·Nghiemphu, P. L.·Pope, W. B.·Ellingson, B. M.
David Geffen School of Medicine at University of California Los Angeles
Los Angeles, CA.

Purpose
In anti-angiogenic therapy for glioblastoma multiforme (GBM) patients, decreased vascular permeability and the resultant decrease in contrast enhancement in T1-weighted postcontrast MRI scans complicate treatment response assessment. The purpose of this study was to determine whether ΔT1 maps (intensity-normalized precontrast T1-weighted images subtracted from T1 postcontrast-weighted images) improve the ability to quantify contrast enhancing tumor burden and predict response in glioblastoma patients treated with bevacizumab as evaluated in both a single institution and a multicenter clinical trial.
Materials & Methods
A total of 100 patients from UCLA and 165 patients from a multicenter clinical trial (BRAIN trial) with recurrent GBM undergoing treatment with bevacizumab (Avastin; Genetech) were enrolled in this study. Pre (T1) and postcontrast T1-weighted images (T1+C) were intensity-normalized, then T1 precontrast images were subtracted from respective T1 postcontrast images, resulting in ΔT1 maps highlighting regions of subtly enhancing tumor. Tumor volumes were calculated based on regions of ΔT1 hyperintensity. Additionally, tumor volumes on standard postcontrast images were contoured for comparison.
Results
After treatment with bevacizumab, T1+C scans exhibited almost complete reduction of enhancement in more than 80% of patients; however, ΔT1 maps clearly demarcated regions of residual contrast enhancement. A pretreatment ΔT1 map-defined volume of contrast-enhancing tumor >15cc was used to identify short-term progression-free (PFS; UCLA, Log-rank, P = 0.0302; BRAIN trial, Log-rank, P = 0.0005, Cox, P = 0.001) and overall survivors (OS; UCLA,

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Log-rank, P = 0.0184; BRAIN, Log-rank, P = 0.0001, Cox, P7.5cc was used to identify short-term PFS (UCLA, Log-rank, P = 0.0089; BRAIN, Log-rank, P<0.0001, Cox, P<0.001) and OS (UCLA, Log-rank, P = 0.0204; BRAIN, Log-rank, P<0.0001, Cox, P<0.001). Additionally, a >25% decrease in enhancing volume identified long-term PFS (UCLA, Log-rank, P = 0.0041; BRAIN, Log-rank, P = 0.0030); however, this change could only stratify OS in the single institution data (UCLA, Log-rank, P = 0.0110) but not in the clinical trial data (BRAIN, Log-rank, P = 0.0509). Cox regression including interaction tests suggests a significant predictive advantage of ΔT1 maps compared with standard T1+C-defined volumes for both PFS and OS.



Conclusion
The ΔT1 mapping technique improves visualization and quantification of tumor burden in evaluation of response to anti-angiogenic therapy. Initial, residual, and the change in ΔT1 map-defined contrast enhancement before and after bevacizumab are all predictors of response and survival in recurrent GBM.

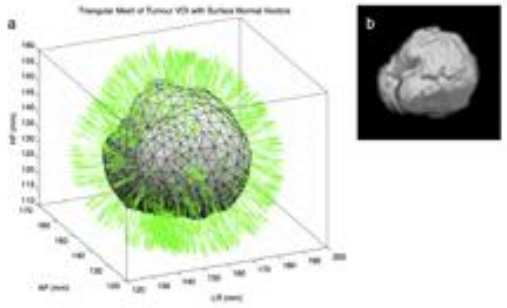
Tumor Boundary Mapping: A Novel Technique for Assessing Tumor Heterogeneity and Deriving a Predictive Biomarker of Outcomes in Glioblastoma Multiforme

Thompson, G.[1]·Mills, S. J.[2]·Jackson, A.[1]
[1]University of Manchester, Manchester, UNITED KINGDOM, [2]Salford Royal NHS Foundation Trust, Salford, UNITED KINGDOM.

Purpose
Glioblastoma multiform (GBM) is the most aggressive primary brain tumor, with dismal clinical outcomes despite advances in chemoradiotherapy. Failure is most commonly adjacent to the original tumor site, occurring within the radiotherapy planning field in the majority of cases. This has been attributed to the presence of microinvasive infiltrating disease - undetectable by standard clinical MR sequences - emanating from the visible, solid tumor edge. These cells exhibit a migratory rather than mitotic phenotype, and are more radioresistant. We previously have presented a modified imaging biomarker of the tumor edge which was based on the boundary change in apparent diffusion coefficient (ADC) between solid enhancing tumor and surrounding parenchyma. This ADC transition coefficient (ATC) was hypothesized to represent tumor invasiveness, and was found to be predictive of overall survival in a retrospective cohort of 22 GBM. An updated technique in which the tumor surface was mapped in three dimensions (ATC-3D) rather than in select axial points in 2D was developed and tested in a prospective validation cohort.
Materials & Methods
Twenty-four patients with subsequently histologically-proven GBM were imaged at 3T prior to surgery. The tumor surface was manually delineated in 3D on a 1mm isotropic postcontrast image. This was coregistered to a 2mm isotropic ADC map from 15-direction DTI. Tumor surface normal vectors were calculated for each surface voxel (Figure), and the ATC was derived. A summary mean ATC was taken as the ATC-3D. This produced both a summary tumor value for comparison with time to progression (TTP) using Cox regression analysis, and a map denoting tumor surface heterogeneity as a function of local ATC. Permeability and quantitative magnetization transfer imaging also were acquired, and spatial correlations were investigated between the local ATC-3D and a variety of vascular and structural imaging parameters.
Results
ATC-3D was predictive of TTP in the prospective cohort (HR=0.986;p=0.028). Spatial correlations also were described between ATC-3D and boundary K^{trans} and v_e from DCE-MRI, and RM_0^A from qMT (p<0.0005).



Conclusion
Presented here is a prospective validation study of a novel imaging biomarker which predicts clinical outcomes in GBM based on the tumor surface diffusion characteristics. This tumor boundary mapping has implications for treatment decisions and may be useful for stratifying patients at presentation. Furthermore, there is added value for identifying areas of differential tumor invasiveness and vascularity, particularly in combination with other advanced imaging parameters, which may help guide surgery and radiotherapy to improve outcomes.

Perfusion MR Imaging Outperforms Diffusion MR Imaging in Differentiating Radiation Injury from Recurrent Tumor in Treated High-Grade Gliomas

Prager, A. J.·Martinez, N.·Zhang, Z.·Beal, K.·Young, R.
Memorial Sloan Kettering Cancer Center
New York, NY.

Purpose
The objective was to assess the utility of diffusion-weighted imaging (DWI) and dynamic susceptibility contrast (DSC) perfusion imaging in differentiating between post-treatment change and recurrent tumor in patients with high-grade gliomas (HGGs).
Materials & Methods
We retrospectively examined 68 consecutive patients with HGGs (primary glioblastoma and anaplastic astrocytoma) who received standard treatment consisting of surgical resection followed by radiation therapy with temozolomide, and then developed increasing enhancing mass lesions indeterminate for radiation injury or recurrent tumor. All patients underwent surgical resection of their indeterminate lesions with diagnosis assigned by pathology results as: radiation injury (no tumor cells) or recurrent tumor (any amount of tumor cells). MR imaging before repeat surgery included contrast T1-weighted imaging, DWI with ADC maps and DSC perfusion imaging. Region-of-interest (ROI) analysis was performed by manually drawing an ROI around the entire contrast-enhancing lesion while excluding areas of necrosis and hemorrhage, then applied to the ADC and DSC maps to calculate ADC_{mean} and $rCBV_{lesion}$ values. In addition, up to four small ROIs (approximately 50mm^2) were placed within the contrast-enhancing lesion to calculate ADC_{ROI}, $rCBV_{ROI,}$ percentage signal recovery (PSR_{ROI}), and relative PH (rPH). Statistical analysis was performed with Wilcoxon rank sum tests with false discovery rate corrected p values for multiple comparisons (ADC p = .05/3 = .0167 and rCBV p = .05/4 = 0.0125). Receiver operating characteristics (ROC) curves also were calculated.
Results
Eleven of the 68 patients (16%) had radiation injury, while 57 patients (84%) had recurrent tumor only (n = 18) or recurrent tumor mixed with treatment effects (n = 36). ADC_{mean} was significantly lower for recurrent tumor group (median = 0.00138 mm^2/s) than for radiation injury (median = 0.00157 mm^2/s) with p = 0.005. $rCBV_{lesion}$ was significantly higher for recurrent tumor (median = 1.81) than for radiation injury (median = 1.02) with p = 0.003. $rCBV_{roi}$ also was significantly different between recurrent tumor (median = 2.98) and radiation injury (median = 1.7) with p = 0.011. The area under the ROC curve (AUC) for distinguishing between radiation injury and recurrent tumor was 0.75 for ADC_{mean} and 0.86 for $rCBV_{roi}$. An ADC_{mean} threshold of 0.0014 had a sensitivity of 53.6 and specificity of 90.9, while an $rCBV_{lesion}$ threshold of 1.27 had the best sensitivity (86.8) and specificity (83.8) overall.
Conclusion
Higher perfusion and lower diffusion were seen in recurrent tumor compared to radiation injury groups. Perfusion showed the best sensitivity and specificity, and $rCBV_{lesion}$ outperformed ADC_{mean} in differentiating radiation injury from recurrent tumor in patients with HGGs. Measuring the entire lesion on a single slice performed better than small fixed ROIs.

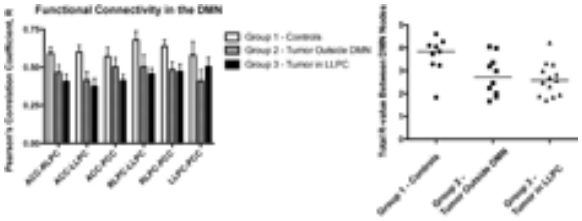
Alterations in Functional Connectivity of the Default Mode Network in Malignant Glioma Patients as Measured by Pseudo Resting-State Functional MR Imaging

Harris, R. J.·Bookheimer, S.·Cloughesy, T. F.·Pope, W. B.·Ellingson, B. M.
David Geffen School of Medicine at University of California Los Angeles
Los Angeles, CA.

Purpose
Recent fMRI experiments have shown that correlated fluctuations of the BOLD signal within specific brain regions occur in the absence of stimuli, a phenomenon known as “resting-state networks”. The most prevalent of these is the default mode network (DMN), with nodes appearing in the anterior cingulate cortex (ACC), posterior cingulate cortex (PCC), left lateral parietal cortex (LLPC), and right lateral parietal cortex (RLPC). We hypothesize that malignant gliomas infiltrating anatomical regions adjacent to a node of the DMN will cause decreased functional connectivity between DMN nodes across the entire network, including distal nodes not anatomically affected by bulk tumor.
Materials & Methods
Twenty-four malignant glioma patients with presurgical task-activation fMRI data and data from nine healthy control subjects (Group 1) were included in this study. Ten patients had tumor in the left hemisphere outside DMN nodes (Group 2) and 13 had tumors in the LLPC node (Group 3). Functional tasks were regressed out of the block paradigm, leaving the “pseudo”-resting state fMRI signal. Four ROIs corresponding to the primary notes of the DMN were placed using a standard DMN template. Quantification of “functional connectivity” between nodes was determined using a Pearson’s correlation coefficient, R, between the averaged DMN ICA time series data for each pairs of nodes. This correlation coefficient then was compared across groups and nodes.
Results
In general, functional connectivity as measured using the correlation coefficient was suppressed in tumor patients (Groups 2 and 3) when compared with controls (Group 1). Specifically, functional connectivity (R-value) was significantly different across groups (2-way ANOVA,

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

P<0.0001), but not across nodes (P = 0.503). Bonferroni-corrected post-tests showed no difference in connectivity between groups for any of the individual nodes. A one-way ANOVA and Tukey's multiple comparisons test confirmed a significant difference between the connectivity of normal controls (Group 1) versus tumor patients (Groups 2 and 3; P<0.05). No significant difference in functional connectivity was observed between patients that had tumors in or outside the LLPC node (P>0.05); however, patients with tumors inside the LLPC node tended to have a lower connectivity compared to patients with tumors outside this node.



Conclusion
This study supports the hypothesis that diffusely infiltrating malignant gliomas globally impair functional connectivity within the DMN. Additionally, tumors localized to a node within the DMN tended to decrease connectivity to a larger extent than tumors outside these regions.

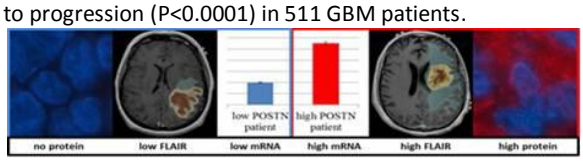
Results of the First Study Validating MR Imaging as a Screening Tool for Genomic Target Discovery for Therapeutic Drug Development

Colen, R. R.[1]·Zinn, P. O.[1,2]
[1]M. D. Anderson Cancer Center, Houston, TX, [2]Baylor College of Medicine, Houston, TX.

Purpose
The search for an effective therapy of glioblastoma multiforme (GBM) continues. Imaging genomics, a newly emerged field, links gene expression profiles with MRI phenotypes (Zinn et al, 2011). MRI-FLAIR was found to correlate with cellular invasion in GBM; thus, whole genome quantitative imaging analysis can reveal functional microRNA-gene regulatory networks as novel targets for cellular invasion in GBM.
Materials & Methods
We performed radiogenomic mapping of MRI and corresponding genomic data in 78 TCGA patients. The top microRNA-gene regulatory network was validated biologically by luciferase reporter assays, gain and loss of function using tet-inducible lentiviral microRNA expression systems, as well as si/shRNA, small molecule inhibitor/recombindant protein in vitro experiments and in vivo orthotopic xenograft models. Small animal 7T MRI-T2/FLAIR was used for imaging-genomic validations.
Results
The top up-regulated gene in high invasion MRI phenotypes was PERIOSTIN (POSTN). The top down-regulated microRNA (miR-219) was validated to bind to POSTN. Glioblastoma-derived stem cells (GSCs) from high FLAIR GBM patients correlated with levels of POSTN and increased invasion in vitro and in orthotopic xenograft tumor models on histological sections and MRI. Functionally, miR-219 overexpression reduced POSTN protein levels, while recombinant POSTN, neutralizing antibody, and shRNA experiments significantly altered cellular invasion in vitro and in vivo. MRI-T2/FLAIR signal highly correlated with POSTN levels and the degree of cellular invasion in orthotopic xenograft models. Furthermore, high POSTN and a high POSTN/miR-219 signature resulted in decreased survival and shorter time to progression (P<0.0001) in 511 GBM patients.



Conclusion
In this study, we validated a novel noninvasive diagnostic method to screen for functional networks of cellular invasion. POSTN inhibition can be a novel therapeutic approach to target invasion in GBM. Furthermore, targeted individualized molecular therapies can be based on diagnostic imaging-genomics and can be monitored throughout the treatment period.

Combining Diffusion and Perfusion to Differentiate Tumor from Bevacizumab-Related Restricted Diffusion

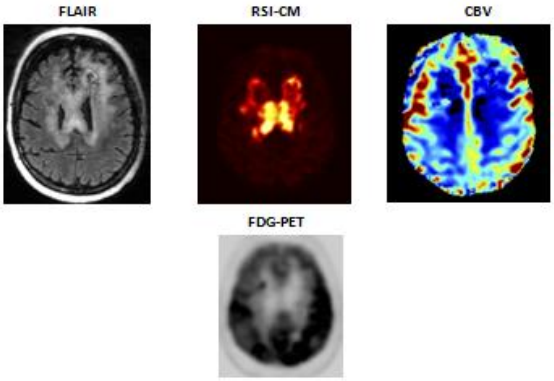
Farid, N.[1]·Almeida-Freitas, D.[1,2]·White, N. S.[1]·McDonald, C. R.[1]·Muller, K. A.[1]·VandenBerg, S. R.[1]·Dale, A. M.[1]
[1]University of California San Diego, San Diego, CA, [2]University of Sao Paulo, Sao Paulo, BRAZIL.

Purpose
With the increasing use of antiangiogenic agents in the treatment of high-grade gliomas and to a lesser extent in the treatment of brain metastases, we are becoming increasingly aware of distinctive imaging findings seen in a subset of patients treated with these agents. Of particular interest is the development of regions of marked and persistent restricted diffusion which have been shown previously to correlate with improved outcomes. Histopathologic data from these regions reveal areas of atypical gelatinous necrosis rather than viable tumor. Our goal was to quantify the degree of restricted diffusion and the cerebral blood volume (CBV) within these "pseudostroke" lesions (i.e., regions of marked persistent restricted diffusion) in order to develop an algorithm by

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

which to differentiate these lesions from viable tumor.
Materials & Methods
Five patients with high-grade glioma and one patient with brain metastasis from NSCLC who developed pseudostroke lesions after the initiation of bevacizumab were included in this study. Five presurgical, treatment-naïve controls with high-grade glioma also were included. Restriction-spectrum imaging (RSI), an advanced DWI technique, was used to create RSI-cellularity maps (RSI-CM) and these were coregistered with CBV maps. Within the pseudostroke lesions, mean RSI-CM intensity values and mean CBV values were calculated and compared to that of the presurgical high-grade gliomas as well as to that of the contralateral NAWM.
Results
Mean RSI-CM intensity values were significantly higher in patients with pseudostroke lesions compared to the treatment-naïve high-grade glioma controls ($p < .05$). Furthermore, mean CBV values were significantly lower in patients with pseudostroke lesions compared to the contralateral NAWM ($p < .01$). Of note, in one patient with a presumed nodule of viable tumor within a large pseudostroke lesion, there was focal increased CBV within this nodule. Histopathologic evaluation of one of the pseudostroke lesions demonstrated necrotic tissue as well as scattered inactive tumor cells.

Fig 1: 45 year old female with GBM who developed a "pseudostroke" lesion which persisted for 11 months after initiation of bevacizumab. Presumed nodule of viable tumor in the right frontal lobe within the pseudostroke lesion which demonstrates elevated CBV and FDG avidity.



Conclusion
When evaluating areas of restricted diffusion in patients with high-grade glioma or brain metastases treated with bevacizumab, one can utilize the RSI-CM intensity values and the CBV values in order to determine whether these areas represent predominantly necrotic tissue related to bevacizumab treatment or viable tumor. Bevacizumab-related restricted diffusion demonstrates RSI-CM intensity values greater than tumor and CBV values lower than the contralateral NAWM.

High-Grade Gliomas and Solitary Metastases: Differentiation by Using Peritumoral Perfusion and Proton Spectroscopic MR Imaging

Sparacia, G.[1]·Sparacia, B.[1]·Robusto, V.[2]·Gadde, J.[3]·Iaia, A.[3]
[1]University of Palermo, Palermo, ITALY, [2]University of Messina, Palermo, ITALY, [3]Christiana Care Health System, Newark, DE.

Purpose
To evaluate whether peritumoral perfusion-weighted and proton spectroscopic MR imaging can be used in preoperative grading and differentiation of primary gliomas and solitary metastases.
Materials & Methods
Ten low-grade gliomas, eight high-grade gliomas, and five metastases were prospectively evaluated by MR imaging, dynamic susceptibility contrast-enhanced perfusion imaging and single-voxel proton MR spectroscopy before surgical resection or stereotactic biopsy. Normalized rCBV values from peritumoral areas were calculated by using regions of interest (ROIs) of 2cm2 drawn around the nonenhancing peritumoral T2 lesion and the contrast-enhancing lesion. Metabolite ratios were measured from peritumoral areas. Tumor grade determined with normalized rCBV values and MR spectroscopy from peritumoral areas was compared with that from histopathologic grading. A ROC analysis was performed to determine which parameters best increased diagnostic accuracy in grading and differentiation of primary gliomas and solitary metastases.
Results
The mean differences of rCBV values between low-grade gliomas and high-grade gliomas ($P < .001$); high-grade gliomas and metastases ($P < .001$); and low-grade gliomas and metastases ($P < .001$) were significant. A clear rCBV cutoff value of 2.6 was detected for differentiation of low-grade gliomas (1.6) versus high-grade gliomas (3.4). Cutoff rCBV values of 1.1 and 1.98 were quite effective in differentiation of metastases from low-grade gliomas and high-grade gliomas, respectively. The overall efficacy of rCBV was higher in grading than in differentiation. Choline to creatine ratio in the peritumoral regions of high-grade gliomas were significantly higher than they were in the metastases. NAA/Cr tumor ratio of <0.44 has the higher probability for a neoplasm to be a high-grade glioma.
Conclusion
Although conventional MR imaging characteristics of solitary metastases and primary gliomas may sometimes be similar, the peritumoral perfusion-weighted and spectroscopic MR imaging enable distinction between the two. Moreover perfusion-weighted imaging technique is complementary technique for glioma grading.

KEYWORDS: Glioma, Metastases, Perfusion MR Imaging, MR Spectroscopy

Semi-Automated Measurement of Recurrent and Residual Disease in Glioblastoma Multiforme: A Potential New Objective Metric

Chow, D.·Qi, J.·Guo, X.·Mathew, N.·Miloushev, V.·Filippi, C.·Zhao, B.·Lignelli, A.
Columbia University
New York, NY.

Purpose
Glioblastoma multiforme (GBM) is an invasive and highly aggressive tumor. Though outcomes are highly variable and difficult to predict, there is some consensus that resection provides symptomatic relief and cytotoxic reduction to augment adjuvant therapy. A limitation in postoperative monitoring has been the lack of objective measures to quantify residual and recurrent disease. Automated computer-assisted analysis of contrast-enhancing tissue represents a potential tool to aid the radiologist in following these patients. In this study, we aim to describe our initial results when comparing automated measures to neuroradiologists' reports.
Materials & Methods
This retrospective study included patients with native glioblastomas with postoperative MR imaging in the immediate 24-48 hour and two-three month follow-up period. All patients received XRT with concurrent TMZ following maximal resection. Tumor contours were delineated on immediate and two-month postsurgery contrast-enhanced T1-weighted images using a semi-automated algorithm that combines the region-based active contours and level set approach. Discrepancies between neuroradiologists' reports and automated detection measurements were assessed. Radiologist reports were divided into decrease enhancement, no significant change, or increase/new enhancement.
Results
A total of 21 patients were included in the study. Decreased enhancement, no significant change, and increased/new enhancement was seen in 14.3% (3/21), 19.0% (4/21), and 66.7% (14/21) of patients respectively. Within these categories, automated detection showed discrepancy in 0% (0/3) of patients with decreased enhancement, 100% (4/4) of patients with no significant change, and 14.3% (2/14) of patients with increased/new enhancement.
Conclusion
Our initial results reveal high concordance between the radiologist report and automated techniques in patients with decreasing enhancement and increasing/new enhancement. The discrepancy seen in patients with no significant change likely stems from the fact that small changes often are attributed to difference in technique. This highlights that automated and objective measures may be important for following patients after glioblastomas resection to potentially monitor and direct patient-specific management.

Bevacizumab: Radiation Combination Produces Restricted Diffusion on MR Imaging

Hesselink, J. R.·Barkovich, M.·Farid, N.·Kesari, S.
University of California San Diego Medical Center
San Diego, CA.

Purpose
To evaluate the effect of bevacizumab on the diffusion properties of irradiated brain gliomas.
Materials & Methods
Imaging studies and medical records of 39 patients undergoing treatment for brain tumors were reviewed to determine the cause of diffusion restriction on post-treatment MRI.
Results
Diffusion restriction on MRI was found in eight patients with cerebral gliomas. All patients received radiation followed by bevacizumab therapy. The diffusion restriction appeared three-four weeks after starting the bevacizumab therapy and persisted up to 18 months. The areas of restricted diffusion showed low T1 and mildly increased T2 signal intensity, no contrast enhancement, and low cerebral blood volume on perfusion MRI. Restricted diffusion typically was observed in areas of the tumor that received relatively high doses of radiation. Areas of restricted diffusion were not metabolically active on MR spectroscopy or PET. One brain biopsy and another autopsy revealed radiation necrosis.
Conclusion
Bevacizumab treatment in combination with radiation therapy of cerebral gliomas is associated with restricted diffusion on MRI.

Thrombosis of Dural Venous Sinuses in Fetuses: Imaging Manifestations and Clinical Outcome

Shifrin, A.[1]·Feygin, T.[2]·Licht, D. J.[2]·Bilaniuk, L. T.[2]·Vossough, A.[2]·Pollock, A. N.[2]·Zimmerman, R. A.[2]
[1]Mount Auburn Hospital, Cambridge, MA, [2]The Children's Hospital of Philadelphia, Philadelphia, PA.

Purpose
To describe imaging findings in a series of cases of fetal dural venous sinus thrombosis on fetal US and MR, and to evaluate the clinical outcomes of these patients on short- and long-term postnatal followup.
Materials & Methods
The cases for this study were selected retrospectively from fetal MR imaging performed at the Children's Hospital of Philadelphia between 2002 and 2012 on a 1.5T scanner for suspected fetal anomalies on obstetric ultrasound. All selected cases demonstrated an abnormal fetal MR appearance of the dural venous sinuses.
Results
A total of 12 cases of suspected fetal dural venous sinus thrombosis was identified on MR. Gestational age at the time of diagnosis varied from 19 to 34 weeks. The indications for fetal MR were varied, including one case of cleft lip and palate, one case of cervical lymphangioma, two cases of arachnoid cyst, three cases of vermian hypoplasia, and five cases of suspected intracranial hemorrhage and possible thrombosis. In seven cases, dural venous sinus thrombosis was an unexpected imaging finding. There was variable extent of thrombosis among these 12 cases, from isolated thrombus in the torcula to massive thrombus of the sagittal, transverse, and straight sinuses as well as the internal cerebral veins. Five cases were further complicated by the presence of mild hydrocephalus. None of the cases revealed any parenchymal changes. Of these 12 cases, nine had postnatal follow-up imaging at our institution. The duration of follow-up imaging varied from three months to five years. All nine of these patients did not show any developmental or neurologic deficit. Postnatal imaging demonstrated spontaneous resolution of dural venous thrombus in three patients, with small residual thrombus apparent in one patient, which did not result in any clinical complication. Two patients were found to have associated venous malformations: one fetal MR showed presence of additional extra-axial venous anomalies which persisted on postnatal follow-up imaging, while another case demonstrated extensive developmental venous anomalies in the posterior fossa, likely a compensatory mechanism for in utero venous obstruction. Workup of coagulopathy in all of the mothers and children was negative.
Conclusion
It is important to recognize the imaging manifestations of this unusual pattern of fetal dural venous sinus thrombosis. Fetal MR provides accurate information about thrombus extension and possible complications, such as mild hydrocephalus, and presence of additional venous anomalies. In our case series, fetal dural venous sinus thrombosis has an apparent favorable long-term clinical outcome.

Screening CT Angiography for Pediatric Blunt Cerebrovascular Injury, with Emphasis on the Cervical "Seatbelt Sign"

Desai, N. K.·Chokshi, F. H.·Kang, J.
Emory University
Atlanta, GA.

Purpose
Despite its low incidence (0.03%-0.09%), blunt cerebrovascular injury (BCVI) has potentially catastrophic neurologic outcomes. There are currently, however, no standard screening guidelines to evaluate BCVI in children, especially those with a cervical "seatbelt sign"; this is a physical sign that often prompts clinicians to pursue CT angiography (CTA) of the neck. The purpose of this retrospective study is to further understand the risk factors associated with BCVI by examining various clinical and radiologic findings on CTA of the neck and adjunct imaging studies.
Materials & Methods
IRB approval was obtained. From a secure database of trauma patients at a level 1 pediatric trauma center, radiology reports between 2002 and 2012 were queried for the keywords "CTA Neck." The electronic medical record (EMR) was reviewed for pertinent clinical history, including mechanism of injury, Glasgow Coma Scale (GCS), and physical exam findings. Reports from adjunct radiographic, CT, and MR imaging studies performed during the initial trauma encounter were reviewed for internal carotid (ICA), common carotid (CCA), and vertebral artery (VA) injury, intracranial hemorrhage (ICH), and fractures of the cervical spine, skull base, maxillofacial region, ribs, and clavicle. Patients with penetrating injury or without history of trauma were excluded. Findings were recorded by two neuroradiologists. Data were analyzed for

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

both descriptive and inference-based statistics.
Results
Over the ten-year period, 463 patients underwent CTA of the neck for various indications, of which 136 had blunt neck trauma. Eighty-six were involved in motor vehicle collisions (MVC). Nine vessels (n = 4 VA, n = 4 ICA, n = 1 CCA) in eight total patients ultimately were diagnosed with various grades (I-IV) of BCVI representing 5.8% of the screened population. Two patients with vertebral artery (VA) injury had no cervical spine fractures, whereas both c-spine fractures and VA injury were found in two additional patients. Although not statistically significant, patients with BCVI had a higher tendency to have additional traumatic injuries, primarily basilar skull fractures (p-value 0.22) and ICH (p-value 0.27). All patients with BCVI had at least one injury. One patient developed infarction in this series; another had nonlocalizing neurologic complaints. Of 42 patients having documented cervical “seatbelt sign” from MVC, none had BCVI.
Conclusion
Blunt cerebrovascular injury is a very uncommon occurrence in the pediatric trauma population. Although no single risk factor was statistically significant in predicting vascular injury in this series, there was a tendency for those with vascular injury to have multiple risk factors, especially basilar skull fractures and ICH. One of the most common indications for neck CTA, the cervical “seatbelt sign”, was not associated with BCVI. These findings suggest that the cervical “seatbelt sign” in children may not be an appropriate reason to perform neck CTA, especially if it is found in isolation. In the current climate of radiation awareness and ALARA (As Low As Reasonably Achievable), cessation of screening CTA of the neck for BCVI may help us “image gently.” Larger, multicenter trials of BCVI should be undertaken before continuing this screening practice.

Brain Parenchymal Signal Abnormalities Associated with Developmental Venous Anomalies in Children and Adolescents

Linscott, L.·Jones, B.·Leach, J. L.
Cincinnati Children's Hospital Medical Center
Cincinnati, OH.

Purpose
Developmental venous anomalies (DVAs) frequently are identified on MR imaging of the brain and typically are considered normal anatomical variants. Developmental venous anomalies can be associated with cavernous malformations (CMs), venous infarction, and signal abnormalities. Associated signal abnormalities have been evaluated in adults but not in children. This study was performed to evaluate the prevalence of brain parenchymal abnormalities subjacent to DVAs in children and adolescents, correlating with DVA morphology and location. This complements previous studies in adults and contributes to our understanding of the natural history of DVAs.
Materials & Methods
Two hundred eighty-five patients with developmental venous anomalies identified on contrast-enhanced brain MRI from 11/2008 - 11/2012 were identified using a radiology database search engine. The examinations were reviewed by a neuroradiologist and pediatric radiology fellow and data were collected regarding the following: location, depth, direction of draining vein, associated cavernous malformations, and associated increased signal intensity on FLAIR and T2-weighted images.
Developmental venous anomalies morphology was described using a previously published system. Exclusions included: subjects with diseases causing multifocal parenchymal signal abnormalities (e.g., TS and NF type 1), surgery or tumor in the DVA drainage territory, Sturge-Weber syndrome, or dural AV fistulas.
Results
Of the 285 subjects identified, 172 met inclusion criteria. Mean age was 11.5 years (+/- 6.3 years) with 91 males and 81 females. In these 172 subjects, 193 DVAs were identified. Of these 193 DVAs, 11 (5.7%) had associated cavernous malformations. Twenty-eight (14.5%) of the 193 DVAs had associated signal-intensity abnormalities in their drainage territory. Six of the 28 DVAs with signal-intensity abnormalities were associated with cavernous malformations. After excluding the DVAs with associated CMs, an adjusted prevalence of 22/182 (12.1%) for associated signal-intensity abnormalities was obtained. Twenty-one of 148 (14.2%) of lobar DVAs had associated signal versus 1/38 (2.6%) of nonlobar DVAs (p = 0.05). Seven of 26 (27%) periventricular DVAs had associated signal abnormalities versus 7/94 (7.4%) juxtacortical or subcortical DVAs (p = 0.02). Fifteen of 69 (21.7%) deep or bidirectional draining DVAs had associated signal abnormalities versus 7/118 (6%) superficial draining DVAs (p = 0.002). The mean age of subjects with DVAs associated with signal abnormalities was 8.3 years versus 11.5 years in subjects without associated signal abnormalities (p = 0.045). There was a trend toward more males with signal abnormalities than females, but this was not statistically significant (p = 0.34).
Conclusion
Signal abnormalities detectable by standard clinical MR images were identified in 12.1% of consecutively identified DVAs. This is similar to the prevalence identified in prior investigations of adult patients, suggesting the underlying pathology of these signal abnormalities arises early in human development. Etiology of these signal intensity abnormalities remains unclear, but may be related to early vascular insult leading to formation of the DVA or secondary to altered vessel hemodynamics in the DVA drainage territory. Signal intensity abnormalities are

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

associated more commonly with younger age, lobar location, periventricular depth, and deep venous drainage.

KEYWORDS: Developmental venous anomalies, Venous drainage

Loss of Gray-White Matter Differentiation of the Temporal Pole in Children with Temporal Lobe Epilepsy: A Neuroradiologic Blind Spot

Desai, N. K.·Olson, L.·Saindane, A. M.
Emory University
Atlanta, GA.

Purpose
Temporal lobe epilepsy (TLE) in children may be secondary to a variety of neoplastic and non-neoplastic causes. An especially subtle finding in some patients with TLE is blurring of the gray-white junction (GWJ) at the temporal pole, with or without mesial temporal sclerosis (MTS), suggesting regional gliosis and/or dysplasia. The purpose of this study was to evaluate the salient MRI and PET findings of this often overlooked entity.
Materials & Methods
Retrospective query of radiology reports was performed using the keyword “anterior temporal” and “temporal pole” for studies between 2008-2012 at a tertiary pediatric referral center after IRB approval. MR imaging and PET examinations were reviewed in a blinded fashion by a pediatric neuroradiologist. After review, patients with all pathologies not resulting in primary blurring of the GWJ at the temporal pole, such as discrete mass lesions, were excluded. Any lesion extending beyond the temporal lobe also was excluded. Each imaging report also was reviewed at a separate session. The electronic medical charts of those patients with blurred gray-white matter at the temporal pole were reviewed for pertinent seizure history.
Results
Five hundred seventy-eight patient reports over a five-year period were retrieved. Five hundred twelve patients were excluded before image review as the temporal pole was being referred to in an insignificant manner. Sixty additional patients were excluded secondary to discrete well defined pathology suggestive of neoplasm, well defined cortical dysplasia and vascular malformations. After exclusion criteria, six total patients remained, all of whom had subtle blurring of the GWJ at the temporal pole. One patient had bilateral findings. This finding was identified prospectively on the initial MRI examination in only one patient (16.7%). Two patients also had coexisting MTS. In two patients, the blurred GWJ could not be identified even in retrospect, one presumably because of immature myelination. In the other patient, even at 3.83 years of age the finding was not present but became apparent at 6.42 years of age. Four patients underwent PET, all of which demonstrated asymmetric, ipsilateral temporal pole hypometabolism. One patient had no medical records at our institution. Average age of seizure onset in five of the remaining patients was 2.03 years. All five patients were diagnosed with complex partial seizures with EEG confirming temporal lobe origin. Three are currently well controlled with antiepileptic drugs, whereas two eventually underwent hippocampectomy with anterior temporal lobectomy. Both of the latter patients are now seizure-free. In one patient, histopathology revealed normal brain parenchyma, a not uncommon scenario per recent literature. In the second patient, a diagnosis of focal cortical dysplasia type IA was made.
Conclusion
Children with TLE may present with a variety of temporal lobe pathologies. An uncommon entity that may occur with or without MTS, is that of subtle gray-white matter blurring at the temporal pole, a finding that may go unrecognized. Recognition of this entity, representative of a primary cortical dysplasia and/or reactive gliosis, is crucial to the eventual care of pediatric patients with refractory TLE that may undergo resection.

Comparison of Fetal Central Nervous System Biometric Values in the Second and Third Trimester in Four Fetal Groups: Normal, Ventriculomegaly, Open Spinal Dysraphism and Agenesis of the Corpus Callosum

Fanou, E. M.[1]·Batty, R.[2]·Griffiths, P.[2]
[1]University Hospital of North Staffordshire, Stoke-on-Trent, UNITED KINGDOM, [2]University of Sheffield, Sheffield, UNITED KINGDOM.

Purpose
To compare the biometric values of the fetal head on in utero MR (iuMR) at two time points in four fetal groups: normal (N), ventriculomegaly (VM), open spinal dysraphism (OSD) and agenesis of the corpus callosum (ACC).
Materials & Methods
Blinded retrospective measurements of the trigones of the lateral ventricles, bony posterior fossa surface area and cerebellar vermis (in the midsagittal plane), maximum transcerebellar diameter and skull circumference were undertaken in gestationally age-matched fetuses in the second and third trimester.
Results
On-going study. Thirty-six fetuses have been included at present (n = eight agenesis of the corpus callosum, n = 12 open spinal dysraphism, n = seven ventriculomegaly, n = nine normal). We aim to correlate the head biometrics with the gestational age and also correlate range of values between the normal and abnormal groups. Preliminary results from the second trimester are presented in Table 1 and from the third trimester in Table 2 with the mean values and standard deviation (SD).

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Table 1

Parameter Fetal Anomaly	Skull circumference (cm)	Trigone diameter (mm)	Superior-inferior vermis (cm)	Surface area of bony posterior fossa (mm²)	Transcerebellar Diameter (cm)
VM	20.7	11.6	1.09	391	2.07
(SD)	-1.43	-1.6	-0.09	-68	-0.16
ACC	20.8	10.5	1.11	379	2.14
(SD)	-1.37	-3.2	-0.14	-55	-0.14
N	21.52	6.7	1.18	376	2.34
(SD)	-1.14	-1.8	-0.08	-21	-0.21
OSD	19.26	11.8	1.11	219	1.86
(SD)	-1.8	-3.7	-0.16	-38	-0.24

Table 2

Parameter Fetal Anomaly	Skull circumference (cm)	Trigone diameter (mm)	Superior-inferior vermis (cm)	Surface area of bony posterior fossa (mm²)	Transcere bellar Diameter (cm)
VM	31.01	10.9	1.92	813	3.67
(SD)	-1.29	-3	-0.2	-122	-0.3
ACC	31.6	15.6	2.02	797	3.68
(SD)	-2.71	-4.7	-0.16	-201	-0.36
N	29.81	6.1	1.86	773	3.72
(SD)	-1.15	-2.3	-0.23	-55	-0.3
OSD	29	16	2.33	506	3.11
(SD)	-1.83	-6.7	-0.28	-77	-0.37

Conclusion

In progress. Th*e preliminary results show altered bony surface area of the posterior fossa in the OSD fetuses in both trimesters. Regarding the trigones of the lateral ventricles, in the second trimester on average there is ventriculomegaly in the VM, ACC and OSD groups, with the largest ventricles seen on average in the latter group. In the third trimester there is significant increase in the size of the ventricles in the OSD and ACC groups. In the VM group however, on average the trigones can return to the upper limit of normal or borderline ventriculomegaly. The superior inferior dimension of the vermis is increased slightly in the OSD group in the third trimester and when compared to the other groups likely due to elongation of the vermis due to anterior posterior compression.

De Novo, Progressive, Multiple, and Recurrent Intracranial Dural Arteriovenous Fistulas: Characteristics and Outcomes

Tsai, T.·Cooke, D. L.·Amans, M. R.·Kim, W. T.·Stout, C.·McSwain, H.·Dowd, C. F.·Higashida, R. T.·Halbach, V. V.·Hetts, S. W.
University of California San Francisco
San Francisco, CA.

Purpose

Although many intracranial dural arteriovenous fistulas (DAVFs) are straightforward to treat, de novo and rapidly progressive ("runaway" or "malignant") DAVFs are more complex, often requiring multiple treatment sessions with suboptimal results. As these are rare entities, we sought to review our experience in the treatment of de novo and progressive DAVFs in order to better understand predictors of disease progression.

Materials & Methods

Under an IRB-approved protocol, 29 patients with multiple, recurrent, de novo, or progressive DAVFs were identified from our quaternary referral hospital's neurointerventional radiology database of 578 patients treated for intracranial DAVFs between 1986 and 2012. One patient with acute traumatic carotid cavernous fistulas was excluded. Patient demographics, clinical presentation, lesion angioarchitecture, treatment approaches, and clinical outcomes were categorized and assessed. Categorical variables were analyzed with odds ratios and 2-sided Fisher's exact tests.

Results

We compared 28 patients with multiple, recurrent, de novo, or progressive DAVFs to 550 DAVF patients without such features. Whereas 18/28 (64%) of patients with multiple, recurrent, de novo, or progressive DAVFs were female, 283/550 (51%) without such features were female (OR 1.7, 95% CI 0.73-4.2, p=0.24). Mean age at presentation in the multiple, recurrent, de novo, or progressive DAVF group was 42±23 years (range 2 months to 77 years) compared to 52±20 years (range 1 day to 87 years) for the entire DAVF cohort. The most common presenting signs and symptoms of the 28 patients treated for multiple, recurrent, de novo, or progressive DAVFs were headache (50%), cranial neuropathy (46%), tinnitus (36%), visual changes (32%), and intracranial hemorrhage (29%). Fifty-nine DAVFs were identified in these 28 patients. Location of fistulas included transverse/sigmoid sinus in 18 (64%), superior sagittal sinus in eight (29%), torcula in six (21%), cavernous sinus in five (18%), marginal sinus in five (18%), and petrosal sinus in two patients (7%). Eight patients had DAVFs in other intracranial locations. Number of interventions per patient ranged from 2 to 19 (mean 5.5, median 4.5). All 28 patients were treated endovascularly; 15 (54%) also were treated with surgery. Embolic agents included coils in 25 patients (89%), ethanol in 23 (82%), polyvinyl alcohol in 21 (75%), N-butyl cyanoacrylate in 10 (36%), and Onyx in five (18%). One hundred fifty-three transarterial, transvenous, and surgical interventions were performed. The time between diagnosis of DAVF and last imaging ranged from 10 days to 21 years. At last followup, 10 patients (36%) had no symptoms or residual DAVFs, 15 patients (54%) had neurologic symptoms and/or residual DAVFs, and three patients(11%) had died due to intracranial hemorrhage or refractory elevations in intracranial pressure related to intracranial venous hypertension. A total of 19/28 patients had de novo or rapidly progressive DAVFs (68%) with all three deaths occurring in that group. No deaths were recorded in the other nine patients with only recurrent or

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

multiple DAVFs.
Conclusion
De novo or rapidly progressive DAVFs constituted 3% of all intracranial DAVF cases treated at our institution. Among these patients, despite aggressive endovascular and surgical care, a minority followed a malignant clinical course.

Brainstem Infarcts in Children

Rollins, N. K.[1]·Plumb, P.[1]·Pride, L.[2]·Dowling, M.[2]
[1]Childrens Medical Center, Dallas, TX, [2]University of Texas Southwestern Medical Center, Dallas, TX.

Purpose
Brainstem infarcts in children differ clinically from those in adults and are sufficiently uncommon that the diagnosis may be delayed. We report a single institution series over 10 years.
Materials & Methods
An IRB-approved query of our institution database yielded 13 patients with brainstem infarcts from 2001-2012. Medical records were reviewed for presenting symptoms; quantitative measure of stroke severity using the Pediatric NIH Stroke Scale (PedNIHSS); findings by MRI/A and catheter angiography; etiology, and outcome using the Pediatric Stroke Outcome Measures (PSOM).
Results
There were 9M/4F; nine months -17 years. Seven patients presented with involuntary rhythmic movements, four with hemiparesis, and three with altered mental status. Time to diagnosis ranged from 12 hours to five days; three patients had orthodontia resulting in suboptimal DWI and MRA. MR imaging showed isolated pontine infarcts in four; and midbrain, pontomesencephalic, or ponto-medullary in one each. Five had pontine infarcts with other posterior circulation infarcts; two had infarcts of different ages. MR angiography showed basilar artery (BA) occlusion in six of nine patients without a vertebral artery (VA) dissection in three; one of five had bilateral distal VA occlusion. Three patients had a VA dissection without BA thrombosis while MRA was normal in two. Catheter angiography showed VA dissection in four of nine; and hypoplasia of VA ipsilateral to the medullary infarct, and multiple peripheral posterior circulation emboli of unclear etiology in one patient each. Onset of symptoms was related temporally to sports in seven; most often football; six had no clear etiology. Management included initial heparinization unless contraindicated, with conversion to long-term anticoagulation or antiplatelet therapy based on results of vascular imaging, echocardiography, and coagulation profile; cardiac ECHO was normal in all patients. Maximum PedNIHSS ranged from 1-34 and was < 10 in seven patients; three in one, 10-20 in two, and > 20 in four. NIHSS with BA occlusion ranged from 5-34. Four patients progressed to locked-in state of which one died after withdrawal of support, one required gastrostomy and tracheotomy, one underwent successful clot extraction; and one survived. Of the 12 survivors, nine have been followed for > six months; PSOM ranges from 0- 4.5. In eight, PSOM is <2.5 and six are <1.0.
Conclusion
Prompt diagnosis of pediatric brainstem infarcts may be delayed by misleading symptoms and absence of risk factors while orthodontia may limit MR diagnosis. Even with BA occlusion and high initial severity, outcome tends to be good if systemic anticoagulation is started promptly.

Diagnosis of Hemimegaencephaly Using in utero MR Imaging

Williams, F.[1]·Griffiths, P. D.[2]
[1]Royal Hallamshire Hospital, Sheffield, Sheffield, UNITED KINGDOM, [2]University of Sheffield, Sheffield, UNITED KINGDOM.

Purpose
Hemimegalencephaly (HME) is a rare disorder characterized by abnormal overgrowth of one cerebral hemisphere. The purpose of this paper is to review our experience of diagnosing HME using in utero magnetic resonance imaging (MRI).
Materials & Methods
The MR imaging database in the Academic Unit of Radiology, University of Sheffield was searched using "Hemimegalencephaly" and "in utero MR" as search terms. The ante-natal histories and reports of ultrasound imaging were reviewed as well as the in utero magnetic resonance images.
Results
Nine cases of fetal hemimegaencephaly were located. One case was referred from ultrasound with the diagnosis of hemimegaencephaly, one as a "complex brain malformation" and one as "mass lesion". The other six were referred as "unilateral ventriculomegaly". A common finding in fetuses imaged in the second trimester was disruption of the normal "transient structures" found in the developing cerebral hemispheres.
Conclusion
Hemimegaencephaly is a difficult diagnosis to make on antenatal ultrasound and in utero magnetic resonance imaging should be considered in cases of unilateral ventriculomegaly diagnosed on ultrasound. Disruption of the transient structures of the cerebral hemispheres is a common finding on in utero magnetic resonance imaging and can sometimes produce mass-like appearances in the region of the germinal matrix/ganglionic eminence.

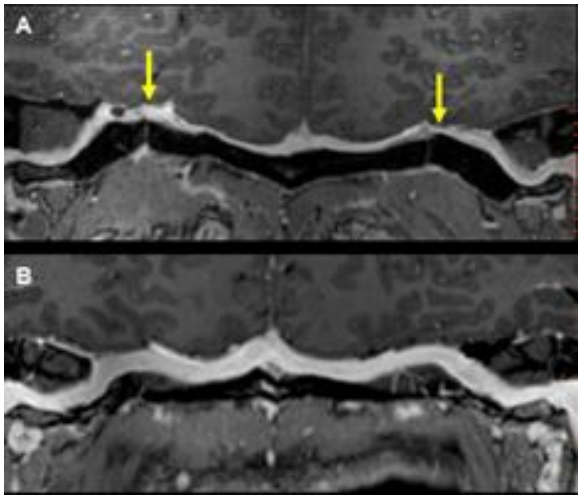
Transverse Sinus Stenosis in Patients with Chiari I Malformation

Saindane, A. M.·Bruce, B. B.·Desai, N. K.·Newman, N. J.·Biousse, V.
Emory University School of Medicine
Atlanta, GA.

Purpose
The Chiari I malformation (CM) frequently presents with headaches which may or may not be related to elevated intracranial pressure (ICP). Transverse sinus stenosis (TSS) nearly always is present in patients with idiopathic intracranial hypertension (IIH), presumably reflecting elevated ICP. The purpose of this study was to determine whether patients with the CM have a higher frequency of TSS than controls.
Materials & Methods
Twenty-two cases of CM and 76 age- and gender-matched controls without presenting symptoms of headache or visual disturbance were identified. All patients underwent standardized contrast-enhanced MRI including a postcontrast 3D T1-weighted dataset from which maximum intensity projections and curved reformats of the transverse sinuses were generated. Two readers blinded to the patient's diagnosis evaluated MRIs for presence or absence of TSS, and for orbital and skull base findings traditionally described in association with IIH. Cerebellar tonsillar position and morphology was noted. MRI findings were compared between the two groups.
Results
Median cerebellar tonsillar position was 12 mm below the foramen magnum in the CM group (17/22 peg-like in morphology), and 2 mm above the foramen magnum in controls (0/76 peg-like in morphology). While only 1/76 controls had TSS, 9/22 patients with CM had TSS. The odds of a CM patient having TSS was 25 times that of controls ($p<0.001$), and of having increased optic nerve (ON) sheath CSF was 6.8 ($p = 0.002$). Scleral flattening and skull base cephaloceles were present significantly more frequently among patients with CM than controls ($p<0.03$). No differences in frequency of ON head protrusion, ON head enhancement, vertical tortuosity of the ON, or pituitary flattening/sellar expansion were noted between the two groups. The figure depicts: A. 34-year-old female with Chiari I malformation with bilateral TSS, and B. 39-year-old male control with normal tonsillar position and normal appearance of transverse sinuses.



Conclusion
Patients with CM have significantly higher likelihood of TSS and some orbital findings traditionally associated with IIH, suggesting that at least a subset of CM patients have elevated ICP.

KEYWORDS: Chiari malformation type 1, Venous stenosis

Diffusion Tensor Imaging in Chiari Type I Malformation

Eshetu, T.·Meoded, A.·Jallo, G. I.·Carson, B. S.·Huisman, T. A. G. M.·Poretti, A.
The Johns Hopkins University School of Medicine
Baltimore, MD.

Purpose
The Chiari I malformation (CI) is defined by at least 5 mm of herniation of the cerebellar tonsils below the foramen magnum. Children with CI may present with different neurologic symptoms including headaches, neck pain and vertigo, or may be asymptomatic. On conventional MRI, differentiation between symptomatic and asymptomatic forms of CI is limited. We used diffusion tensor imaging (DTI) to study the integrity of the brainstem and cerebellar white matter tracts in children with CI.
Materials & Methods
The inclusion criteria were 1) isolated CI and 2) availability of high-quality presurgical DTI data. DTI data were acquired on a 1.5T MR scanner. Balanced pairs of diffusion gradients were applied along 20 orthogonal directions with a b value of 0/800s/mm2; TR/TE=8500/86ms, slice thickness=2.0mm, FOV=240×240mm; matrix=192×192. DTI postprocessing was performed off-line using MRI-Studio software. FA, color-coded maps, eigenvectors and eigenvalues were calculated after rigid transformation for adjustment of the position and rotation of images. Mean (MD), axial (AD) and radial (RD) diffusivity maps were generated. The quantitative analysis of FA, MD, AD and RD was performed. Regions of interest (ROI) were positioned

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

manually on the pontine corticospinal tracts (CST), medial lemnisci (ML), and middle cerebellar peduncles (MCP). An additional cross-sectional ROI was drawn at the level of the lower brainstem. For each anatomical structure, three ROIs were drawn on different MR slices and the median value was calculated. The same postprocessing was performed twice by the first and once by the second author. Generalized linear mixed effects models were used to evaluate the differences between asymptomatic and symptomatic children for each region and DTI scalar. These models were performed from the inter-rater and intra-rater perspectives and intraclass correlation coefficients were calculated to assess these effects.
Results
Between September 2010 and April 2012, MR images were acquired in 197 children with CI in our tertiary pediatric hospital. The majority of the patients were excluded because of 1) absence of DTI data, 2) severe artifacts, and 3) incorrect DTI acquisition parameters. Fifteen patients met the inclusion criteria (10 males, 5 females). Nine children were asymptomatic, six symptomatic. Median age of the patients was 6.43 years (mean age 7.18 years, range 2.87 to 15.34 years). Interclass correlation showed an interclass correlation coefficient > 0.8 for the majority of the DTI scalars. In the left MCPs, FA values were significantly higher (P=0.02), while MD (P=0.02) and RD (P=0.02) values were significantly lower for symptomatic versus asymptomatic patients. In the right MCPs, RD values were significantly lower in symptomatic versus asymptomatic patients (P=0.03), while a marginally significant difference was found for MD values (lower in symptomatic than asymptomatic patients, P=0.05).
Conclusion
This study suggests that MCPs may play a role in CI. Involvement of MCP in CI was shown previously in a study comparing pre and postsurgical FA and MD values. Higher FA values and lower MD and RD values in symptomatic versus asymptomatic patients are unexpected. Further studies of larger cohorts of CI patients are needed to elucidate the significance of these results.

Prenatal Diagnosis of Lissencephaly Using in utero MR Imaging

Williams, F.·Griffiths, P. D.
Royal Hallamshire Hospital Sheffield
Sheffield, UNITED KINGDOM.

Purpose
Lissencephaly is a rare disorder of cortical developmental with a prevalence of one in 100,000 live births per annum. Clear genetic links have been established and the risk is increased if a previous pregnancy was affected. Lissencephaly is a challenging prenatal diagnosis to make. Our purpose was to add to the experience of in utero magnetic resonance imaging in the diagnosis of prenatal lissencephaly and to establish whether in utero magnetic resonance imaging can provide a confident diagnosis of fetal lissencephaly during the second trimester of pregnancy especially in at-risk pregnancies where a previous diagnosis was made.
Materials & Methods
Twenty pregnant women who previously had carried a child with proven lissencephaly were recruited. Magnetic resonance (MR) imaging was performed three times during the pregnancy, at around 20 weeks, 25 weeks and 30 weeks gestation. In utero magnetic resonance imaging was carried out in the Academic Unit of Radiology at the Royal Hallamshire Hospital, Sheffield. Additionally, the cases were followed up with clinical data obtained on those that progressed to term and were delivered and postmortem data obtained on those that did not. The information then was used to corroborate the in utero magnetic resonance imaging findings.
Results
Eighteen cases progressed to term, one underwent termination of the pregnancy and one miscarried during the process. Six cases were identified as having in utero magnetic resonance imaging features suggestive of lissencephaly including the two cases which did not progress to term. Of the two cases that did not proceed to term lissencephaly was confirmed on postmortem diagnosis confirming the initial radiologic diagnosis. The remaining cases had lissencephalic features confirmed on postnatal imaging and were moderately to severely mentally disabled.
Conclusion
Lissencephaly is a rare diagnosis and poses diagnostic difficulties. In utero magnetic resonance imaging provides an excellent diagnostic tool for the assessment of the fetal brain and can be used with a degree of confidence in the prenatal diagnosis of lissencephaly.

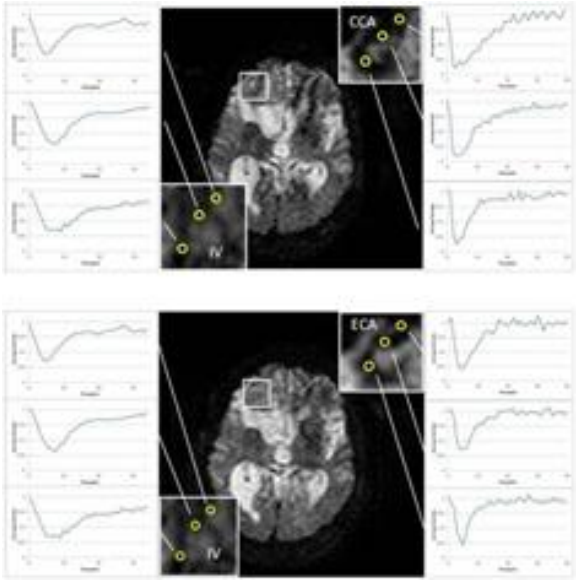
Intra-Arterial MR Perfusion Analysis of Meningiomas: Comparison to Intravenous MR Perfusion and Digital Subtraction Angiography

Lum, M. A.·Martin, A. J.·Saloner, D.·Hetts, S. W.
University of California San Francisco
San Francisco, CA.

Purpose
Pre-operative embolization can prevent excessive blood loss during intracranial meningioma resection. The degree of embolization safely achievable is determined largely by tumor blood supply, with branches of the internal carotid artery (ICA) less amenable to embolization than those of the external carotid artery (ECA). Tumor supply from pial arteries is not safe for embolization. We sought to determine if intra-arterial (IA) and intravenous (IV) perfusion MRI could characterize meningioma blood supply as sensitively as digital subtraction angiography (DSA).
Materials & Methods
Studies were performed in a combined XMR suite comprised of an x-ray angiography unit and 1.5T MR scanner, permitting intraprocedural patient movement between the two imaging modalities. Patients underwent meningioma embolization, evaluated with IV and IA T2* dynamic susceptibility contrast perfusion MR pre-embolization. Intra-arterial perfusion was performed by injecting dilute contrast (5mM Magnevist) into the ECA and common carotid artery (CCA). Twelve patients with IA CCA and ECA data were selected for detailed region-of-interest (ROI) analysis. Based on DSA, 18 ROIs were uniformly drawn on pre-operative CCA images representing ECA dural (n=11), ICA dural (n=4), and pial (n=3) supplies. From these ROIs, perfusion curves were generated with the following parameters extracted: peak-height, full-width at half-maximum (FWHM), and time to percent signal recovery for 50%-60% (TSR50-60%). One-sided t-tests were used to analyze ROI data.
Results
No differences in peak-height (p=0.66), FWHM (p=0.78), TSR50% (p=0.41), and TSR60% (p=0.55) were found between ECA and ICA dural ROIs. On that basis, ICA and ECA dural ROIs were combined and compared to pial ROIs. Pial ROIs demonstrated shorter FWHM (t=7.9s versus t=16.9s, p=0.025), shorter TSR50% (t=5.2s versus 12.6s, p=0.043), and shorter TSR60% (t=6.5s versus t=16.4s, p=0.046). No difference in peak-height was found. A selected patient whose meningioma supply was characterized on DSA as mixed dural-pial demonstrated decreasing FWHM and TSR50-60% as ROIs moved from dural to pial on CCA and ECA runs with the opposite trend observed on IV perfusion (see Figure).



Conclusion
No difference in MR perfusion measures of ICA and ECA dural supplies was found. However, perfusion curve analysis confirms greater "leakiness" among dural supplies when compared to pial supplies as quantified by differences in FWHM, TSR50%, and TSR60%. These IA MR perfusion measures can identify ICA pial supply not amenable to embolization. Intravenous perfusion imaging in the selected patients did not capture the difference between dural and pial supply, thus limiting its ability to triage patients to pre-operative embolization.

Treatment Response in Metastatic Brain Tumor following Gamma-Knife Radiosurgery: Utility of Initial and Final Area under the Curve Ratio of Dynamic Contrast-Enhanced T1-Weighted Perfusion MR Imaging

Suh, C.·Kim, D.·Kim, H.·Kim, S.·Kang, S.·Choi, C.
Asan Medical Center
Seoul, KOREA, REPUBLIC OF.

Purpose
To determine the utility of initial and final area under the curves ratio (AUCR) derived from dynamic contrast-

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

enhanced (DCE) perfusion MR imaging for the prediction of treatment response in metastatic brain tumor following gamma-knife radiosurgery (GKRS).

Materials & Methods

Our institutional review board approved this retrospective study. Sixty-two consecutive patients with metastatic brain tumor, who showed enlarged, contrast-enhancing lesions within the radiation field following GKRS, were assessed using conventional and DCE perfusion MR imaging. Histogram parameters of AUCR, including mean AUCR at higher curve ($mAUCR_H$) and 50^{th}($AUCR_{50}$), 75^{th} ($AUCR_{75}$) and 90^{th} ($AUCR_{90}$) percentiles of cumulative AUCR histograms, were correlated with the final clinicoradiologic diagnosis and were compared with normalized cerebral blood volume (nCBV) derived from dynamic susceptibility contrast (DSC) perfusion MR imaging with respect to correlation coefficient and diagnostic accuracy. The best predictor for differentiating tumor progression (TP) from radiation necrosis (RN) was determined by receiver operating characteristic (ROC) curve analyses.

Results

Study patients were stratified into TP (*n* = 25, 40.3%) and RN (*n* = 37, 59.7%) groups. There were statistically significant differences of $mAUCR_H$, $AUCR_{50}$, $AUCR_{75}$, and $AUCR_{90}$ between the two groups ($P < .001$, each). Receiver operating characteristic curve analyses showed the $mAUCR_H$ to be the best single predictor of TP, with a sensitivity of 92.3% and a specificity of 86.1%. $AUCR_{50}$ was found to be the most specific predictor of TP, with a sensitivity of 85.6% and a specificity of 87.5%. A significant positive correlation was found for AUCR with nCBV among all study patients ($r = 0.76$, $P < .001$).

Conclusion

A bimodal histogram analysis of AUCR derived from DCE perfusion MR imaging can be a potential, noninvasive imaging biomarker for monitoring treatment response in patients with metastatic tumors after GKRS.

Lymphomatosis Cerebri: Multimodal MR Imaging Findings

Trunet, S.·Leclercq, D.·Galanaud, D.·Hoang, K.·Mokhtari, K.·Gerber, S.·Martin-Duverneuil, N.
Hôpital de la Pitié Salpétrière
Paris, FRANCE.

Purpose

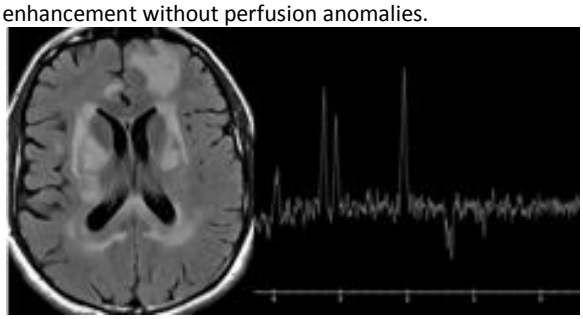
Lymphomatosis cerebri (LC) is a rare subtype of cerebral non-Hodgkin lymphoma which is assumed to be caused by widespread infiltration of the white matter by lymphoma cells. The most common symptoms at onset are personality changes, cognitive deficit, and gait ataxia, mimicking dementia. On MRI, the observed extensive white matter changes can be mistaken for subcortical ischemic vascular dementia, infectious leukoencephalitis, or gliomatosis cerebri. The features of lymphomatosis cerebri on multimodal imaging including perfusion and spectroscopy have not be reported. The purpose of this presentation is: 1. to present the MRI aspects of pathologically confirmed LC with conventional MRI, spectroscopy and perfusion. 2. Determine whether conventional imaging, perfusion and spectroscopy can help distinguish LC from other leukoencephalopathy.

Materials & Methods

We retrospectively reviewed the MRI findings, clinical information and pathology reports of four patients presenting with LC between 2006 and 2012 treated in our institution. All patients underwent a multimodal MRI protocol including at least T2-weighted images, FLAIR images, T1-weighted images with and without gadolinium injection, diffusion-weighted images, MR perfusion and spectroscopy (TE: 35ms, 144ms). Maximal rCBV (relative cerebral blood volume), and rCBF were obtained using the software provided by the manufacturer (Functool, General Electric, Milwaukee, WI).

Results

Patients were two male and two female. Average age at diagnosis was 65 years. Extensive diffuse leukoencephalopathy in both hemispheres was present, with no or minimal mass effect in four patients. White matter changes extended in the subcortical and deep white matter in four patients, the splenium of the corpus callosum in three patients, the middle cerebellar peduncle in three patients and along the corticospinal track in two patients. Lenticular nuclei were involved in two patients. The cortex was spared. Lesions were in high T2 signal, low T1 signal and high diffusion signal without restriction of the ADC. Spectroscopy sequences showed a mild choline peak, decreased NAA and the presence of lactates. No lipids were measured. In perfusion sequences, rCBV values were normal and there was no blood-brain barrier disruption. One patient presented small foci of enhancement without perfusion anomalies.



Conclusion

We present the first reported results of multimodal MRI in primary lymphomatosis cerebri in four patients. We confirm a MR pattern markedly different from what is observed in more conventional brain lymphoma, with extensive and diffuse leukoencephalopathy without evidence of blood-brain barrier disruption, no or minimal

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

contrast enhancement, no restriction of ADC and no increased free lipids on MR spectroscopy.

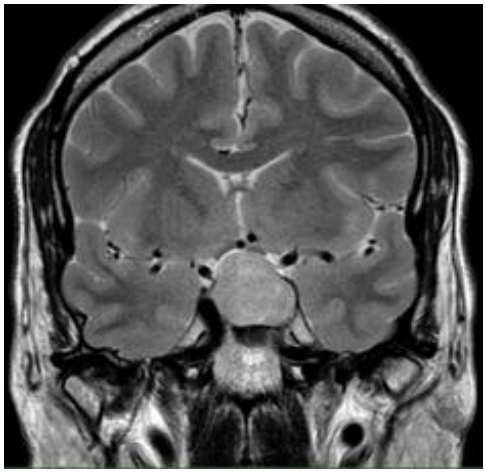
Correlation between MR Imaging Findings and Visual Field Exam in Optic Chiasm Compression

Tavares, F. C.·Zan, E.·Boland, M.·Ying, H.·Yousem, D. M.
Johns Hopkins Institution
Baltimore, MD.

Purpose
To our knowledge there is no MR imaging-based literature demonstrating the relation between extrinsic optic chiasm compression and the manifold visual field defects experienced by the patients. Classically, bitemporal hemianopia (BTH) has been described in pituitary macroadenomas with clinical manifestation of partial blindness where the outer half of right and left visual fields is missing. We sought to determine the incidence of visual field deficits in patients with pituitary macroadenomas and to assess which imaging findings best predicted visual field deficits in this patient population.
Materials & Methods
This study was HIPAA compliant and approved by the institutional IRB. We retrospectively evaluated 50 patients with pathology proven macroadenoma and optic chiasm displacement recorded on MRI. In these patients we reviewed the the visual field exam (VFE) charts, MRI reports and electronic medical record notes. The MRI studies were re-evaluated by two neuroradiologists for imaging findings in a blinded fashion, as the reviewers were unaware of the visual deficits at the time of image review.
Results
In 36/50 (70%) patients, MRI showed optic chiasm compression by the macroadenoma with clinical correlation of BTH. MR imaging was able to lateralize the compression to being greater on the left or the right in 11/35 (31%) patients which corresponded to the patients' reported symptoms of visual loss and to VFE lateralization of BTH. In 14/50 (30%) there was elevation of the optic chiasm by the mass. Nine of 14 (64%) had normal VFE whereas 5/14 (36%) had either left- or right-sided temporal or nasal hemianopia. In 3/5 cases we were able to demonstrate the CSF cleft between the pituitary mass and either left or right side of the optic chiasm which corresponded to unilateral temporal hemianopia on VFE (Figure 1). Twenty-four of 50 (48%) patients had initial symptoms related to vision and, of those, 20/24 (83%) complained of various degrees of BTH. Four patients had complaints of visual deficits but on testing had normal VFE. However, of 26 patients whose initial symptoms were other than visual problems, BTH was evident in 16/26 (65%) by ophthalmologic examination.



Conclusion
Most patients with pituitary adenomas and optic chiasm displacement have BTH on VFE (36/50=72%). MR imaging sometimes shows optic chiasm elevation but the patient does not have BTH; in fact nine of 50 such patients have normal visual fields. Lateralization on MRI corresponds well to vision deficits on the side of the optic chiasm compressed.

Imaging Profile of Dysembryoplastic Neuroepithelial Tumors

Mironov, A.·Ayeni, S.·Brumback, R.
Creighton University Medical Center
Omaha, NE.

Purpose
Dysembryoplastic neuroepithelial tumors (DNETs) represent developmental glio-neuronal tumors most common inflected by intractable epilepsy. The glial lineages are composed by astrocytic and oligodendroglial phenotypes; the neuronal component is composed of both more mature, ganglionic cells and more immature population of cells with a neurocytic appearance. The study includes 13 cases treated by surgical and conservative approaches. The purpose is to assemble the radiologic features with relation to morphology in unique classification according to the literature and own experience.
Materials & Methods
Clinical, imaging and pathologic features of 13 patients with complex partial seizure disorders featuring DNET (aged 12-45 years) were reviewed. They underwent CT, MR and angiographic studies. In eight cases histological studies were obtained. All patients were followed up to 10 years.
Results
The imaging exhibits a versatile morphologic spectrum and

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

could be divided into four groups: 1) Well-circumscribed inhomogeneous temporo-occipital located hypointense of T1 and hyperintense on T2 lesions. The central part was multinodular with multicystic appearance and calcifications. They showed intensive nodular patchy contrast enhancement (two cases). 2) Multicystic cortical lesions restricted in mesial regions limited to one lobe with associated cortical dysgenesis. They showed uniform appearance with small multiple cystic areas hypointense on T1 and FLAIR and hyperintense on T2 without contrast enhancement (seven cases). 3) Diffuse multicystic and nodular not circumscribed lesions with variable cortical and subcortical extension and preferred mesial orientation; they were not demarcated and did not show contrast enhancement, harboring the same signal behavior as Group 2 lesions; they had diffuse appearance and involved more than one lobe with frequent cortical dysgenesis (three cases). 4) Mixed DNET and ganglioglioma with extended ossifications. The MR imaging discovered a complex brain malformation in left parietal-occipital area with cortical dysgenesis. A poorly circumscribed mass with mild inhomogeneous contrast enhancement inside of the massive ossification was identified as DNET and another smaller well circumscribed cortical mass with strong homogeneous enhancement represented a ganglioglioma (one case).

Conclusion

Three pathologic features characterize DNETs: glioneuronal element, nodular component and associated cortical dysplasia. The occurrence in young but matured brain implies the persistence of certain types of neural progenitor cells, which usually are expected in the subventricular zone, the hippocampal dentate fascia, and the cortical subpial layer. The glioneuronal fraction contains neuronal and glial cells with different mucoid substance accumulation. This implies the multicystic appearance with cortical/subcortical and mesial location for the majority of lesions. The second and the third group are composed dominantly of glioneuronal component and emphasize unique imaging findings without contrast enhancement. The nodular component is variable and may contain neurons, astrocytes, and oligodendrocytes associated with cortical dysplasia, which implies the inhomogeneous solid appearance in first and forth groups. The mixed appearance of DNET and ganglioglioma is due to the common embryogenesis from subpial granular layer.

Use of MR Imaging in Predicting Surgical Resectability of Pituitary Adenomas with Parasellar Involvement

Connor, S.[1]·Hogarth, K.[2]·Wilson, F.[3]
[1]Kings College Hospital, London, UNITED KINGDOM, [2]John Radcliffe Hospital, Oxford, UNITED KINGDOM, [3]Starship Hospital, Auckland, NEW ZEALAND.

Purpose

To evaluate preoperative magnetic resonance (MR) imaging in its ability to predict complete removal of parasellar pituitary adenoma (PA) on postoperative MRI. Criteria for the radiologic assessment of parasellar involvement of pituitary adenomas have been defined previously (Cottier et al, 2000 and Vieira et al 2006) but no previous study has evaluated these imaging criteria for their value in predicting the likelihood of achieving a complete surgical resection as assessed by postoperative imaging.

Materials & Methods

Three hundred fifty-four patients with a histological diagnosis of pituitary macroadenoma were operated on at King's College Hospital between December 2004 and January 2010. Both pre and postoperative imaging was available for 49 patients with clear unilateral parasellar involvement (28 male, 21 female; mean age = 53 years, range 23-85, SD = 15 years) remained in the study. Pre and postoperative MR images were reviewed retrospectively by two neuroradiologists and a consensus was obtained. All of the images of pituitary tumors with parasellar involvement were evaluated according to criteria previously described by Cottier et al 2000 and Vieira et al 2006. The postoperative images then were evaluated for residual tumor as defined by signal abnormality in the same location as, or continuous with, the tumor shown on the preoperative images and with the same signal characteristics as the tumor tissue. Preoperative and postoperative MR findings were compared using the Fisher's exact test. *P* values of less than 0.05 were considered to indicate statistical significance. The odds ratio for incomplete resection/indeterminate outcome for each significant criterion was obtained by logistic regression.

Results

Only two MRI criteria reached statistical significance (Table 1). These were the nondepiction of the inferolateral and lateral compartments of the cavernous sinus. The results for the percentage of the intracavernous carotid surrounded by tumor were evaluated with a rank sum test, which also reached significance. The odds ratios indicate that nondepiction of the lateral venous compartment means that a partial/indeterminate outcome is six times more likely and that for every quarter increase of encasement of the intracavernous carotid, the likelihood of a partial/indeterminate outcome is increased 3.4 times. A 50% encasement of the intracavernous carotid by tumor would make a partial/indeterminate result 6.8 times more

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

likely.
Table 1

MR imaging criterion	Fisher's exact score
Total encasement of cavernous carotid	0.056
Displacement of cavernous ICA	0.361
Asymmetry of the right/left CS compartments	0.51
Non-depiction of the superior compartment of the CS	0.117
Non-depiction of the carotid sulcus compartment of the CS	0.182
Non-depiction of the inferolateral compartment of the CS	0.001
Non-depiction of the lateral compartment of the CS	0.001
Lateral bulging of the lateral dural venous wall	0.228
Crossing the intercarotid lines	0.188

Conclusion
Three MR imaging features are useful in predicting the complete removal of the parasellar component of a pituitary adenoma as assessed by pos-operative MRI: (1) involvement of the lateral compartment of the cavernous sinus (2) involvement of the inferolateral compartment of the cavernous sinus and (3) tumor surrounding the intracavernous carotid by 50%.

KEYWORDS: Pituitary adenoma, Parasellar, magnetic resonance imaging

Neuroepithelial Tumors of the Temporal Lobe: Relevance of Limbic Involvement to Histopathology and Tumor Biology

Capizzano, A. A.·Chaudhry, U.·Moritani, T.·Kirby, P.
University of Iowa Hospitals & Clinics
Iowa City, IA.

Purpose
To evaluate distinctive pathologic and clinical features of limbic versus nonlimbic neuroepithelial tumors of the temporal lobe.
Materials & Methods
IRB approved retrospective study between 2005 and July 2012. A search of pathologic reports of primary temporal lobe tumors excluding glioblastoma was performed. Cases with preoperative MRI were included. Based upon tumor extension on preoperative MRI, cases were divided into limbic and nonlimbic tumors after the limbic lobe definition of Heimer and van Hoesen. Limbic tumors were further categorized according to groups proposed byYasargil into: 1. mediobasal temporal (MBT), 2. insular-temporo-opercular (I-TO) and 3. frontoorbital-insular-temporopolar (FO-I-TP). MR imaging protocols included axial T1- and T2-weighted, FLAIR, GRE and DWI sequences and axial, coronal and sagittal postcontrast T1-weighted images acquired in 1.5 and 3T clinical scanners.
Results
Fifty cases were included with mean age at diagnosis 38 ± 19.9 years with 14 women and 36 men. Pathologic diagnoses were: 20 anaplastic astrocytomas, 11 gangliogliomas, eight astrocytomas WHO grade II, three pilocytic astrocytomas, two dysembryoplastic neuroepithelial tumors, two oligodendrogliomas grade II, two anaplastic oligodendrogliomas, one low-grade glioneuronal tumor and one atypical extraventricular neurocytoma. Thirty-six tumors were limbic centered (16 MBT, 11 I-TO, 8 FO-I-TP, 1 pantemporal) and 14 involved nonlimbic regions. There were no differences between limbic and nonlimbic tumors in age, sex, pathologic diagnosis and presentation with seizures. When considering three subtypes of temporal lobe limbic tumors, there was a significant difference in glial versus neuronal differentiation (Chi-Square = 7.8, df 2, p = 0.02) with MBT tumors having more frequent neuronal differentiation (50%) compared to I-TO (0%) and FO-I-TP (25%). Furthermore, taking only the eight tumors confined to the hippocampal-amygdala allocortex, seven (87%) had neuronal differentiation versus 36% in 14 nonlimbic tumors ($p<0.05$). When comparing low-grade (WHO I and II) versus high-grade (WHO III) tumors, there were significant differences for age and neuronal versus glial differentiation ($p<0.01$) but not for limbic location or subtype. Neuronal differentiation correlated with lower grade (0.49, $p<0.01$) and younger age (0.52, $p<0.01$). Limbic tumors had less gadolinium enhancement compared to extralimbic tumors including all diagnoses ($p<0.01$) and when comparing only anaplastic astrocytomas ($p<0.05$).
Conclusion
Limbic involvement of neuroepithelial tumors was proven relevant by Yasargil from a neurosurgical perspective regarding routes for tumor spread and surgical approach. Mediobasal temporal limbic tumors had more frequent neuronal differentiation than other limbic or extralimbic temporal lobe tumors. This may result from lesion proximity to the neurogenic subgranular zone of the hippocampus. Neuronal differentiation was maximal in

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

hippocampal-amygdala and lowest in insular-temporal tumors. Neuronal differentiation correlated with lower tumor grade and younger age at diagnosis. Furthermore, limbic tumors displayed less gadolinium enhancement on MRI compared to extralimbic tumors. Therefore, consideration of tumor anatomy in relationship to the limbic lobe boundaries is important for the neuroradiologist considering differential diagnoses. In conclusion, although neglected in modern literature, the category of limbic tumors has distinct biologic features which may prove relevant for diagnosis and management.

Utility of SPGR versus Fast-SPGR Imaging in the Detection of Brain Metastasis for Pre-Gamma-Knife Planning

Lee, J. H.·Keller, I. A.·Basak, S.·Hargreaves, E. L.·Danish, S. F.
University of Medicine and Dentistry of New Jersey
New Brunswick, NJ.

Purpose
Prior to performing gamma-knife surgery, a gadolinium-enhanced spoiled gradient (SPGR) recall MRI of the brain is performed for localization of intracranial metastasis (IM). SPGR performed on the day of surgery has been shown to detect additional IM that are not seen initially on a conventional outpatient postcontrast axial T1WI (T1+c) and can be considered the gold standard for detecting metastatic lesions. Detection of additional lesions on the day of the procedure potentially renders a patient ineligible for a radiosurgical option. While an SPGR sequence improves surgical planning, its long total scan time makes it impractical to use in all patients with suspected IM for screening purposes. To address this issue, a faster SPGR sequence (f-SPGR), with decreased spatial resolution, was developed to compete with SPGR. This study aims to investigate if f-SPGR can provide adequate resolution for lesion detection without overburdening the outpatient throughput.
Materials & Methods
A retrospective chart review was performed with a subject pool chosen from within the gamma-knife treatment population who underwent the SPGR (28 minutes), f-SPGR (8 minutes), and T1+c (5 minutes) sequences prior to gamma- knife treatment. Four independent observers (two neuroradiologists, one neurosurgeon, and one radiology resident) reviewed SPGR, f-SPGR, and T1+c images for detection of IM. Diagnosis was obtained from independent review by the four observers with SPGR being the gold standard. The f-SPGR sequence was compared against the SPGR and T1+c sequences in its ability to detect IM.
Results
Twenty-five total patients (eight men; 17 women; mean age 57 years) with 27 total scans were evaluated. An average of 181.0 lesions was identified per observer on the SPGR sequences. The overall detection rate was not statistically different for the SPGR versus the f-SPGR sequences (182.7 lesions; 100.0% of SPGR; $p = 0.096$). However, there was a statistically significant increase in the overall detection rate for both the f-SPGR and SPGR versus the T1+c sequences (166.0 lesions; 90.9% of f-SPGR, $p = 0.001$; 91.7% of SPGR; $p = 0.002$). There was no increase in the number of extra lesions detected in f-SPGR versus SPGR. But, there was an observed increase in the number of extra lesions detected in f-SPGR versus T1+c (extra lesions detected in 14 studies; 51.9% increase).
Conclusion
Misclassification of patients with brain metastasis remains a significant outpatient challenge. Fast-SPGR is a statistically comparable alternative to SPGR in its ability to detect IM, but has the added advantage of having an overall scan time savings of 20 minutes. Fast-SPGR provides a statistical advantage over T1+c in IM detection with only an added cost of three extra minutes of scan time. Therefore, f-SPGR provides a viable solution to the "lesions that we can't see" concept without significantly affecting outpatient throughput.

Assessment of Irradiated Brain Metastases by Dynamic Contrast-Enhanced MR Imaging

Almeida-Freitas, D. B.[1]·Pinho, M. C.[2]·Leite, C. C.[1]
[1]Universidade de São Paulo, São Paulo, BRAZIL, [2]University of Texas Southwestern Medical Center, Dallas, TX.

Purpose
Radiological criteria to evaluate the response of brain metastases to stereotactic radiosurgery (SRS) on the early post-treatment period have not been well established. The most used approach for this purpose is tumor size, which may increase as a result of both early radiation-related changes and tumor progression. The rule of dynamic contrast-enhanced (DCE) MRI, a technique that provides additional information about blood-brain barrier integrity, has not been characterized for assessment of irradiated brain metastases. The objectives of this study are to evaluate the effect of SRS on the transfer coefficient (Ktrans) of cerebral metastasis using DCE MRI and to correlate early Ktrans measurements with long-term treatment outcomes.
Materials & Methods
Twenty-six adult patients with a total of 34 cerebral metastases underwent T1-weighted DCE MRI in a 1.5T magnet prior to SRS and four to eight weeks post-treatment. Parametric maps were generated and Ktrans measurements were determined with a region-of-interest analysis. Mean Ktrans prior and after SRS were compared using generalized estimation equation to take into account the correlation between the different metastasis within

the same individual. Early Ktrans changes were correlated with tumor volume changes at long-term MRI followup (> 20 weeks).
Results
The mean (SD) Ktrans value was 0.13 (0.01) at the baseline and 0.08 (0.01) after treatment ($p < 0.001$). The reduction of Ktrans values was correlated with tumor volume reduction at long-term MRI followup ($r = 0.46$; $p = 0.04$). Local control was observed in 73% of the brain metastases, and a decrease in Ktrans was four times more frequent in these cases compared to the progression group ($p = 0.04$).
Conclusion
Stereotactic radiosurgery was associated with a reduction of Ktrans values of the cerebral metastases in the early post-treatment period. Ktrans changes were correlated with tumor volume at long-term MRI followup. These results suggest that Ktrans evaluation with DCE MRI may be a valuable biomarker in the early post-treatment period to predict long-term tumor volumes. Precocious assessment of treatment response is clinically desirable to select unresponsive patients for alternative therapies.

Neuroimaging Features of Leptomeningeal Carcinomatosis

Raz, E.[1]·Knopp, E.[1]·Wu, S.[1]·Zagzag, D.[1]·Saba, L.[2]·Hygino da Cruz, L.[3]·Fatterpekar, G.[1]
[1]New York University, New York, NY, [2]Cagliari University, Cagliari, ITALY, [3]Federal University of Rio de Janeiro, Rio de Janeiro, BRAZIL.

Purpose
Leptomeningeal carcinomatosis (LC) is a rare presentation of solid tumors, occurring in up to 5% of all patients with cancer. Prognostic factors for LC are cerebrospinal fluid (CSF) proteins, the Karnofsky performance status scale and the time from diagnosis of primary tumor. However, there is only sparse radio-pathologic correlation of LC. The purpose of our study was to correlate the incidence of LC with the primary tumor organ, the incidence of presence of associated intraparenchymal metastasis and determine if the extent of LC influenced the prognosis.
Materials & Methods
We retrospectively evaluated MRI positive studies of 131 pathology proven cases of LC in patients with a known primary tumor (excluding primary tumors of the brain and spinal cord). Gender, age, primary tumor, location of the leptomeningeal disease, presence of parenchymal metastases, CSF findings, categorization of the different histotypes, underlying molecular signature, and the overall survival of these patients.
Results
We evaluated 131 patients (M:F = 58:73) with MRI evidence of LC. Mean age was 55.8 (+/- 15.2) years. The most common types of tumor were breast (n = 47; 35.8%), lung (n = 35; 26.7%), melanoma (n = 18; 13.7%), hematologic malignancies including lymphoma and leukemia (n = 12; 9.1%) and others including thyroid, GI tract (n = 19; 14.5). LC was noted to be positive in 29 cases (22.1%) in the spinal canal, in 39 cases in the supratentorial compartment (29.7%), in 16 cases in the infratentorial (12.2%), and in 47 both compartments were involved (35.8%). The incidence of infratentorial location was more common among patients with breast cancer compared to the other primary tumors (chi square test $p<0.0001$). Forty-nine patients (37.4%) had parenchymal CNS metastases. There was no an association between the presence of intraparenchymal CNS metastases and leptomeningeal disease. There was no statistically significant difference between the extent of LC and the overall prognosis. Data will be presented regarding the CSF findings, categorization of the different histotypes and different molecular signatures.
Conclusion
We establish the radiopathologic correlation of LC in a large retrospective cohort of patients. Specifically, the most common type of tumor with imaging evidence of LC is breast, and simultaneous involvement of supra and infratentorial compartment is most common. There is no association between the presence of intraparenchymal CNS metastasis and LC. There was no statistically significant difference between the extent of LC and the overall prognosis.

Intracranial Post-Transplant Lymphoproliferative Disorder: Review of Imaging Findings with Clinical and Pathologic Correlation

Waters, J.·Parmar, H. A.·Ibrahim, M.·McKeever, P.·Junck, L.
University of Michigan
Ann Arbor, MI.

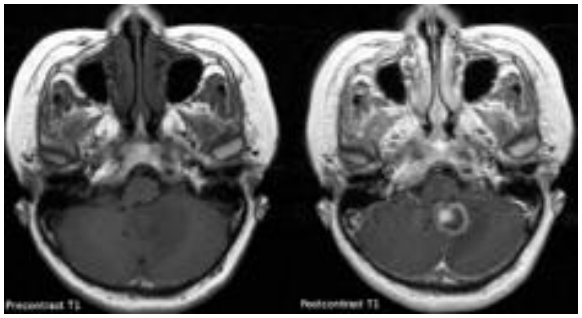
Purpose
Post-transplant lymphoproliferative disorder (PTLD) is a well recognized complication of organ transplantation. Epstein-Barr virus (EBV) has a causative role, with more than 90% of tumors associated with EBV. The actual incidence of PTLD is variable, based on recipient's age, type of organ transplanted and the duration and extent of immunosuppression. Predominant or isolated involvement of central nervous system (CNS) with PTLD is considered very rare. Since the first description in 1970, only about 45 cases or so are reported in literature, most of which are in the clinical journals with little if any emphasis on the imaging features. The aim of this study is to identify all cases of CNS PTLD at a single institution and review their MRI findings with clinical and pathologic correlation.
Materials & Methods

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

A total of seven patients with intracranial PTLD diagnosed at the University of Michigan from 2004 through 2012 were reviewed retrospectively. Lesions were diagnosed by brain biopsy (four patients), at autopsy (one patient), and by biopsy of extracranial PTLD (two patients). Clinical characteristics recorded include type of transplantation, time since transplant at presentation, presence of extracranial PTLD, and follow-up details. MR imaging characteristics investigated included number of lesions, lesion location (supratentorial or infratentorial), T1 and T2 signal characteristics, enhancement pattern on postcontrast T1-weighted images, and pattern of diffusion restriction (if any).

Results

Transplant	Time since transplant at diagnosis (months)	Solitary or multiple lesions	Lesion location	T1 (with respect to gray matter)	T2 (with respect to gray matter)	Enhancement	Diffusion restriction	Extracranial PTLD documented	Follow-up
Renal	64	Solitary	Infratentorial	Hypointense	Slightly hyperintense	Rim with internal enhancing nodule	Peripheral	No	Expired 5 months after diagnosis
Renal	81	Multiple	Supratentorial	Hypointense	Slightly hyperintense	Rim	None	No	Alive at 52 months with no evidence of disease
Renal	12–106 (patient with two transplants 94 months apart)	Solitary	Supratentorial	Internally hypointense with rim of hyperintensity	Internally hyperintense with rim of hypointensity	Rim	Internal and peripheral	No	Alive at 28 months
Cardiac	4 months	Multiple	Supratentorial and Infratentorial	Hypointense	Hyperintense	Solid enhancing and nonenhancing	Internal and peripheral in enhancing lesions	Right supraclavicular lymph node	Expired 14 months after diagnosis
Cardiac	8 months	Multiple	Supratentorial and infratentorial	Hypointense	Hypointense	Rim enhancement and nonenhancing	Internal and peripheral	Stomach, Cecum and transverse colon, right lower pulmonary lobe	Expired 5 months after diagnosis
Cardiac	42 months	Multiple	Supratentorial	Hypointense and isointense	Hyperintense	Solid nodular	Throughout	No	Alive 47 months after diagnosis
Bone marrow	4 months	Multiple	Supratentorial and Infratentorial	Hypointense	Hyperintense	Rim and patchy internal	Internal and peripheral in different lesions	Left cervical lymph node and stomach	Expired 9 months after diagnosis



Conclusion

Lesions proven to be CNS PTLD on tissue sampling occurred as both single and multiple lesions in both the supratentorial and infratentorial compartments. The predominant imaging pattern is represented by a T1 hypointense, T2 hyperintense, peripherally enhancing lesion with restricted diffusion corresponding to the areas of enhancement. These imaging features differ from those typically associated with intracranial lymphoma, which usually demonstrate a homogeneous pattern of contrast enhancement and diffusion restriction. In patients with a history of transplantation, lesions with these imaging characteristics should be considered highly-suspicious for PTLD, irrespective of diagnosed PTLD diagnosed elsewhere.

Locally Linear Embedding: Applications in Neuroimaging

Starkey, J.·Liu, X.·Schuff, N.
University of California San Francisco
San Francisco, CA.

Purpose

Locally linear embedding (LLE) is a statistical method that allows for simplification of complex datasets from multiple dimensions to fewer dimensions. It was introduced in 2000 and has been employed in applications such as facial recognition. Recently, its utility in medicine has been recognized. Although modern machine learning algorithms are being used increasingly in neuroradiology, such as the prediction of Alzheimer disease (AD) from structural MRI, finding a good representation for multivariate brain MRI features in which their essential structure is revealed and easily extractable has been difficult. Because LLE is an unsupervised algorithm, no assumptions need to be made regarding the model of potentially complex relationships of sampled data. We aimed to apply LLE to Alzheimer disease and Parkinson disease classification and introduce this method to members of the ASNR.

Materials & Methods

Using LLE, we transformed regional brain volume and cortical thickness calculated by Free Surfer to a locally linear space with fewer dimensions, while also utilizing the global nonlinear data structure. The embedded brain features then were used to train a classifier for predicting future conversion to AD based on a baseline MRI. We tested the approach on 413 individuals from the Alzheimer's Disease Neuroimaging Initiative (ADNI) who had baseline MRI scans and complete clinical followups over three years with the following diagnoses: Cognitively normal (CN; n = 137), stable mild cognitive impairment (s-MCI; n = 93), MCI converters to AD (c-MCI, n = 97), and AD (n = 86). We also tested the approach on 100 individuals from the Parkinson's Progression Markers Initiative (PPMI) who had baseline MRI scans with the following diagnoses: Health control (HC; n = 40) and Parkinson disease (PD; n = 60).

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Results

In AD, we found classifications using embedded MRI features generally outperformed ($p < 0.05$) classifications using the original features directly. Moreover, the improvement from LLE was not limited to a particular classifier but worked equally well for regularized logistic regressions, support vector machines, and linear discriminant analysis. Most strikingly, using LLE significantly improved ($p = 0.003$) predictions of MCI subjects who converted to AD within three years and those who remained stable (accuracy/sensitivity/specificity: = 0.69/0.58/0.82), whereas predictions using the original features performed no better than chance (accuracy/sensitivity/specificity: = 0.51/0.57/0.45). Preliminary results suggest that original MRI features are unhelpful in PD and regularized logistic regressions also perform no better than chance. The LLE analysis is pending but will be completed in the next month, well in advance of the May meeting.

Conclusion

Locally linear embedding is an effective tool for classification studies of AD using multivariate MRI data. The improvement in predicting conversion to AD in MCI could have important implications for health management and for powering therapeutic trials by targeting nondemented subjects who will later convert to AD. Additionally, LLE is a promising method of classification in other neurologic diseases.

Phantom Study on Radiation Effective Doses of Cerebral Blood Volume Measurement Using Flat-Detector Digital Subtraction Angiography

Guo, W.[1,2]·Lin, C.[1,2]·Chen, W.[2]·Hung, S.[1,2]·Chu, W.[1]·Chiu, C.[1]·Wu, T.[2]
[1]Taipei Veterans General Hospital, Taipei, TAIWAN, [2]National Yang-Ming University, Taipei, TAIWAN.

Purpose

Quantitative x-ray digital subtraction angiography (DSA) and cerebral blood volume measurement using flat-detector (FD) DSA is feasible, currently. However, the effective radiation dose remains one of the major concerns. We aimed to estimate effective dose that involved in cerebral blood volume measurement using FD DSA.

Materials & Methods

A radiation experiment using an anthropomorphic phantom (Rando Alderson phantom; Radiology Support Devices, Long Beach, CA) on a biplane FD DSA suite (AXIOM-Artis®, Siemens Healthcare, Erlangen, Germany) was conducted. A clinical DSA imaging protocol (one 8-second rotational mask run with 60 frames/second followed by another 8-second rotational contrast medium filled run with same frame rate) for cerebral parenchyma blood volume measurement (syngo DynaPBV® Neuro, Siemens Healthcare, Erlangen, Germany) was used. The scanning parameters were: 73 kV, 483-555 mA, 4.0-4.1 ms, 48 cm field-of-view (FOV). Two PBV scan ranges, 8-cm slab (slab-PBV, from sella turcica to convexity) and whole brain PBV, were undertaken. 80 lithium fluoride thermo-luminescent dosimeters (TLDs) (TLD-100H, Bicron-Harshaw, Solon, OH) divided into 22 organ sites were embedded in the phantom. We followed the guidelines of International Commission on Radiation Protection Number 103 (ICRP-103) to measure the effective dose. For comparison, repeated two CT scans on the same phantom and TLDs distribution were performed on a 256 slice multidetector CT, (MDCT, Brilliance *i*CT®, Phillips Healthcare, Best, Netherland). A clinical CT perfusion (CTP) scanning protocol was used. The parameters were: 8 cm scan coverage identical to slab-PBV, 5 mm slice thickness, 64x1.25 mm collimation, 20x20 cm FOV, 80 kVp, 250 mA, 100 mAs, 0.4 second tube rotation time, scan interval of 1.5 seconds and lasted for one minute.

Results

The dose area product/entrance skin dose was 2631.6 μGym^2/228 mGy and 6884.4 μGym^2/240 mGy for slab-PBV and whole brain PBV, respectively. The effective dose was 0.84±0.56 and 4.18±0.90 mSv (ICRP-103), respectively for slab-PBV and whole brain PBV. As a comparison, the dose length product of MDCT CTP was 1177.3-1232.9 mGy*cm, equivalent to the effective dose of 2.46-2.58 mSv. The effective dose of MDCT CTP measured by TLDs was 2.55±1.60 to 2.84±1.54 mSv (ICRP-103).

Slab-PBV Scanning Results

Conclusion

The effective dose measurement presented in the study is reliable and reproducible. Cerebral PBV® measurement

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

using FD DSA is a dose-saving imaging protocol. The effective radiation dose of slab-PBV is about one-third of MDCT CTP. Taking the advantages of on-site and immediate morphologic imaging availability, saving of procedural time and patient transportation, FD-DSA slab-PBV is recommended.

Modeling the Pattern of Contrast Extravasation in Acute Intracerebral Hemorrhage Using Dynamic Contrast-Enhanced MR Imaging

Liu, R. T.[1,2]·Huynh, T. J.[1,2]·Huang, Y.[1]·Rideout-Gros, S.[1]·Van Slyke, P.[1]·Dumont, D.[1]·Hynynen, K.[1]·Aviv, R. I.[1]
[1]Sunnybrook Health Sciences Centre, Toronto, ON, CANADA, [2]University of Toronto, Toronto, ON, CANADA.

Purpose
Intrahematoma contrast extravasation in spontaneous intracerebral hemorrhage (ICH), coined the spot sign, has been shown to predict subsequent hematoma expansion and poor clinical outcomes. The dynamic relationship of the site of active contrast extravasation and the influence on the pattern of ICH formation are poorly understood. We used an animal model of acute ICH with contrast extravasation to characterize the dynamic pattern and rate of contrast extravasation.
Materials & Methods
Intracerebral hemorrhage was created within the basal ganglia in five yorkshire pigs utilizing a novel ICH animal model permitting real-time observation of contrast extravasation with dynamic contrast-enhanced (DCE) MRI (3T Signa MR750; GE Healthcare). Dynamic contrast-enhanced MRI was performed after intravenous bolus injection of Gadobutrol (Bayer Healthcare) utilizing a 3D T1-weighted spoiled gradient-recalled echo sequence with total acquisition time of 12 minutes. A 10-second temporal resolution was employed allowing dynamic visualization of hematoma growth. Contrast extravasation volume was measured using computerized planimetry (MIPAV, version 5.3; National Institutes of Health) at each time point. Spatial vector analysis was used to characterize asymmetric extravasation and hematoma growth. Vectors at each time point determined the rate of expansion along three-dimensional axes. Temporal phases of growth and stability were defined by maximizing the coefficient of determination for period of growth while minimizing the gradient for periods of stability. Rate of contrast extravasation was calculated using in-house software using a Patlak model (IDL, version 6.1; RSI, Boulder, Colorado).
Results
The ICH animal model exhibited asymmetric growth and variable rates of expansion. Initial rate of contrast extravasation was 8.9±3.4 ml/100g/min. A triphasic pattern of ICH growth was seen (Figure 1) with rapid initial average diameter expansion (156±17%) in the primary phase, followed by relative stability in the secondary phase. The tertiary phase was associated with further overall expansion (30±12%). In the primary phase, expansion in the superior-inferior (SI) plane outpaced the growth in the anterior-posterior (AP) plane (4.0±1.2 mm/min versus 1.2±0.3 mm/min; t-test p=0.003). In the tertiary phase, diameter expansion was greatest in the AP plane and was similar to the AP growth demonstrated in the primary phase (t-test p=0.126).

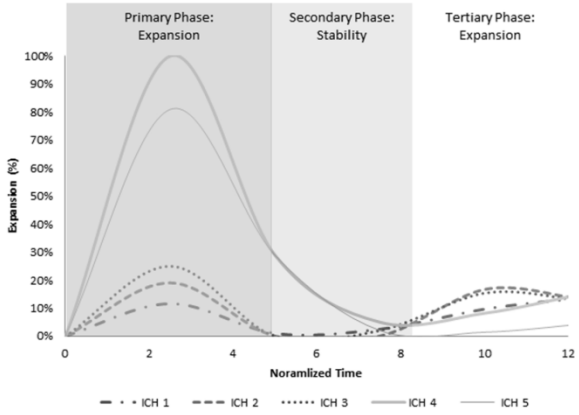

Figure 1. Percentage of contrast extravasation volume in the medial-lateral axes versus normalized time
Conclusion
A novel model of ICH formation demonstrating contrast extravasation is feasible and provides real-time study of the dynamics and rate of contrast extravasation. These data facilitate the understanding of rate and pattern of ICH formation.

Time of Arrival Parametric Maps and Sliding Window Virtual Bolus Images Derived from High-Resolution Whole Brain Contrast-Enhanced 4D MR Angiography Improve the Display of Arteriovenous Malformation Vascular Anatomy and Flow Characteristics

Maksimovic, J.·Wu, Y.·Johnson, K.·Loecher, M.·Mistretta, C.·Turski, P. A.
University of Wisconsin
Madison, WI.

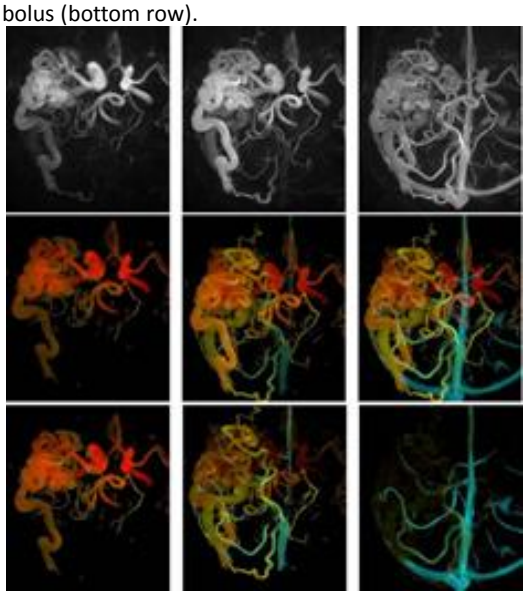
Purpose
Time-of-arrival (TOA) maps can be derived from high-resolution 4D MRA datasets to provide a qualitative description of contrast material arrival time in each voxel. The purpose of this project is to determine whether TOA-enhanced 4D MRA and/or virtual bolus imaging improve the characterization of brain AMVs.
Materials & Methods
High-resolution whole brain contrast-enhanced 4D MRA

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

exams with subsecond temporal resolution were acquired by using radial acquisition and highly constrained projection reconstruction (4D CE HYPR MRA) in seven AVM patients. The TOA maps are based on signal intensity changes over time for each voxel. The TOA for each voxel was defined as the time point when the signal intensity reached 20% of its maximum. The TOA maps were generated, color encoded and then multiplied with the time-resolved contrast-enhanced MRA images at each time frame to form new 4D MRA images (TOA-enhanced 4D MRA) which not only represent the contrast enhancement of vessels at different time frames, but also contain the contrast arrival times with defined color encoding. In addition, each time frame also can be weighted by a Gaussian distribution in the time domain to form a virtual 4D bolus map. This 4D bolus map was then color coded and multiplied with the 4D MRA images to form a DSA-like virtual bolus, where at each time frame, only vessels with certain TOA values within the defined bolus length appear.

Results

4D MRA, TOA maps and virtual bolus images from seven AVM patients were scored by two observers for diagnostic confidence (0-100%) for detecting AVM arterial feeders, nidus and draining veins using DSA as the reference standard. For both observers, six of seven of the TOA maps improved identification of the arterial feeders and made evaluation of the nidus and venous drainage easier in all seven cases. The virtual bolus images improved the delineation of the venous drainage in five of seven patients. Figure 1 demonstrates axial projection 4D MRA (top row), TOA-enhanced 4D MRA (second row) and virtual bolus (bottom row).



Conclusion

TOA-enhanced 4D MRA provide serial images and time of arrival maps in one simple display. Our preliminary results suggest that TOA mapping improved delineation of the arterial supply, nidus and venous drainage in AVM patients. Virtual bolus images isolate the venous structures by providing better arterial/venous separation.

Quiet PROPELLER MR Techniques Provide Equivalent Quality for Routine Brain MR Imaging

Corcuera Solano, I.[1]·Gui, D.[2]·Gaddipati, A.[2]·Tanenbaum, L.[1]
[1]Mount Sinai School of Medicine, New York, NY, [2]GE Healthcare, Waukesha, WI.

Purpose

Switching of magnetic field gradients is the primary source of acoustic noise in MRI. Sound pressure levels (SPL) can run as high as 100-120 dB, potentially producing physical discomfort and at least temporary hearing loss, mandating hearing protection. To date two methods have been used to reduce noise - dampen/isolate the gradient coil from the patient bore, or reduce switching rate. Both methods have drawbacks, the first resulting in reduction of bore space and the second reducing performance. New technology has made quieter techniques feasible which range from as low as 80 dB (1/10000 as loud) to nearly silent. The purpose of this study is to evaluate the quality of “Quiet” MR FSE acquisitions in comparison to techniques in current day to day practice in imaging of the brain.

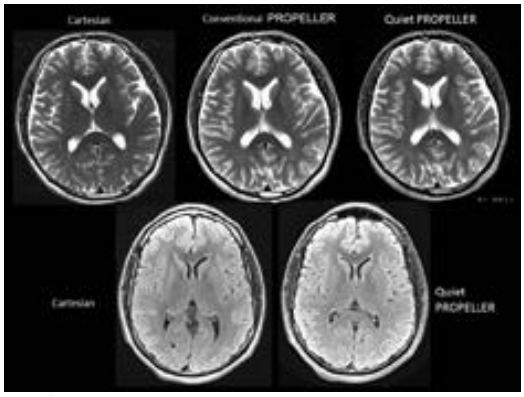
Materials & Methods

This novel ”Quiet” method reduces acoustic noise levels approximately 30 dB for T2 and T2 FLAIR PROPELLER employing an acoustic noise model to optimize gradient waveforms while minimizing the impact on scan time. An additional 180 degree preparation is used to minimize the effect on image quality. Fifty patients were scanned with preclinical “Quiet” techniques in addition to routine T2 and T2 FLAIR PROPELLER imaging sequences on a clinical 1.5T MR scanner. Conventional and “Quiet” PROPELLER FSE images were reviewed retrospectively by two experienced neuroradiologists who qualitatively assessed image quality for contrast resolution, artifact and, when appropriate, lesion conspicuity.

Results

“Quiet” PROPELLER T2 and T2 FLAIR were comparable in quality to conventional PROPELLER acquisitions with no significant tradeoffs aside from longer scan times.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Conclusion
"Quiet" PROPELLER T2 and T2 FLAIR provide equivalent quality at comfortable sound pressure levels and can replace conventional sequences for routine evaluations of the brain.

KEYWORDS: Brain, MR imaging safety, Quiet

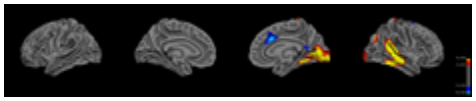
Surface-Based Analyses of Brain Cortical Features in Patients with Periventricular Nodular Heterotopia

Beltran-marin, M.[1]·Azagra, A.[1]·Sadeghi, N.[1]·Jissendi-Tchofo, P.[2]
[1]Erasme Hospital, Brussels, BELGIUM, [2]Lille University Hospital, Lille, FRANCE.

Purpose
First, to analyze brain cortical features, including thickness (CT), complexity in terms of gyration and sulcation (CC) and intracortical intensity gradient (CG) in patients with periventricular nodular heterotopia (PNH) and, secondly, to correlate the volume and topography of the heterotopic gray matter with the white matter volume (WMV) and cortical gray matter volume (GMV) of the affected hemisphere.
Materials & Methods
The brain cortex of 14 patients (six M/eight F, mean age 33 years) with PNH and 28 healthy controls (16 M/12 F, mean 25.5 years) were analyzed after an automatic segmentation processed by FreeSurfer, using a 3D T1 sequence. Surface features such as CT, CC and CG were extracted. The heterotopic gray matter was segmented manually in every patient side by side and corresponding volumes were calculated. The surface features variations were assessed using z scores, intraindividually and as compared with the control group. The correlations between the volume and topography (0 = absent, 1 = anterior, 2 = osterior, 3 = diffuse from anterior to posterior) of the heterotopic gray matter with the white matter (WMV) and cortical gray matter volume (GMV) of the affected hemisphere were obtained using the Pearson's test.
Results
Seven patients had bilateral PNH, three on in the right hemisphere (rh) and four on the left (lh). PNH were located anteriorly (four), posteriorly (five) and diffusely (four). Auto z scores did not show significant variations of cortical features intraindividually (z>2, z<-2). The comparisons with the control group showed various pattern of differences. Areas of increased and decreased (z>3, z<-3) CT were found in the affected hemispheres involving prefrontal, central, parietal and temporal cortices. The CC was increased more often in various areas including, the prefrontal, orbitofrontal, anterior cingulated and temporal lateral cortices (z>3, z<-3). We found only subtle and seldom differences in the CG in temporal and prefrontal cortices (z>3, z<-3). The volume of PNH was correlated inversely with the GMV of the affected hemisphere (r= -0,26 -lh; r= -0,41 -rh). Eventually, the WMV likely was more reduced in anterior PNH while the GMV was more reduced in diffuse PNH.



Conclusion
Periventricular nodular heterotopia causes alterations of brain cortical features in individuals, which likely are related to the impaired cortical development. Thickness, complexity and gradient of the cortices are altered at different degrees and areas. The PNH volume likely is more associated with diminished gray matter than reduced white matter.

Dynamic Contrast-Enhanced MR Imaging: Measuring Permeability on MR Imaging as a Novel Biomarker of Human Cerebral Cavernous Malformations

Shah, A.·Mikati, A.·Li, L.·Shenkar, R.·Zhao, L.·Guo, X.·Gao, J.·Shi, C.·Dey, M.·Awad, I.·Christoforidis, G.
University of Chicago
Chicago, IL.

Purpose
Patients with familial cerebral cavernous malformations (CCM) have one of three gene mutations and display multiple cavernomas whereas patients with sporadic CCM typically harbor one lesion. Data from murine haploinsufficient models suggest that these gene mutations play a role in dysfunction of the interendothelial cell junction proteins, demonstrate increased vascular permeability on Evans blue dye studies and that restoration of normal permeability by Rho kinase inhibition is associated with decreased lesion burden. Thus a marker for permeability could serve as a target for treatment. This study sought to replicate findings in heterozygous mice by determining if permeability within cavernomas and permeability within unaffected brain differed between patients with familial and sporadic CCM

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

using dynamic contrast-enhanced (DCE) magnetic resonance imaging (MRI).

Materials & Methods

Thirteen patients with either sporadic (five patients) or familial (eight patients) cavernomas were imaged using 3.0T Philips Achieva MRI (Philips Medical Systems) and an eight-element phased array receiver head coil. A saturation recovery gradient recalled sequence was used both for an initial T1 measurement and for the subsequent dynamic imaging. Each slice was acquired after application of a nonselective saturation prepulse with a saturation time delay (TD). T1 measurements were derived from 10 TD values varying from 120 ms to 10 seconds. Gadodiamide (0.05mmol/kg) was injected at 4mL/sec followed by 20mL saline. Arterial input function was obtained using a slice specifically acquired perpendicular to a major arterial vessel (carotid or basilar) identified on MR angiography. Permeability maps were derived using a one compartment Patlak model on Matlab. Mean measurements by two independent observers were obtained by drawing regions-of-interest within cavernomas as well as gray and white matter near and distant (>2cm) from the cavernoma.

Results

Permeability measures are summarized in Figure 1. For each category, mean permeability was significantly higher in the familial versus sporadic cases ($P < 0.05$, Student *t*-test). Significant, interobserver difference was only present when measuring gray matter far from the lesion ($p<0.001$).

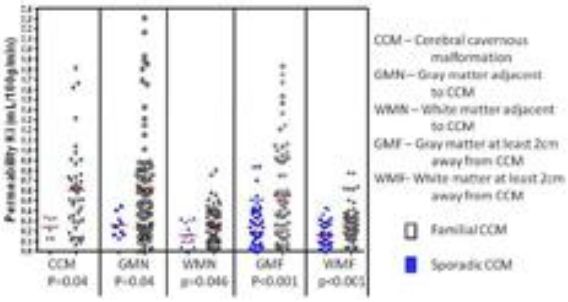

Figure 1: Comparison of permeability in patients with familial and sporadic CCM

Conclusion

Pilot data presented here suggest that patients with familial CCM compared to patients with sporadic CCM have increased permeability on DCE MRI both within the CCM and nonaffected brain. Further studies will be needed to determine if permeability on DCE MRI predicts bleeding risk and if treatments which reduce permeability affect the natural course of CCM formation and hemorrhage.

T1-Weighted 3D Fast Spin-Echo: CUBE MR Outperforms 2D Imaging of the Pituitary and Parasellar Region

Lien, R. J.[1]·Black, A.[2]·Pawha, P. S.[1]·Naidich, T. P.[1]·Tanenbaum, L. N.[1]

[1]Mount Sinai Hospital, New York, NY, [2]Bard College at Simon's Rock, Great Barrington, MA.

Purpose

The relatively thick slices provided by conventional 2D MR techniques are limited by volume averaging, which may obscure small pituitary lesions and suboptimally delineate parasellar structures. Gap-free, thin-slice 3D acquisitions reduce volume averaging, but typically employ GRE techniques that suffer from susceptibility artifacts at the bone-air-soft tissue interfaces of the skull base. The purpose of this study was to show how a novel T1-weighted 3D FSE sequence (CUBE) might outperform conventional 2D FSE techniques for contrast-enhanced imaging of the pituitary and parasellar region.

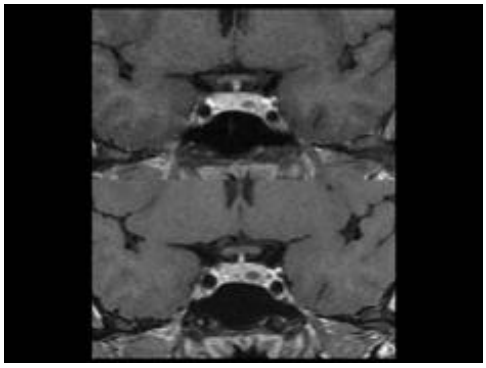
Materials & Methods

Ninety-one patients were scanned with CUBE (50% overlapped 1 mm slices) and conventional 2D FSE (2.5 mm thickness with a 0.8 mm gap) on a clinical 3.0T MR scanner. Images were reviewed retrospectively by two experienced neuroradiologists, who graded the degree of delineation of the infundibulum, optic apparatus and medial wall of the cavernous sinus, as well as the degree of artifact at the sellar floor from one (poorest) to five (best). The degree of lesion conspicuity or confidence in lesion exclusion was graded on a similar scale.

Results

CUBE demonstrated improved image quality compared to the conventional 2D sequence, and was better or equal to the 2D in 84% and 86% of the cases for readers A and B. Both readers graded the degree of artifact at the sellar floor as less problematic on 3D (mean score of 3.2/3.2 on 2D and 4.3/3.9 on 3D for readers A and B). The readers graded the infundibulum as being better visualized on 3D (mean of 3.0/2.7 on 2D and 4.1/3.6 on 3D for readers A and B). The optic apparatus was graded as being slightly better visualized on 3D (mean of 3.2/2.9 on 2D and 3.7/3.0 for readers A and B). The medial wall of the cavernous sinus was graded as better visualized on 3D (mean of 2.5/3.0 on 2D and 3.6/3.6 on 3D for readers A and B). The degree of conspicuity of a lesion and confidence in excluding a lesion was also greater on 3D (mean of 3.6/2.9 on 2D and 4.3/3.4 for readers A and B).

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Conclusion
CUBE provides superior quality with thinner slices and diminished artifact, and can replace conventional 2D FSE sequences for routine evaluations of the pituitary and parasellar region.

"Silent-Zero TE" MR Techniques Provide Equivalent Quality for Routine T1-Weighted MR Imaging of the Brain

Corcuera Solano, I.[1]·McKinnon, G.[2]·Sun, W.[2]·Akao, J.[2]·King, K.[2]·Tanenbaum, L.[1]
[1]Mount Sinai School of Medicine, New York, NY, [2]GE Healthcare, Waukesha, WI.

Purpose
Switching of magnetic field gradients is the primary source of acoustic noise in MRI. Sound pressure levels (SPL) can run as high as 100-120 dB, potentially producing physical discomfort and at least temporary hearing loss, and mandating hearing protection. To date two methods have been used to reduce noise - dampen/isolate the gradient coil from the patient bore, or reduce switching rate. Both methods have drawbacks, the first resulting in reduction of bore space and the second reducing performance. New technology has made quieter techniques feasible which range from as low as 80 dB (1/10000 as loud) to nearly silent. The purpose of this study is to evaluate the quality of nearly silent MR T1-weighted (T1W) GRE acquisitions in comparison to techniques in current day to day practice in imaging of the brain.
Materials & Methods
This novel technique is an essentially silent 3D isotropic gradient echo acquisition with a nearly zero TE and low flip angles. It uses a 3D spiral radial sampling scheme with no in-plane phase and frequency direction, as well as no slice selection phase. Due to the K-Space trajectory and data sampling scheme, the gradient steps are relatively small, accounting for the extremely quiet behavior. An inversion Prep pulse is used to generate T1-weighted contrast similar to BRAVO IR-FSPGR. In addition because of the non-Cartesian nature of the acquisition fat suppression is needed to reduce the effects from chemical shift. Fifty patients were scanned with this pre-clinical "Silent" T1 technique in addition to routine T1-weighted imaging approaches on a clinical 1.5T MR scanner. Conventional and "Quiet" images were reviewed retrospectively by two experienced neuroradiologists who qualitatively assessed image quality for contrast resolution, artifact and, when appropriate, lesion conspicuity.
Results
"Silent" T1-weighted scans were comparable in quality to conventional T1-weighted acquisitions.

Conclusion
"Silent" T1-weighted scans provide equivalent quality at nearly zero sound pressure levels and can replace conventional sequences for routine T1-weighted evaluations of the brain.

Development of an Automated Quantitation Method for Cerebrospinal Fluid Dynamics in the Cerebral Ventricles and the Spinal Subarachnoid Space Using MR Imaging Spin Labeling Technique

Shiodera, T.[1]·Nitta, S.[1]·Takeguchi, T.[1]·Yui, M.[2]·Yamashita, Y.[2]·Yamamoto, T.[2]·Yamada, S.[3]
[1]Toshiba Corporation, Kawasaki, JAPAN, [2]Toshiba Medical Systems Corporation, Tochigi, JAPAN, [3]Tokai University Oiso Hospital, Kanagawa, JAPAN.

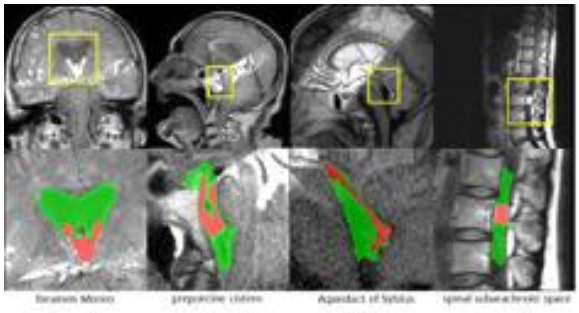
Purpose
Using the time-spatial labeling inversion pulse (Time-SLIP) technique, a regional cerebrospinal fluid (CSF) dynamics can be traced without using contrast medium. Previous studies have evaluated visual assessments of CSF dynamics using the Time-SLIP technique. The objective of this study is automated quantitation of CSF dynamics in the cerebral ventricles and the spinal subarachnoid space using the Time-SLIP technique.
Materials & Methods
A series of 2D images with incremental inversion recovery times was obtained using 1.5T MRI scanner with Time-SLIP sequence. Observation regions were the foramen Monro,

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

the prepontine cisterns, the aqueduct of Sylvius and the spinal subarachnoid space. These regions of interest were automatically outlined based on signal intensity analysis and shape of region. Subsequently, labeled CSF regions were further detected using the image binarization method. Average speed of the labeled CSF region was calculated using a regression line fitting. To evaluate the proposed method, experiments comparing the average speed and visual assessment by three neurosurgeons were conducted. Correlations between the proposed method and manual annotations of the average speed were evaluated in the spinal subarachnoid space.

Results

Seventy-nine datasets including 76 patients with various diseases (idiopathic normal pressure hydrocephalus, secondary normal pressure hydrocephalus, cerebral infarction, etc.) and three healthy volunteers for intracranial CSF dynamics, and 19 datasets from three healthy volunteers for the spinal subarachnoid CSF dynamics were studied. The proposed method detected the labeled CSF dynamics as shown in Figure 1. For cerebral ventricles, Table 2 shows correlation of the average speed between visual assessment and the automated quantitation method in these regions. Concordance ratios were 87 to 91%. For the spinal subarachnoid space, the correlation factor between the proposed method and manual annotations was R2 = 0.83 ($p < 0.001$). The processing time was less than three seconds.



comparison results between average speed and visual assessment

observation region	visual assessment results by neurosurgeons / average speed by the proposed method [mm/sec.]		
foremen Monro	no reflux	slow reflux	normal reflux
	0.40 ± 0.30	1.20 ± 0.62	3.06 ± 0.45
prepontine cisterns	no movement	normal movement	-
	0.55 ± 0.25	1.23 ± 0.49	-
aqueduct of Sylvius	slow movement	normal movement	fast movement
	0.22 ± 0.26	1.09 ± 0.54	3.68 ± 1.66

Conclusion

This paper presented a new automated quantitative method of CSF dynamics using the Time-SLIP technique.

Correction of Cerebral Blood Volume Perfusion Maps from T1 Leakage Effect Allows a Better Correlation of Perfusion Dynamic Susceptibility Contrast MR Imaging with Histopathologic Glioma Grading and an Estimation of Vascular Permeability

Viry, F.[1]·Galanaud, D.[1]·Mitulescu, A.[2]·Chaibi, Y.[2]·Reina, V.[1]·Leclercq, D.[1]·Dormont, D.[1]
[1]Pitié-Salpêtrière Hospital, Paris, FRANCE, [2]Olea Medical, La Ciotat, FRANCE.

Purpose

Capillary proliferation is a major histopathologic criterion in glioma grade determination, known to correlate with CBV. However, in case of blood-brain barrier (BBB) disruption, contrast agent extravascular leakage increases the signal in voxels inducing underestimation of CBV. Sophisticated mathematical models taking into account BBB disruption and arterial input function (AIF) can be used to correct this misestimation and enable permeability constant K2 calculation. We hypothesized that CBV corrected from vascular leakage can better differentiate glioma grade than uncorrected CBV and that K2 increases with glioma grade.

Materials & Methods

Fifty-four patients with steretotaxic biopsy-confirmed gliomas (20 WHO grade II, 13 grade III and 21 grade IV) explored by multimodal MR imaging including dynamic susceptibility contrast (DSC) gradient-echo perfusion MR (1.5T-3T) were included retrospectively. Preprocessing included motion correction, automatic AIF determination and leakage correction (Perfscape/Neuroscape-Olea Medical). Perfusion maps including relative CBV (corrected/uncorrected), relative CBF and K2 were calculated. Regions-of-interest were delineated within the tumor (biopsy site), and in the symetrical contralateral normal-appearing region.

Results

Differences in corrected rCBV were stastistically significant ($p<0.05$) between grade II-IV, III-IV, II-III (nonparametric Steel-Dwass test). Uncorrected rCBV does not statistically differentiate grades II-III. K2 could only differentiate grade II-IV. Corrected rCBV had a stronger correlation to glioma grade than uncorrected rCBV (Spearman $r = 0.73$ and $r = 0.66$ respectively, $p<0.01$). K2 was correlated weakly to glioma grade ($r = 0.34$, $p<0.01$).

Conclusion

Taking into account BBB disruption in DSC perfusion imaging improves glioma grades differentiation with rCBV. K2 has a weak correlation with glioma grade, which could

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

be explained partly by the heterogenous parameters of DSC sequences in this study.

Applications for PET Imaging: Current Applications and Best Practices

Loevner, L. A.
University of Pennsylvania Medical Center
Philadelphia, PA.

Presentation Summary
The strengths and potential pitfalls of FDG-positron emission tomographic imaging in patients with head and neck cancer, especially those who have undergone surgery and/or chemotherapy and irradiation will be reviewed. Positron emission tomography (PET) currently is performed using the radiopharmaceutical ^{18}F-FDG, a D-glucose analog. The increased vascularity of tumors and glucose metabolism by malignant cells result in preferential uptake of FDG by tumor cells. The inability to process the metabolites of the modified glucose molecule causes intracellular accumulation of F^{18} containing radioisotopes. This metabolism has been invaluable in the evaluation of many cancer patients, and PET plays a pivotal role in the diagnosis, staging, and restaging of head and neck oncology patients. The ability to assess the functional status of tissue with FDG-PET has been remarkable, and addresses this well known limitation of

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

conventional cross-sectional CT and MR imaging. Conversely, the excellent spacial resolution and the ability to analyze the relationship of neoplasms relative to critical adjacent structures on CT and MR imaging is a very important adjuvant to, and limitation of PET. This presentation will emphasize physiologic variations seen in PET imaging with particular attention to those seen in the treated neck, and will illustrate the complimentary roles that PET and cross-sectional imaging play in assessing patients with newly diagnosed and treated head and neck cancer. **Evaluating Head and Neck Cancer.** Direct visualization combined with endoscopy is very sensitive in evaluating the mucosa of the aerodigestive tract. However, submucosal infiltration of the deep spaces of the head and neck is difficult to detect on physical and endoscopic examination unless there are symptoms to suggest that such spread is present. As a result, patients often are clinically understaged. CT and MR play a critical role in delineating the extent of deep tumor spread. The need for and type of surgery and the use of chemotherapy and irradiation are guided by the site of origin of the primary tumor and staging at the time of clinical presentation. One of the major limitations of cross-sectional CT and MR imaging is that they are morphologic studies that look at the structure of organs; however, often do not identify regions of biologically active tumor in areas that are morphologically relatively normal in appearance. Surgery, irradiation, and increasingly adjuvant chemotherapy are the arsenal for treating head and neck cancer and result in altered anatomy related to surgical absence of tissue, anatomical distortions, as well as inflammatory changes both in the site of the primary tumor as well as in the lateral neck treated for regional nodal metastases. It can be difficult even for an experienced radiologist to reliably distinguish post-treatment changes and its complications from tumor due to the overlapping densities and intensities of muscle, tumor, edema, and inflammation on CT and MR imaging, respectively. FDG-PET plays a critical role in further assessing these patients. In patients with head and neck cancer, an important factor in determining prognosis, treatment, and long-term survival is the identification of regional nodal metastases. Necrosis within cervical lymph nodes usually is indicative of the presence of metastatic disease. At least 10% of cervical lymph nodes harboring cancer are normal by CT and MR imaging criteria (not enlarged and with normal architectural features). FDG-PET frequently detects metabolic activity in cancer-harboring nodes that are normal on conventional imaging. Such identification frequently alters management. For example, detection of contralateral nodal metastases on PET not suspected clinically or on conventional imaging may result in a neck dissection. The inability to consistently identify small osseous and solid organ metastases is another limitation of CT and MR imaging. Detection of distant metastases may determine that a patient is no longer a surgical candidate. **Limitations of FDG-PET in Evaluating Head and Neck Cancer.** While PET has dramatically improved the detection of tumor(s), it is of paramount importance to understand and recognize the limitations of PET which include but are not limited to spatial resolution, anatomical localization, and physiologic variations in FDG distribution and uptake. Other potential issues with PET include reduced or absent uptake in tumors that are largely cystic or necrotic, and very importantly, some neoplasms are of histologic types that frequently do not take up FDG glucose. Imaging with FDG-PET alone has the limitations of reduced spacial resolution and suboptimal anatomical localization. PET may identify a neoplasm at the skull base, but the resolution is such that it cannot illustrate the involvement of prevertebral muscle, the encasement of the carotid artery, or the contiguous intracranial extension. The most significant contribution that CT has added to the combined PET-CT study is the ability to accurately localize regions of FDG uptake. Everything that is “hot” is not always cancer, and this has particular significance in the head and neck. There are a spectrum of physiologic variations in the distribution of FDG radiotracer that may result in regions of normal, avid FDG uptake. These variations in FDG distribution are compounded and even more complex in patients who have been treated for head and neck cancer. The altered anatomy from surgery results in functional and compensatory differences that change the pattern of radioisotope uptake on FDG-PET images. A solid understanding of both the post-treatment anatomy and the biology of head and neck cancer based on its site of origin in the aerodigestive tract, typical patterns of lymph node metastases, as well as post-treatment anatomy and expected variations in radiotracer distribution is essential to provide accurate interpretations of PET scans and avoid interpretive errors. Physiologic variations of FDG uptake and distribution in the treated neck may occur in the lymphoid tissue of Waldeyer’s ring (mistaken for tumors), the salivary glands**,** within brown fat, as well as in muscles (including the true vocal cords, skeletal muscles, and oral cavity tongue). A common pitfall of PET is the misinterpretation of uptake in a submandibular gland for a malignant lymph node when the contralateral gland is surgically absent as part of a neck dissection. The uptake of FDG in brown adipose tissue (fat) may serve as another potential source of false positive FDG-PET interpretations. Brown fat plays an important role in cold-induced and weight-loss induced thermogenesis. It is frequently formed in patients with rapid weight loss, such as patients being treated for cancer, and is more common in the winter. It also is more common in children and in women. The brown color of the fat is likely related to its vascularity and increased mitochondrial density. FDG uptake in metabolic brown adipose tissue is explained by the presence of glucose transporters. Brown fat commonly occurs bilaterally and often symmetrically. It has a propensity to occur in the mediastinum, paravertebral and intercostals regions, the lateral neck, supraclavicular fossa, axilla, and the abdomen**.** Uptake in metabolically active brown fat may be misinterpreted as tumor, especially when

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

deposited in an asymmetric pattern. Fused PET-CT images are useful in avoiding this pitfall by precisely localizing the focal FDG uptake to regions of hypoattenuating fat. Some muscles in the neck that may be common have physiologic uptake include the spinal cervicalis and splenius capitus muscles, the prevertebral muscles (longus colli and longus capitus), and the scalene muscles. To minimize skeletal muscle uptake, it is important that the patient be at rest prior to imaging. Muscular uptake may be symmetric or asymmetric, and usually is elongated in appearance on sagittal and coronal reconstructed PET images. In treated necks patients often compensate for surgical absence of muscles, nerve injury, and pain by using different muscle(s). Asymmetric uptake in these compensatory muscles may be misinterpreted as pathologic lymph nodes. Mucositis occurs in patients managed with irradiation and chemotherapy. These patients often have continual tongue motion in order to manage dry mouth and oral secretions frequently resulting in physiologic uptake in the tongue which should not be misinterpreted as neoplasm. Clinical correlation and manual palpation by the clinical subspecialists are necessary. Another common misinterpretation is in the setting of hemi-tongue paralysis and denervation in which the contra-lateral functioning side of the tongue may show physiologic FDG uptake that is misinterpreted as oral cavity tumor. In patients with vocal cord paralysis there often is normal physiologic uptake in the contralateral vocal cord which frequently is misinterpreted as a glottic cancer. Review of cross-sectional imaging frequently shows the secondary findings of vocal cord paralysis including dilatation of the ipsilateral piriform sinus, vallecula and laryngeal ventricle. These findings as well as patient history will assist in avoiding this false positive pitfall. Sequelae of treatment and its complications also may result in false positive interpretations on PET-CT imaging. Specifically, inflammation frequently seen with radiation therapy, early radiation necrosis, and infection-abscess formation may result in FDG uptake that can be mistaken for recurrent or residual neoplasm. Knowledge of the timing of irradiation and type of surgery if performed is critical when assessing the PET images. While PET is very sensitive in this scenario, it is not specific in the early weeks to months immediately following treatment where tumor, treatment sequela and complications of treatment may be FDG avid and may have overlapping appearances on the CT portion of the study. Specificity on PET imaging increases with time, and usually FDG uptake 12 weeks or more out of therapy is worrisome for the presence of neoplasm. The presence of air in the involved soft tissues on the CT scan is an important associated finding and should raise concern for infection or radiation necrosis. Reparative bone formation in patients that have undergone surgical placement of reconstructive grafts, such as positioning of a mandibular implant following a partial mandibulectomy, also can result in physiologic uptake of FDG. Other potential pitfalls of FDG-PET in the treated neck include inability to detect hypermetabolic activity in cancer-harboring nodes. Reduced or absent FDG avidity within nodes harboring cancer may be related to multiple factors including low cellularity, cystic adenopathy, or in lymph nodes that are primarily necrotic. While the majority of malignant neoplasms in the head and neck are squamous cell carcinomas and are FDG avid, there are other neoplasms that do not always show FDG avidity, and one must be aware of these when ordering and interpreting PET-CT studies. Neoplasms that may not always demonstrate FDG avidity include mucinous adenocarcinomas, salivary tumors especially adenoid cystic and mucoepidermoid carcinomas, and thyroid cancers (iodine avid differentiated cancers and some medullary cancers).

Advanced Techniques and Biologic Imaging of Head and Neck Cancer

Srinivasan, A.
University of Michigan Health System
Ann Arbor, MI.

Presentation Summary

Accurate assessment of the neck after surgery or chemoradiation of head and neck malignancies is important. Detection of residual neoplasm and/or early recurrences negatively impact patient outcome. However, conventional imaging in the post-therapy neck presents challenges due to the distortion of anatomical boundaries and the frequent presence of grafts or flaps, which can result in both false positive and false negative interpretations. Biologic imaging, which can be defined as imaging of biologic processes such as perfusion of a tissue or its metabolic status, has the potential to detect malignant disease at a much earlier stage than conventional imaging alone, and therefore is gaining interest in more institutions. Preliminary studies also have suggested that biologic imaging may play a role in prediction of response to therapies, thus allowing individualization of management strategies rather than follow a "one-for-all" approach. The different biologic imaging modalities including CT perfusion, MR perfusion, diffusion-weighted MRI, MR spectroscopy and dual energy CT will be introduced with discussion of the parameters measured on each modality and its specific role in assessment of the pre and post-treatment neck. Diffusion imaging in the head and neck has shown promise in many clinical scenarios that include differentiation of benign and malignant pathologies, identification of metastatic lymph nodes in a patient with known primary neck tumor, differentiation of recurrent malignancy and benign post-therapeutic change, and prediction and monitoring of response to chemoradiation. MR and CT perfusion measure physiologic parameters that can help in prediction and monitoring of response to chemoradiation and stratify patients into complete and poor responders. Prediction of response to chemoradiation during early stages of therapy can be crucial since this would be the

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

first step towards developing modified treatment strategies (e.g., escalated radiation doses) in potentially unresponsive patients. The recent introduction of dual energy CT has opened the possibility of better tissue characterization on CT through material density analysis and this may help in differentiation of benign and malignant tissues. The primary challenge that the head and neck radiologist is faced with on a daily basis is identification of residual or recurrent neoplasm within the treated neck. While there are some conventional imaging features such as increase in size, appearance of new enhancement and perineural spread that suggest presence of malignancy, often it is challenging to assess the treated neck. Diffusion-weighted imaging has shown promise in multiple studies with the ADC value in recurrent tumor consistently being lower than in nonmalignant granulation tissue. Adequate and accurate knowledge of the anatomical and functional status of head and neck cancer is essential to understanding the prognosis, making the right treatment options and a more accurate assessment of the post-treatment lesion. However, it should be remembered that the information derived from biologic imaging modalities cannot be interpreted in isolation and the anatomical and functional information need to be synthesized together for a comprehensive assessment of head and neck cancer.

Standard Imaging Techniques for Mild Traumatic Brain Injury

Anzai, Y.
University of Washington
Seattle, WA.

Presentation Summary
Traumatic brain injury (TBI) is a highly prevalent and a leading cause of death and disability among young adults. The CDC estimated that there are approximately 1.5 million people suffering from TBI annually and 75% of them sustain mild TBI. The common etiologies of TBI include motor vehicle accident, motorcycle accidents, fall, and assaults. The vast majority of TBI is so-called mild TBI. Although many mTBI have a predictable favorable course requiring few if any special medical attention, some mTBI patients suffer from impaired memory, attention, executive function as well as emotional instability. One of the major challenges related to diagnosis and management of mTBI is lack of clear consensus as to the definition of mTBI. The terms used to describe mTBI are “concussion”, mild TBI, minor TBI, minimal TBI, and grade 1 TBI. Some use mTBI and concussion interchangeably, and others don't. Some include GCS 13 under mild TBI, and others suggest excluding GCS 13 from mild TBI. Some include negative CT as an inclusion criterion for mTBI, thus presence of structural abnormality indicate at least moderate TBI. American Congress of Rehabilitation Medicine (ACRM) defines a diagnosis of mTBI, of which at least one of the followings must be present: 1) Loss of consciousness of less than 30 min and GCS score of 13-15 after the period of loss of consciousness, 2) Loss of memory of the event immediately before or after the accident (event) with posttraumatic amnesia of less than 24 hours, 3) Any alternation in mental state at the time of accident. CDC conceptual definition of mild TBI includes one of the following signs and symptoms: 1) Any period of transient confusion, disorientation, or impaired consciousness, 2) Any period of dysfunction of memory around the time of injury, 3) Observed signs of other neurologic or neuropsychologic dysfunction, 4) Any period of loss of consciousness lasting 30 min or less. The definition includes patients with CT abnormality or focal neurologic symptoms, though they suggest distinguishing such cases with imaging or neurologic abnormality from those without for outcome assessment. VA and DOD definition of mTBI are: a traumatically induced injury and or physiologic disruption of brain function as a result of an external force and include: 1) Loss of consciousness (LOC) less than 30 min, 2) Alternation of mental state less than 24 hours, 3) Post-traumatic amnesia (PTA) up to one day, 4) GCS score 13-15, 5) Normal structural imaging (i.e., Head CT). It is important to notice up to 15% of TBI patients with GCS score of 14 or 15 will have an acute intracranial injury on noncontrast head CT. Advanced imaging studies such as fMRI, DTI, PET, and EEG are not

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

considered currently accepted criteria for measuring severity of TBI in the clinical setting. Evidence-based practice guidelines by the ACEP-CDC (American College of Emergency Physician)-(Centers of Disease Control and Prevention) summarize the current evidence for mTBI. Critical analysis of the medical literatures using MEDLINE and the Cochrane Database from January 2000 to 2007 were reviewed, limited to English literatures, human study, and age 16 years or older. We will focus on the following critical questions: 1) Which patients with acute mTBI should have a noncontrast head CT in ED? Patients with LOC or PTA only if one of the following is present: Headache, vomiting, age >60, drug and alcohol intoxication, short-term memory deficit, physical evidence of trauma above clavicle, post-traumatic seizure, GCS less than 15, focal neurologic deficit, or coagulopathy. Both New Orleans Criteria (NOC) and Canadian Head CT Rule (CHTR) have 100% sensitivity in identifying lesions requiring neurosurgical intervention, though specificity was higher in CHT (37%) than NOC (5.6%). Other major prediction rules include NICE (National Institute for Health and Clinical Excellence), and NCRFNS (Neurotraumatology Committee of the World Federation of Neurosurgical Societies. 2) Is there a role of MRI over noncontrast CT in the ED evaluation of a patient with acute mTBI? There is no evidence-based recommendation of the routine use of brain MRI in acute TBI clinical setting, as compared with CT. Several studies compared brain MR with head CT and documented that MR revealed 10-57% more lesions than noncontrast head CT. These findings include small hemorrhagic or nonhemorrhagic contusion, small extra-axial hematoma, and diffuse axonal injury. None of the studies demonstrated clinical relevance of these abnormal MR in the timeframe relevant for the disposition of patients at ED. One of the added complexities is the difference in timing of CT and MR. In addition to the routine brain MR including FLAIR, T2, DWI, and SWI (susceptibility-weighted imaging) or GRE (gradient echo imaging), DTI has been reported to correlate well with severity of postconcussion symptoms. Diffusion tensor imaging is currently largely a research tool and requires further investigation before the implementation of DTI in clinical care for individual patient level. Nevertheless, many mTBI patients remain symptomatic and face difficulty in returning to daily activity or work for weeks or months, despite lack of abnormality in conventional imaging. The damage caused in mTBI and concussion patients are beyond the resolution or sensitivity of current morphologic imaging studies. The pathophysiology of mTBI/Concussion is likely at molecular, cellular and synaptic level. We must investigate advanced imaging techniques that are sensitive and robust enough to detect these axonal and synaptic changes in an individual patient in order to better refine mTBI.

O-589 **3:50 PM - 4:10 PM**

Advanced Imaging Using Diffusion Tensor Imaging

Lipton, M. L.
Albert Einstein College of Medicine
Bronx, NY.

Presentation Summary
Diffusion tensor imaging (DTI) is an area of much interest for the evaluation of traumatic brain injury (TBI) because of its ability to assess axonal microstructure, the brain substrate of traumatic axonal injury (TAI). This presentation will summarize the literature applying DTI to TBI and assess it in light of evidence-based medicine standards, with comparison to the level of evidence supporting other neuroradiologic applications.

Room 5AB

(61) General Session: Neuroimaging: What Is It and How Can It Help Us?

O-591 **3:15 PM - 3:45 PM**

Introduction to Neuroimaging

Lake, D.
University of Michigan-Flint
Flint, MI.

Dr. Dan Lake is a Marketing Lecturer at the University of Michigan-Flint's School of Management. Dan has taught marketing, advertising and consumer behavior for eleven years following a decade of professional marketing-related experience at Ford Motor Company, U.S. Steel Corporation and McCann-Erickson Worldwide Advertising. Dan's research interests include celebrity/athlete endorsements and the impact of "committed 'fandom'" on consumers cognitive and affective responses to negative publicity. Dan

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

is completing his PhD this year at Michigan State University following studying at Michigan State University, Northwestern University and The University of Chicago.

Presentation Summary
Dr. Lake will be setting the foundation of marketing core topics and current trends in research/practice, including the cognitive consumer decision-making process (consumer behavior). Dr. Lake will discuss how marketing researchers struggle to accurately measure and account for the real reasons behind consumer purchases as most individuals claim not to be formally influenced by advertising and marketing strategies.

O-592 **3:45 PM - 4:15 PM**

The Role of Imaging Techniques (MR, PET, etc.) Used in Neuromarketing

Kilts, C.
University of Arkansas for Medical Sciences
Little Rock, AR.

Dr. Kilts is currently the founding Director of the UAMS Brain Imaging Research Center (BIRC), a human neuroscience and neuroimaging technology application resource in the Psychiatric Research Institute. He has had a long-standing interest in the modes of neural information processing related to human mental health and illness. While at Emory University he created collaborative relationships with faculty in the Goizueta Business School and with a commercial marketing and strategic planning entity that focused on the application of fMRI technology in business problem-solving. These enterprises resulted in published articles in the NY Times, Harvard Business Review, and peer-reviewed publications in scientific journals on the topic of business neuroscience.

Presentation Summary
This presentation will discuss the history of the academic roots of the field of neuromarketing or the application of brain imaging technology to the understanding of consumer choice behavior. This multimodal imaging science has led to both commercial and academic representations of neuromarketing. I will discuss my personal experiences in developing a collaborative enterprise in business neuroscience and neuroimaging, the response of the anti-business "consumer advocates", and our functional magnetic resonance imaging studies of the business neuroscience topics of moral reasoning, cognitive fitness and strategic ability. This discussion will conclude with a critical assessment of the place of neuromarketing research in academic medical center settings, the confining and charged properties of the term, and the scientific and societal value of a going forward research program in business neuroscience.

O-593 **4:15 PM - 4:45 PM**

What is the Role of our Neuroradiology in Neuromarketing?

Holodny, A. I.
Memorial Sloan-Kettering Cancer Center
New York, NY.

Presentation Summary
Functional MRI (fMRI) currently is used clinically for mapping of essential areas of the brain (e.g., language and motor) prior to brain tumor surgery. This use has associated CTP codes, is covered by insurance and is rapidly becoming the standard of care. However, the vast majority of fMRI manuscripts in the scientific literature currently study the neuroanatomical and functional basis of normal brain function (such as linguistics, development, decision-making, ethics and religion) as well as neurologic disorders outside of brain tumors (such as psychiatric disorders, MS or cortical reorganization after neurologic insults). Hence, it is essential for neuroradiologist to understand these new delineations of brain function and incorporate them into routine clinical reports. For example, instead of reporting a "left frontal lobe metastasis", a neuroradiologist should incorporate the clinically relevant functional anatomy into the report, for example, "metastasis in the pars triangularis, in the expected location of Broca's area." Neuromarketing uses fMRI (as well as other technologies) to study the responses of the brain to optimize various marketing strategies. Neuromarketing has been used by many major corporations; however, it does have its detractors. Notwithstanding, it is essential for neuroradiologist to understand how fMRI scans are being used by others outside of their immediate professional community as well as the functional neuroanatomy underlying these principles of neuromarketing.

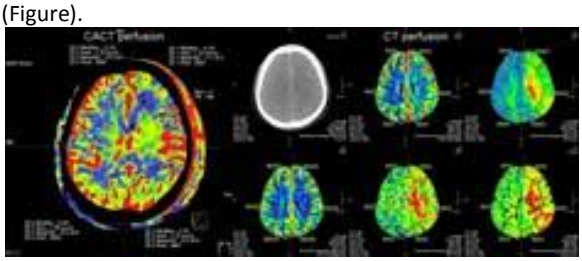
Intraprocedural C-Arm Computed Tomography Perfusion as Assessing Method for Balloon Occlusion Test: A Case Report

Zhang, Y.[1]·Yang, Z.[1]·Huang, Q.[1]·Hong, B.[1]·Liu, J.[1]·Ye, H.[2]
[1]Center of Clinical Neuroscience, Shanghai, CHINA,
[2]Siemens China, Shanghai, CHINA.

Purpose
To treat some complex lesions, such as intracranial huge aneurysm, traumatic fistula or tumor, it may be necessary to block off a vessel. In such situation, balloon occlusion test (BOT) is required before carotid sacrifice. There have been several reports on strokes after carotid ligation in patients who even had been identified with adequate collateral flow by preoperative BOT. A case tolerated BOT test, but with abnormal cerebral blood volume (CBV) maps generated by intraprocedural C-arm computed tomography (CACT) perfusion is reported. The potential value of CACT CBV measurement for BOT is discussed.
Case Report
A 47-year-old female admitted to our institute. A giant intracranial aneurysm located at the ophthalmic segment of the left internal carotid artery (L-ICA) was demonstrated. A treatment of L-ICA occlusion was adopted. Before the procedure, a BOT was performed. During the BOT, no neurologic impairments were found. A CACT perfusion (syngo DynaPBV Neuro, Siemens, Germany) also was performed to check the perfusion status during the BOT. Since the patient can tolerate the BOT, L-ICA occlusion was performed. The patient's postoperative status was almost uneventful, but three days later, she suffered paroxysmal slurred speech. CT perfusion showed abnormal in perfusion. The diffusion-weighted MR demonstrated an acute infarction in left parietal lobe. With intensive medical care, no further neurologic impairments occurred and the patient was discharged a week later.
Imaging Findings
The intraprocedural CACT perfusion showed there was a relative hypopefusion in the hemisphere with balloon occlusion (Figure). The CT perfusion three days postprocedure showed prolonged time-to-peak (TTP) and mean transit time (MTT) in the occlusion side, as well as decreased cerebral blood flow (CBF) and minor increased CBV, which was a typical sign of early phase of ischemia (Figure).



Summary
This case demonstrated that the classic BOT might not be enough to ensure the safety of the carotid sacrifice treatment. The intraprocedural CBV measurements by CACT could detect ischemia during the BOT at an early phase. It may have a good prediction value to detect the patients with high risk of ischemia after carotid occlusion. Large scale clinical trials are needed to evaluate its value.

KEYWORDS: C-arm CT CBV, Balloon test occlusion

EE-2

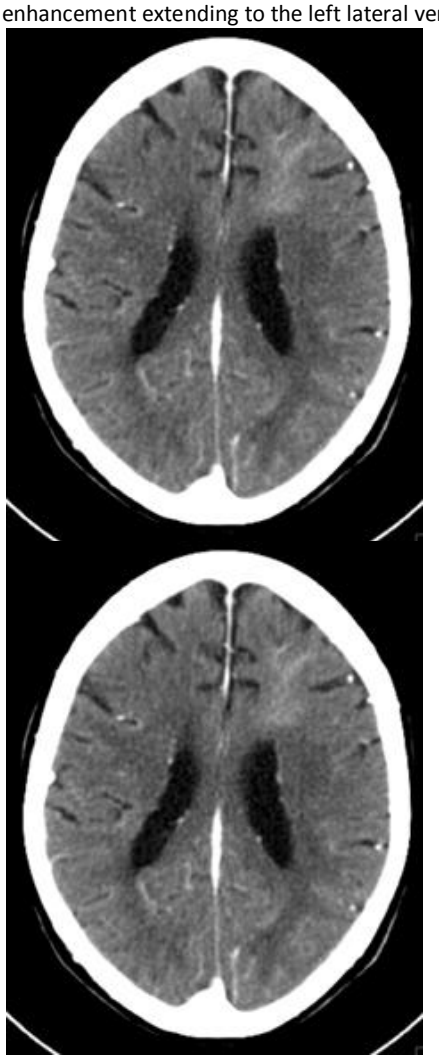
Rare Case of Amyloidoma in Patient with Plasma Cell Dyscrasia

Javadi, P.·Coffey, M.·Patel, T.·Etesami, M.·Blackham, K.
University Hospital Case Medical Center
Cleveland, OH.

Purpose
Tumefactive amyloid deposition is the rarest form of amyloid deposition disease in the brain. This case highlights and reviews common imaging findings of this disease entity.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Case Report
A 65-year-old female with three months history of memory loss underwent a CT of the head which revealed a left frontal white matter lesion. This finding was confirmed with MRI and the patient underwent stereotactic-guided brain biopsy for the left frontal lesion. The specimen showed abundance of amyloid deposition which demonstrated positive congo red stain and lambda light chain. The patient was diagnosed with monoclonal gammopathy of unknown significance (MGUS) following bone biopsy. Patient developed an episode of small right-sided frontal intraparenchymal hemorrhage seven months after the initial presentation, from which she subsequently recovered.
Imaging Findings
Initial precontrast CT images of the head revealed diffuse patchy white matter changes which were most pronounced within the left cerebral hemisphere. Focal enhancing white matter lesion was seen in the posterior left frontal lobe on postcontrast CT images. MR imaging confirmed this white matter lesion which was hypointense on T1 and T2 and showed irregular, radiating enhancement extending to the left lateral ventricle.



Summary
Amyloidoma should be included in the differential diagnosis of supratentorial white matter lesions without significant mass effect. Imaging findings include irregular, radiating, enhancing margins extending to the lateral ventricles.

KEYWORDS: Amyloid, Brain neoplasms, Amyloidoma

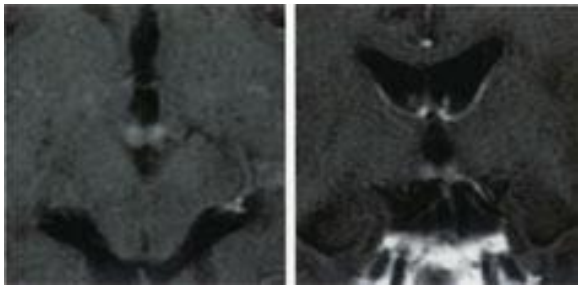
EE-3

Clinical Significance of Mammillary Body Enhancement in Wernicke Encephalopathy: Two Case Reports

Konno, Y.
Yamagata University
Yamagata, JAPAN.

Purpose
To share two cases of acute Wernicke encephalopathy in which the only abnormal finding on MRI was abnormal enhancement of the mammillary bodies.
Case Report
[Case 1] A 75-year-old woman presented at our hospital with bilateral double vision. She had undergone radical pancreaticoduodenectomy for treatment of cholangiocarcinoma. The neurologic examination at the hospital revealed divergence palsy and mild cognitive impairment. The only detectable abnormal finding on MRI with contrast enhancement was diffuse symmetric enhancement of the mammillary bodies (Figure). Acute Wernicke encephalopathy was proposed and a decrease in serum thiamine level was confirmed. With continued thiamine administration, the patient returned to a normal life without any after-effects. [Case 2] A 40-year-old man with high levels of alcohol intake was transported to the emergency room. He had experienced double vision for the preceding month. His consciousness was lucid. A physical examination disclosed extorsion restrictions of both eyeballs, lateral gaze nystagmus, gait ataxia, dysesthesia in bilateral lower limbs, muscle weakness and disappearance of the deep tendon reflex. Acute Wernicke encephalopathy was suspected, and his serum thiamine level was observed to have decreased. MR imaging with contrast enhancement revealed a highly intense gadolinium enhancement only in the mammillary bodies. With continued thiamine administration, he left the hospital without serious after-effects such as memory defects.
Imaging Findings
In two cases of Wernicke encephalopathy, mammillary body enhancement alone was detected on MRI. Considering the high frequency with which mammillary bodies are damaged in Wernicke encephalopathy, abnormal enhancement of this region on MRI will be an important first sign as it becomes more generally known.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Summary
In two cases of Wernicke encephalopathy in which the initial symptom was double vision, the only abnormal finding on MRI was abnormal enhancement of the mammillary bodies. The mammillary bodies are the region most vulnerable to abnormal enhancement. Because MRI with contrast enhancement can detect such abnormal enhancement at an early stage, it should be performed more often on patients with oculomotor disorder to avoid underdiagnosis of Wernicke encephalopathy.

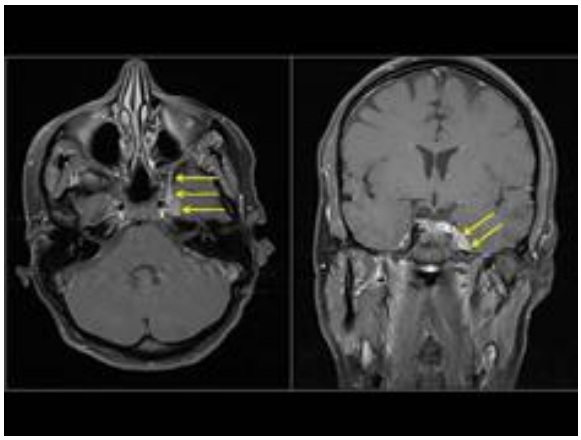
KEYWORDS: Wernicke encephalopathy, mammillary body

EE-4

Cavernous Sinus Amyloidoma

Patel, S. H.·Barry, K. A.·Patel, S. R.·Wang, A. M.·Al-Hakim, M. M.
William Beaumont Hospital
Royal Oak, MI.

Purpose
To the best of our knowledge, this is the first pathologically proven case of an amyloidoma presenting in this unusual location. We report this rare case of an amyloidoma involving the cavernous sinus and Meckel's cave in a patient who presented with trigeminal neuralgia. Central nervous system amyloidomas are extremely uncommon and usually present as supratentorial masses and cortical senile plaques. This unique case report allows the reader to consider amyloidoma in the broad differential of cavernous sinus masses.
Case Report
A 43-year-old female with no significant past medical history presented with new-onset left facial pain and numbness in the distribution of all three branches of the trigeminal nerve. Further investigation by magnetic resonance imaging (MRI) revealed a homogeneously enhancing mass involving and expanding the left cavernous sinus and Meckel's cave with extension to the left foramen ovale and rotundum. The usual differential diagnosis was offered including trigeminal schwannoma, meningioma, pseudotumor, sarcoidosis, lymphoma, and perineural tumor spread. The patient underwent elective surgery for diagnosis and resection of the mass. A left temporal craniotomy was performed with a left preauricular middle fossa approach, which revealed the lesion involving the left cavernous sinus and Meckel's cave with intradural extension. A gross total resection of the lesion was carried out and the specimens were sent for histopathologic analysis. The specimens showed scattered benign ganglion cells and fragments of nerve embedded in a pink acellular material and special staining with Congo red showed apple green birefringence under polarized light, consistent with amyloidoma. After surgery, the patient had resolution of the preoperative left facial pain. However, left facial numbness persisted, greatest over the V1 and V2 areas and milder over the V3 distribution. Further investigation for systemic amyloidosis or multiple myeloma was negative.
Imaging Findings
MR imaging examination of the internal auditory canals (IACs) demonstrated a homogeneously enhancing T2 hypointense and T1 isointense mass measuring 24 mm x 9 mm in the left cavernous sinus extending to Meckel's cave and the foramen ovale and rotundum.



Summary
Although it is extremely unusual, amyloid deposition can involve the cavernous sinus and present as a cause of trigeminal neuralgia. Therefore, amyloidoma should be considered in the broad differential diagnosis of a mass lesion affecting the cavernous sinus.

KEYWORDS: Amyloid, Cavernous sinus

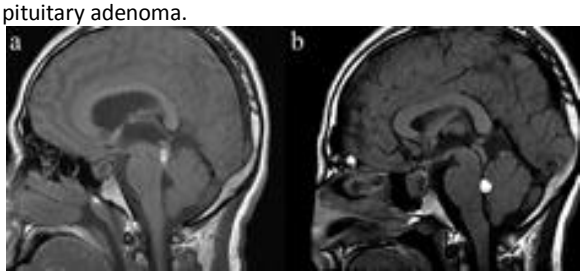
Paradoxical Migrating Cyst: An Unusual Presentation of Intraventricular Neurocysticercosis with a Coincidental Pituitary Adenoma

Ghosh, S.·Al-Khalili, R.·Liu, J. K.·Slasky, S. E.
University of Medicine & Dentistry of New Jersey/New Jersey Medical School
Newark, NJ.

Purpose
We present a novel case of intraventricular neurocysticercosis with paradoxical transaqueductal migration of the cyst from the cerebral aqueduct to the

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

fourth ventricle shortly after ventricular drain placement for acute hydrocephalus with the presence of a coincidental sellar/suprasellar mass.
Case Report
A 26-year-old previously healthy man who recently immigrated from Ecuador, presented with headache and altered mental status for two days. Over the course of two hours in the emergency department the patient became obtunded having sluggish dilated pupils.
Imaging Findings
CT of the head without contrast showed dilatation of the third and lateral ventricles, consistent with obstructive hydrocephalus at the level of the cerebral aqueduct. A focus of calcification was noted in the cerebral aqueduct. A small cystic lesion within the right parietal lobe also was seen. MR imaging of the brain showed a 6.7 mm ovoid lesion in the aqueduct of Sylvius, demonstrating T1 shortening. A 4 mm ring-enhancing lesion in the right postcentral sulcus and a similar 2 mm lesion in the left frontal lobe were seen. There was also a 2.4 cm mixed solid and cystic sellar and suprasellar lesion, exerting mass-effect on the optic chiasm and optic nerves. An external ventricular drain was placed emergently to relieve the hydrocephalus and resulted in significant improvement in the neurologic exam. A repeat MRI was performed about 48 hours after the initial MRI for operative planning, for resection of the pituitary mass. The MRI demonstrated migration of the aqueductal lesion to the fourth ventricle. Hydrocephalus had improved. The mixed solid and cystic sellar and suprasellar lesion was unchanged in size and configuration. The patient underwent endoscopic endonasal transsphenoidal resection of the pituitary mass and surgical pathology confirmed the diagnosis of a pituitary adenoma.



Summary
Our case demonstrates that the intraventricular cysts of neurocysticercosis can migrate in a paradoxical fashion in the setting of cerebrospinal fluid diversion. This resulted in spontaneous relief of obstruction at the cerebral aqueduct, thus restoring normal CSF pathways and precluding the need for permanent CSF shunting. Migrating cysts present a unique challenge to preoperative planning for cyst removal, potentially resulting in surgical exploration of the incorrect ventricular cavity. Additionally, although the presence of a sellar and suprasellar mass in a patient with known neurocysticercosis should raise clinical suspicion for the possibility of sellar neurocysticercosis, pituitary macroadenoma is a more common entity and a more likely etiology for a sellar lesion.

EE-6

MR Imaging Review of West Nile Virus Neuroinvasive Disease

Brace, J. A.·Scott, H. D.·Yetkin, Z. F.·Mendelsohn, D. B.
University of Texas Southwestern Medical Center
Dallas, TX.

Purpose
For 2012, Centers for Disease Control reported a record 5,245 cases of West Nile virus (WNV), including 236 deaths. Of these, 2,663 (51%) were classified as neuroinvasive in the form of meningitis or encephalitis with or without acute flaccid paralysis. A third of cases (1,714) were reported in Texas with 76 related deaths; 35 alone in the Dallas-Fort Worth metropolitan area. On the heels of such an unprecedented epidemic, we provide review (n = 3) of the MR imaging findings of West Nile neuroinvasive disease (WNND) from confirmed 2012 cases at our institution in Dallas, Texas along with a literature review.
Case Report
1: Brain MR in a 43-year-old immunocompromised male showed abnormal FLAIR and T2 signal within the bilateral basal ganglia, thalami, medial temporal lobes, cerebral peduncles and dorsal pons without restricted diffusion. Cerebrospinal fluid (CSF) and serum were positive for West Nile IgM. 2: Brain MR in a 30-year-old female demonstrated scattered foci of nonspecific FLAIR signal within the bilateral cerebral white matter without restricted diffusion. Abnormal FLAIR signal and leptomeningeal enhancement also was seen within the bilateral parietal, occipital, and cerebellar sulci. LP demonstrated mild protein elevation and moderate pleocytosis with lymphocytic predominance. CSF and serum were both positive for West Nile IgM. 3: Lumbar spine MR in a 74-year-old elderly female with left lower extremity weakness revealed smooth enhancement of the cauda equina. Cerebrospinal fluid was positive for West Nile IgG; serum was positive for both West Nile IgG and IgM.
Imaging Findings
Abnormal MR findings in patients with WNND are nonspecific but not uncommon. Studies by Ali and Petropoulou show nearly 70% of patients had abnormal MR findings. Ali defined five MR imaging patterns including: 1) normal; 2) isolated abnormalities of diffusion restriction within white matter; 3) hyperintensity on T2 and FLAIR in the lobar gray and white matter, cerebellum, basal ganglia, thalamus and internal capsule, pons and midbrain; 4) meningeal involvement; and 5) spinal cord and cauda equine/nerve root involvement. Petropoulou noticed that diffusion weighted imaging may be useful in

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

the early detection of inflammation when FLAIR abnormalities are absent. CT is normal in most cases of WNV.

Summary

It is important for the radiologist to have an awareness of the MR imaging findings, though nonspecific, in West Nile neuroinvasive disease especially when factors such as season, geographic area, and exposure to mosquitoes are known. Larger retrospective or prospective studies are needed to correlate the above MR findings with clinical presentation, course, and outcome to determine their prognostic importance. The potential role of environmental factors in the 2012 West Nile virus outbreak raises the concern that changes in climate may lead to disease propagation and more serious outbreaks of mosquito-borne diseases.

KEYWORDS: Encephalitis, West Nile virus

Progressive Left-Sided Headache: Ophthalmoplegia and Visual Loss Secondary to Left Cavernous and Orbital Aspergillosis

Al-Jaber, A.·Harb, J. G.
Oakland University William Beaumont School of Medicine
Royal Oak, MI.

Purpose

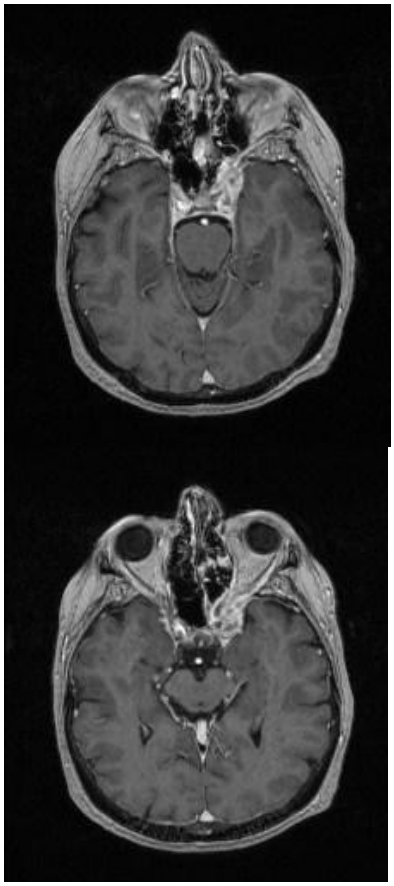
Headache is one of the most frequently encountered health issues causing patients to seek medical attention. Additionally, it is a symptom of a long list of common and uncommon medical conditions. We present an unusual case of left cavernous sinus and orbital aspergillosis causing ophthalmoplegia and necrotizing optic neuritis.

Case Report

The patient's clinical history, physical examination, laboratory results, radiographic and intra-operative findings were reviewed.

Imaging Findings

A 67-year-old Caucasian female presented to her primary care physician with worsening left-sided headache and visual changes for three months. The patient had a past medical history of asthma, chronic renal failure, hypertension, and hyperthyroidism. Full workup including blood and CSF testing, ophthalmic exam, CT and MRI of the brain and orbits were obtained. The MRI showed a large lesion in the left sphenoid wing, extending into the sphenoid sinus as well as along the cavernous sinus and anteriorly into the orbital apex. Subsequently, trans-sphenoidal biopsy of the left cavernous sinus was performed and the pathology specimen showed evidence of chronic inflammatory changes without definite malignancy. Due to the patient's critical symptomatology and the need for a definitive diagnosis, she underwent surgical resection. Portions of the skull base mass involving the anterior and middle cranial fossa as well as the left cavernous sinus and left orbit were resected. Final pathology of the specimen showed evidence of invasive aspergillosis. The patient was started on Amphotericin and Voriconazole. During her hospital stay, she reported improvement of the headache. However, there was no significant change in her left ophthalmoplegia and visual loss.



Summary

Cavernous and orbital aspergillosis is a rare cause of headache, ophthalmoplegia, and visual loss. This disease requires a prompt diagnosis as well as adequate management and early intervention in order to avoid serious complications.

KEYWORDS: Fungal disease, Cavernous sinus, Orbital

EE-8

West Nile Virus Encephalitis and Its Mimickers

Bermudez Allende, M. Z.·Hijaz, T.·Futterer, S.·Lester, M.·Oustwani, C.
Northwestern Memorial Medical Center
Chicago, IL.

Purpose

There has been a recent, much publicized increase in the number of reported cases of West Nile virus (WNV) encephalitis in the United States. We review the clinical features and magnetic resonance imaging (MRI) findings in

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

three patients at our institution with confirmed WNV infection in order to increase radiologists' awareness of and familiarity with this entity.
Case Report
We describe three patients who initially presented to our institution with fever, diarrhea, mood disturbance, and progressive weakness and were ultimately confirmed to have WNV infection by the presence of cerebrospinal fluid IgM to the virus. All three patients underwent initial computed tomography (CT) and MRI, and we review the imaging findings of WNV encephalitis in each patient. We also discuss the imaging findings of several mimickers, such as thrombosis of the internal cerebral veins and thalamic glioma.
Imaging Findings
West Nile virus is a mosquito-borne flavivirus that can cause meningitis, encephalitis, and myelitis, sometimes leading to significant morbidity and mortality. Many infected individuals are asymptomatic, and those who do present clinically often do so in a nonspecific manner, with flu-like symptoms, headache, malaise, myalgia, and fatigue. Consequently, the diagnosis of WNV encephalitis can be elusive, although the findings on magnetic resonance imaging (MRI) of the brain may increase the likelihood of early, accurate diagnosis. Head CT in all three of our patients was normal. On MRI, all three patients demonstrated enlargement of the thalamus with accompanying hyperintense T2/FLAIR signal, with varying degrees of extension of the signal abnormality into the brainstem and basal ganglia. Two patients demonstrated restricted diffusion, and one had rim enhancement of the thalamic signal abnormality. West Nile virus infection was confirmed in all three patients by cerebrospinal fluid IgM. The Centers for Disease Control (CDC) have reported an increase in U.S. cases of WNV in 2012. In light of this increased incidence and the nonspecific clinical presentation of the disease, it is important that radiologists be familiar with the imaging findings of WNV in order to be able to include it in a useful differential diagnosis.
Summary
The clinical presentation of WNV encephalitis, a serious illness, is usually nonspecific. Particularly given a recent increase in reported cases of this entity in the U.S., radiologists should be aware of its typical imaging findings in order to facilitate its rapid and accurate diagnosis.

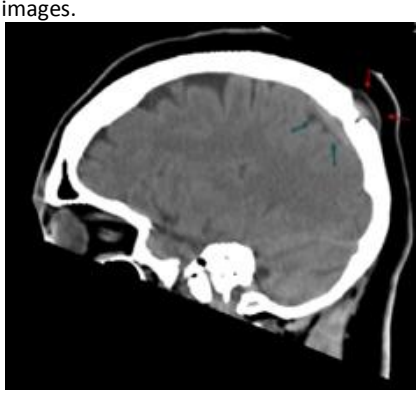
KEYWORDS: Encephalitis, Infections, Virus

EE-9

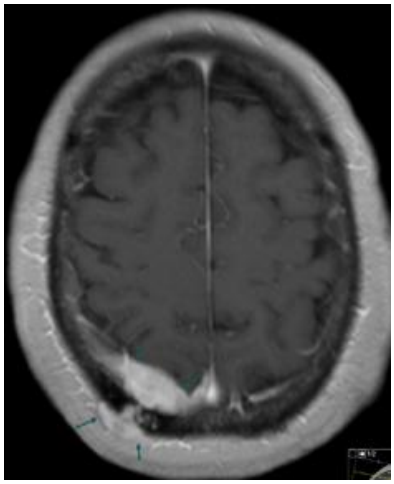
Rare Case of Rosai-Dorfman Disease Presenting as an Isolated Intracranial Mass

Javadi, P.·Coffey, M.·Patel, T.·Etesami, M.·Blackham, K.
University Hospital Case Medical Center
Cleveland, OH.

Purpose
Rosai-Dorfman disease is a rare benign histiocyte proliferative disorder, predominantly involving cervical lymph nodes, but also affecting the skin, upper respiratory tract, and paranasal sinuses. Isolated intracranial involvement without nodal and sinus disease as presented here is extremely uncommon.
Case Report
A 52-year-old female with history of stroke presented with new onset transient left-sided parasthesia and weakness. Head CT revealed an extra-axial mass in the posterior right parietal region with associated irregularity of the skull and soft tissue thickening of the scalp. MR imaging of the brain confirmed a homogeneously enhancing meningeal mass with calvarial and subgaleal extension. The patient underwent a right parieto-occipital craniotomy and mesh repair with resection of the tumor for presumed diagnosis of meningioma. Evaluation of the pathologic specimen revealed histocytes with immunologic staining confirming diagnosis of Rosai-Dorfman disease. Postoperative course was uncomplicated and follow-up imaging to date failed to show any evidence of recurrence.
Imaging Findings
CT of the head revealed a hyperdense extra-axial convex mass in the posterior right parietal region with associated lucency and irregularity of overlying skull and subgaleal extension through the defect in the soft tissue of the scalp. The lesion demonstrated isointense signal on T2WI, low signal on T1WI, and avid enhancement on T1 postcontrast images.



Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Summary
Rare case of extra-axial mass mimicking meningioma highlights the fact that Rosai-Dorfman disease should be included in the differential consideration when osteolysis and soft tissue extension to the scalp is present.

KEYWORDS: Dural, Meningioma, Rosai-Dorfman

EE-10

MR Imaging Findings in Central Nervous System Hemophagocytic Lymphohistiocytosis

Bezerra, R.·Berkowitz, F.·Toaff, J.·Lee, E.
Georgetown University Hospital
Washington, DC.

Purpose
To describe the imaging findings of three cases of hemophagocytic lymphohistiocytosis (HLH), one of which demonstrates a distinctive triad of imaging findings.
Case Report
We present three patients with bone marrow biopsy proven HLH: Patient 1: 54-year-old gentleman with history of hypertension, diabetes mellitus and chronic alcohol abuse, presented with acute episode of confusion and fever. Lab workup revealed pancytopenia, hyperferritinemia and increased liver functions. Patient 2: 21-year-old female with a past medical history of depression and malaria with several recent admissions due to fevers and chills was admitted with acute kidney failure, pneumonia and respiratory failure and developed seizures and multisystem organ failure. High ferritin and ammonia levels were found. Patient 3: 39-year-old man with a history of ankylosing spondylitis and recently diagnosed systemic lupus erythematosus was admitted due to several weeks of sinusitis, fever, blurred vision and weight loss (9 kg over 3 months). He was found to have sustained endgaze nystagmus bilaterally. Lab workup revealed pancytopenia, hyperferritinemia and increased liver functions.
Imaging Findings
Patient 1: FLAIR hyperintense lesions in the periventricular white matter, most of them along the perivenular spaces, corpus callosum (one lesion with restricted diffusion), internal capsules, middle cerebellar peduncles. In addition, there is an enhancing T2 hyperintense lesion in the left caudate nucleus. Patient 2: FLAIR hyperintense nonrestricting left parietal cortical and subcortical lesion with microhemorrhages, as well as symmetric T2 hyperintense signal in the basal ganglia, insula and cingulate gyrus. Patient 3: Scattered areas of leptomeningeal enhancement, multiple FLAIR hyperintense nonenhancing nonrestricting foci in the deep gray matter bilaterally, some of which are associated with perivascular enhancement.
Summary
Hemophagocytic lymphohistiocytosis is a rare disorder, characterized by proliferation of benign lymphocytes and histiocytes in multiple organs, with CNS involvement in 10-73%. Three progressively severe neuropathologic stages include leptomeningeal infiltration with lymphocytes and macrophages (stage 1), perivascular infiltrates (stage 2) and massive tissue infiltration of lymphocytes and histiocytes and tissue necrosis (stage 3). Reported brain imaging findings include parenchymal atrophy, leptomeningeal and perivascular enhancement, parenchymal T2 hyperintense lesions which may demonstrate nodular or ring enhancement as well as restricted diffusion, parenchymal calcifications and subdural fluid collections. Our first case matches previously described imaging findings, with deep gray matter abnormalities and periventricular white matter lesions along the periventricular spaces, sometimes associated with demyelination. The second patient demonstrates findings suggestive of HLH with a cortical and subcortical lesion. In addition, symmetric deep gray matter T2 hyperintensity is compatible with hyperammonemia. When imaging findings consist of focal parenchymal abnormality accompanied by enhancement along the perivascular spaces, especially with adjacent meningeal enhancement, as demonstrated in our third patient, the differential diagnosis is usually between sarcoidosis and lymphoma. Our third case shows that HLH should be added as a diagnostic consideration. Patients presenting with neurologic symptoms in HLH, may demonstrate expected imaging findings reflecting primary neural HLH infiltration, as well as complications from extensive multiorgan involvement in HLH.

KEYWORDS: MR imaging brain, Hemophagocytic lymphohistiocytosis

EE-11

Pachymeningitis and Choroid Plexus Granulomas in ANCA-Associated Vasculitis: A Report of Two Cases

McDonnell, O.·Khaleel, Z.
Sir Charles Gairdner Hospital
Perth, AUSTRALIA.

Purpose
ANCA vasculitides are rare and are associated with multiple clinical syndromes. Central nervous systen involvement is rare with incidence reported between 10-40% and has various clinical and imaging manifestations. We present two cases of known ANCA positive vasculitis, one patient with Wegener's granulomatosis and one with microscopic polyangiitis, who presented with new onset neurologic symptoms and the unusual MR imaging findings of pachymeningitis and choroid plexus granulomas.
Case Report
Two patients with known Wegener's granulomatosis and microscopic polyangiitis presented acutely with neurologic symptoms. Case 1, a 71-year-old female was admitted to hospital complaining of increasing nausea, vertigo and ataxia. She had a previous diagnosis of Wegener's granulomatosis confirmed on renal and lung biopsy and was C ANCA positive. At time of admission she was on maintenance treatment with prednisolone and azathioprine. Case 2, a 58-year-old female, had a two-year history of systemic MPO ANCA positive vasculitis microscopic polyangiitis. She was admitted with a 2-week history of mania, pressured speech, grandiose delusions and agitation. She was on maintenance prednisolone 2mg daily at time of admission. Both patients were afrebile and clinical examination was unremarkable. Apart from mildly elevated ESR and CRP all blood and cerebrospinal fluid laboratory investigations were unremarkable.
Imaging Findings
MR imaging in each case demonstrated T2 hypointense dural thickening and enhancement and enhancing choroid plexus lesions presumed to represent granulomas. In case 1 MRI head demonstrated several enhancing T2 hypointense mass lesions in relation to the choroid plexus within the fourth ventricle and foramina of Lushka and temporal horns and bilaterally in the frontal meninges and anterior falx cerebri. In case 2 MRI demonstrated abnormal T2 hypointense dural thickening and enhancement in the anterior cranial fossa bilaterally related to the central falx and an enhancing ovoid T2 hypointense mass within the right foramen of Lushka with secondary brain parenchymal edema.
Summary
Central nervous systen involvement is unusual in ANCA vasculitis and we present two symptomatic cases with combination of dural and choroid plexus involvement demonstrated at MRI which regressed following immunosuppressive therapy. There are few reported cases of these imaging findings. There are only two reported cases of choroid plexus granulomas in Wegener's granulomatosis. Although pachymeningitis has been reported previously in microscopic polyangiitis choroid plexus involvement has not been reported previously in microscopic polyangiitis.

KEYWORDS: Adult brain, Wegener's granulomatosis, Microscopic polyangiitis

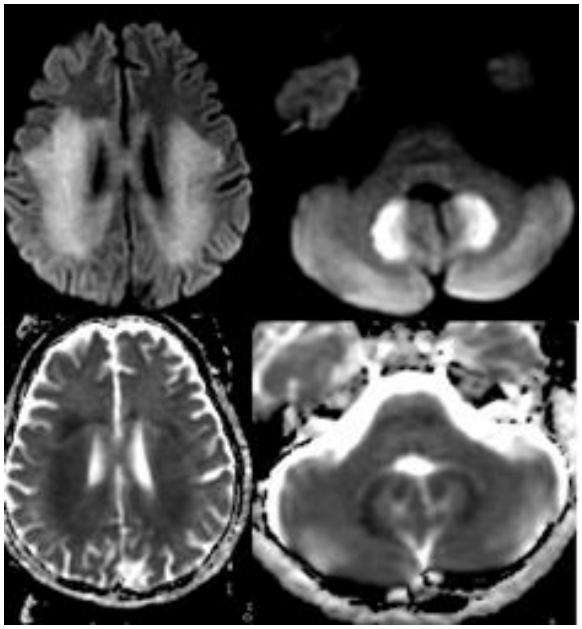
EE-12

Diffusion Restriction in Metronidazole Neurotoxicity

Torres, F.·Wang, S.·Lerner, A.·Go, J.·Hoque, K.·Rajamohan, A.
University of Southern California
Los Angeles, CA.

Purpose
We will present a case of metronidazole-induced neurotoxicity demonstrating unusual imaging features that are distributed topographically in the previously described pattern.
Case Report
A 45-year-old Chinese female with a history of gallbladder neuroendocrine cancer presented with fever, abdominal pain and elevated alkaline phosphatase and total bilirubin. The patient then was started on metronidazole for presumed cholangitis after endoscopic evaluation. After receiving a total of two grams of metronidazole a day for a total of 20 days, she was found unresponsive and an MR of her brain was performed.
Imaging Findings
MR imaging demonstrated diffuse increased T2/FLAIR hyperintensity throughout the white matter of the bilateral cerebral hemispheres, splenium of the corpus callosum, posterior limb of internal capsules, dorsomedial thalamic nuclei, midbrain, dorsal pons, vestibular nuclei, facial nuclei, and dorsal medulla. In addition, there is associated symmetric restricted diffusion representing cytotoxic edema within the subcortical and periventricular white matter of the cerebral hemispheres, as well as within the dentate nuclei.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Summary
Metronidazole-induced encephalopathy (MIE) is a rare toxicity that has been described previously as presenting with symmetric areas of vasogenic edema with a topographic distribution involving the dentate nuclei, midbrain, dorsal pons, splenium of the corpus callosum, and dorsal medulla with minimal to no involvement of the cerebral white matter. Our case of metronidazole-induced encephalopathy demonstrates pronounced restricted diffusion within the dentate nuclei, as well as an unusual amount of involvement of the cerebral white matter, which also demonstrated cytotoxic edema. As the exact pathophysiology of MIE is unknown, we hope our case can aid in future studies investigating the exact cause MIE.

KEYWORDS: Diffusion-weighted imaging, Medication, metronidazole-induced encephalopathy

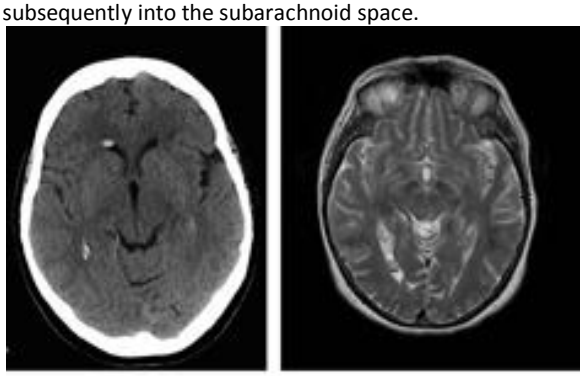
Silicon! Could It Be in Our Heads?

Djoukhadar, I. A.[1]·Cosgrive, J.[2]·Jameison, s.[2]·Warren, D. J.[1]
[1]Leeds Radiology Academy, Leeds, UNITED KINGDOM,
[2]Leeds Teaching Hospitals, Leeds, UNITED KINGDOM.

Purpose
To describe the radiologic findings of silicon oil migration into the ventricular system following treatment of retinal detachment.
Case Report
A 74-year-old female presented to the neurology outpatient clinic with six-month history of right-sided headache. She had a history of left phthisis bulbi, which occurred following multiple attempted surgical repairs for retinal detachment 20 years ago. She wore a cosmetic lens over the left eye. Her neurologic examination was unremarkable.
Imaging Findings
Initial unenhanced CT examination demonstrated a high attenuation abnormality in the left orbit replacing the vitreous with posterior extension along the optic nerve and two further foci of high attenuation in the suprasellar region and in the frontal horn of the right lateral ventricle. A subsequent MRI at two weeks interval showed abnormal high T2, intermediate T1 material within the globe and in the left optic nerve. The abnormality had a low T2 signal rim and showed signal suppression on T1 fat saturated imaging. Similar abnormality was seen in the suprasellar region. Interestingly the previously seen lesion in the right frontal horn has migrated posteriorly to lie adjacent to the medial aspect of the right choroid plexus within the right collateral trigone. The signal characteristics demonstrated on both the CT and MRI are consistent with silicone oil migration from the vitreous cavity into the optic nerve and subsequently into the subarachnoid space.



Unenhanced CT and T2 Axial images demonstrating the moving nature of the silicon oil deposit

Summary
This case report highlights an unusual radiologic presentation of silicon oil migration following oil endotamponade for retinal detachment. This is a rare but recognized complication. It is important to be aware that intra-orbital silicon oil can migrate into the ventricular system so that imaging findings in this rare situation can be diagnosed confidently without the need for unnecessary patient distress or invasive investigations.

KEYWORDS: Orbits, Abnormalities, Silicone

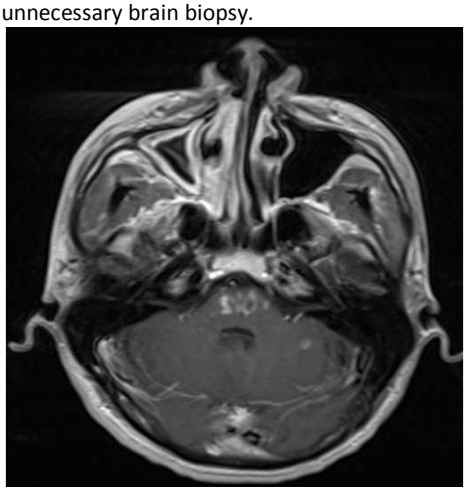
Chronic Lymphocytic Inflammation with Pontine Perivascular Enhancement Responsive to Steroids

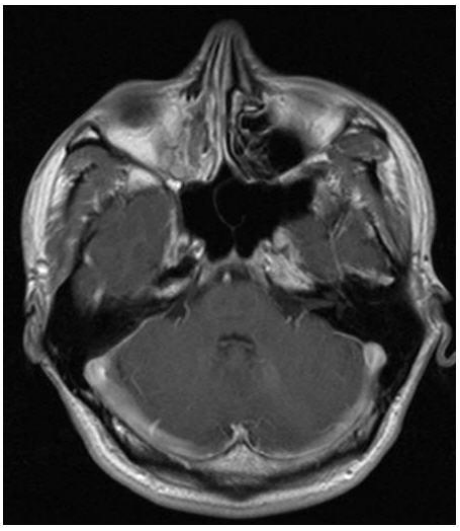
Grigg, A.·Bray, M.·Hart, B.
University of New Mexico
Albuquerque, NM.

Purpose
Only a handful of reports have presented the neuroimaging findings of a recently described disease termed chronic lymphocytic inflammation with pontine

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

perivascular enhancement responsive to steroids (CLIPPERS). The purpose of this study is to describe the clinical and neuroimaging findings in a case of CLIPPERS.
Case Report
A 21-year-old male noticed diplopia and general weakness with a subacute onset three weeks prior to admission. Additionally, he developed facial tingling and paraesthesia in his fingertips. His past medical history and family history were unremarkable. Neurologic examination on admission revealed a cerebellar syndrome with minimal gait and stance ataxia, as well as left cranial nerve VI palsy. The remainder of the neurologic examination was normal. Extensive systemic workup included the following: complete blood count; renal and liver function; sedimentation rate; antinuclear antibody; IgG for MS; HIV, viral, fungal and tuberculosis serologies. All tests were all within normal limits or negative. Treatment: After MRI and due to the progressively worsening diplopia, the patient was started on high-dose oral prednisolone. There was a dramatic clinical improvement within one week, followed by improvement on follow-up MR imaging. Discussion: CLIPPERS is a recently described, perhaps underdiagnosed, treatable inflammatory brainstem CNS disease. Exclusion of various inflammatory, infectious and paraneoplastic disorders is necessary before this diagnosis should be considered. The pathogenesis of CLIPPERS is unknown. The clinical response to immunosuppressive therapies suggests an autoimmune or other inflammatory mediated pathogenesis.
Imaging Findings
MR imaging (T2-weighted images) revealed multiple punctate hyperintensities in the pons, medulla, cerebellum and upper cervical spinal cord with corresponding curvilinear enhancement on T1 imaging (Figure1). The largest single lesion measured approximately six mm in greatest dimension, but most lesions measured between one and three mm. The majority of lesions were clustered in and around the pons. Follow-up MRI 10 days later showed marked improvement (Figure 2).
Summary
This excerpta presents the neuroimaging and clinical findings of a recently described disease termed chronic lymphocytic inflammation with pontine perivascular enhancement responsive to steroids (CLIPPERS). The described imaging findings must be correlated with the clinical features along with exclusion of other inflammatory and infectious process to arrive at an accurate diagnosis. Awareness of this entity may help the radiologist differentiate this disease process from other brainstem disorders and possibly save the patient from an unnecessary brain biopsy.





KEYWORDS: Inflammatory, Brainstem, CLIPPERS

EE-15

Inexorably Progressive Balo's Concentric Sclerosis: Sequential MR Imaging of Dramatic Lesion Growth and an Educational Review of Imaging Manifestations

Matys, T.[1]·Wing, L.[1]·Zaccagna, F.[1]·Antoun, N.[1]·Massoud, T. F.[2]
[1]Addenbrooke's Hospital, Cambridge, UNITED KINGDOM,
[2]University of Cambridge, Cambridge, UNITED KINGDOM.

Purpose
Balo's concentric sclerosis (BCS) is a variant of multiple sclerosis. Its pathologic hallmarks are large demyelinated lesions characterized by a peculiar pattern of alternating layers of preserved and destroyed myelin. MR imaging has made diagnosis of BCS rings possible, and early treatment has markedly improved its prognosis. Balo's concentric sclerosis remains a rare disease. Until eight years ago there were only 60 cases reported in the literature. We present a unique case of treatment refractory BCS

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

highlighting unusual and rapidly progressive imaging manifestations.

Case Report

A 52-year-old Caucasian male presented with a three-week history of progressive leg weakness. He had no sensory deficit, but had an upper motor neurone weakness affecting his left leg. Outpatient head CT[Imaging 1] followed by MRI [Imaging 2] confirmed the diagnosis of BCS. He was admitted to hospital three weeks later when clinically worse. Brain MRI[Imaging 3] showed slight progression in size of the right cerebral lesion. Soon his lateralizing signs progressed. He was treated with steroids and five days of plasma exchange with stabilization of his weakness. Over the following three months, his clinical condition gradually deteriorated. MR images performed at one, two, and three months[Imaging 4-6] after admission demonstrated further progression. He was treated with six cycles of cyclophosphamide, during which his symptoms continued to progress, including cognitive impairment and no improvement in motor symptoms. Azathioprine was started but subsequently stopped 10 months after initial presentation. MR imaging [Imaging 7] demonstrated significant progression of disease. A five-day course of monoclonal antibody treatment and IV steroids then was attempted, followed by maintenance steroids, but there was no change clinically. He became significantly disabled. There was further MRI[Imaging 8] progression of disease during a period of neurorehabilitation, but he subsequently died 15 months after initial presentation.

Imaging Findings

CT scan [Imaging 1] initially revealed an ill-defined small nonenhancing area of hypodensity in the medial right centrum semiovale, thought to be a likely low-grade tumor. MR imaging followed shortly [Imaging 2], and revealed a classic T2 hyperintense lesion of BCS. Peripheral rings showed enhancement and restricted diffusion. Subsequent follow-up imaging [Imaging 3-8] over the next 14 months revealed dramatic lesion growth and invasion of brain. This involved first the entire white matter of the right cerebral hemisphere with some minor sparing in the occipital lobe, and some T2 hyperintensity also in deep gray nuclei. This was followed by spread through the genu of the corpus callosum and rapid involvement of most white matter of the anterior left frontal lobe prior to patient death. Widespread areas of patchy and linear enhancement and restricted diffusion were still present at the advancing front of the disease.

Summary

We present a rare case of devastatingly progressive BCS refractory to treatment and resulting in patient death within 15 months of presentation. Imaging findings were initially typical, but its inexorable spread through the brain has resulted in dramatic imaging findings that are seldom viewed by neuroradiologists. In this exhibit we also review literature accounts of BCS contrast enhancement, DWI, and MRS.

KEYWORDS: Multiple sclerosis, MR plaque imaging

EE-16

Chronic Lymphocytic Inflammation with Pontine Perivascular Enhancement Responsive to Steroids Syndrome with Infratentorial and Supratentorial Involvement: A Case Report

Yan, Z.·Hoefling, N.·Peyster, R.·Chaudhry, A.
SUNY at Stony Brook
Stony Brook, NY.

Purpose

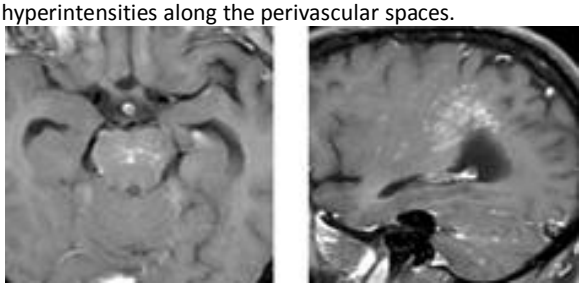
Previously reported cases of chronic lymphocytic inflammation with pontine perivascular enhancement responsive to steroids (CLIPPERS) syndrome have described only infratentorial involvement. We present a unique case of CLIPPERS syndrome that demonstrates both supratentorial and infratentorial involvement.

Case Report

A 70-year-old female presented with progressive right lower extremity weakness and multiple episodes of falls. Initial MRI showed abnormal contrast enhancement in the supratentorial, pontine and cerebellar white matter. The patient's symptoms markedly improved with five day course of intravenous corticosteroids. Follow-up MRI demonstrated resolution of abnormal enhancement.

Imaging Findings

Ill defined patchy areas of T2 and FLAIR hyperintensities are noted in pons, middle cerebellar peduncles and adjacent cerebellar white matter and also in cerebral white matter bilaterally, left greater than right, without mass effect. On postcontrast images, there is linear and mild nodular enhancement within those T2 and FLAIR hyperintensities along the perivascular spaces.



Summary

Chronic lymphocytic inflammation with pontine perivascular enhancement responsive to steroids is a rare and new entity with evolving definition. All reported cases to date have shown exclusive involvement of the posterior fossa. To the best of our knowledge, we present the first case of this syndrome that also demonstrates supratentorial involvement.

KEYWORDS: Brain abnormalities

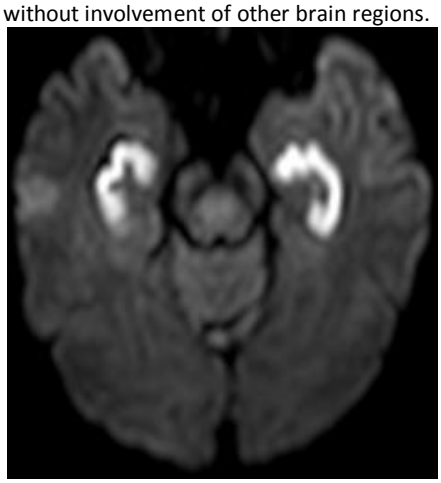
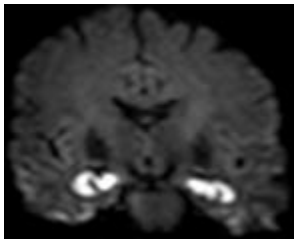
Hippocampi en Fuego

Romano, J.[1]·Banker, P.[2]
[1]Montefiore Medical Center, Bronx, NY, [2]University of California Los Angeles, Los Angeles, CA.

Purpose
To illustrate a unique imaging finding and a diagnostic problem. We present a case of restricted diffusion in both hippocampi exclusive of other brain regions in a patient with a multifactorial history.
Case Report
A 58-year-old female with prior history of severe depression and multiple suicide attempts was brought to the ED in an unresponsive state. The patient had been taking acetaminophen/oxycodone, and zolpidem, the amounts unknown. The patient's prescription medications included a dopaminergic medication (Carbidopa/Levodopa) for intermittent parkinsonian symptoms of tremor and gait disturbance, selective serotonin reuptake inhibitors (citalopram and sertraline) for depression, and diazepam for anxiety. On exam by EMS, the patient was tachycardic and tachypneic with normal blood pressure. In the ED, she was found to be hypoglycemic, hypoxic, and in hypokalemic lactic acidosis. She was intubated shortly after presentation for respiratory failure. Laboratory evaluation revealed evidence of liver failure with elevated levels of acetaminophen, for which she was treated with N-acetylcysteine. The patient's hospital course was notable for persistent short-term memory loss without focal neurologic deficit. She did not have witnessed seizures or seizure history.
Imaging Findings
The patient presented with symmetric intense restricted diffusion throughout the entire hippocampi bilaterally without involvement of other brain regions.





Summary
We illustrate a distinct noteworthy diffusion MRI appearance for which the etiology is not clear. We analyze possible causes for this finding considering diseases that manifest restricted diffusion and occur in the hippocampus (e.g., infarction, hypoxia, peri-ictal signal changes, hypoglycemic encephalopathy and limbic encephalitis). Cases of this kind illustrate a gap in our knowledge between our comprehension of imaging manifestations of disease and what we can see in our practices. As such, this is a fertile opportunity toward improving our understanding.

KEYWORDS: Hippocampus, Diffusion-weighted imaging

EE-18

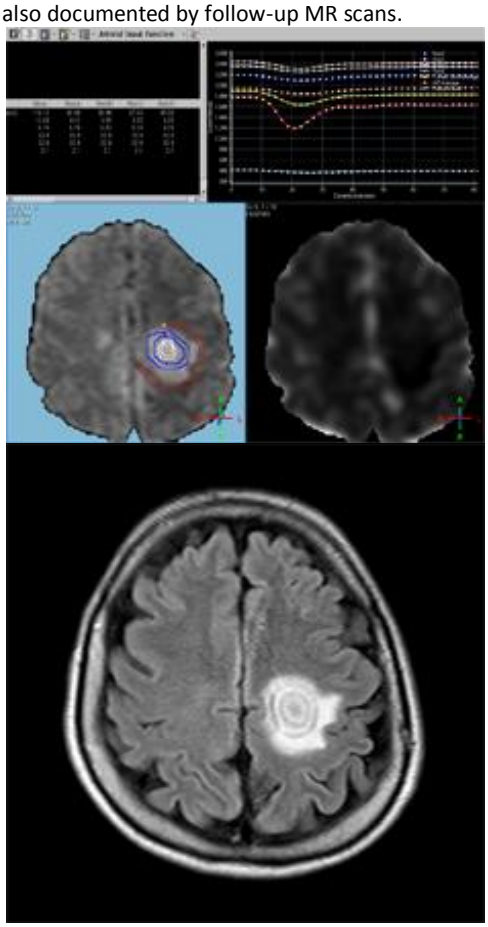
Basic and Advanced Perfusion-Weighted Imaging, Diffusion Tensor Imaging and Spectroscopic Imaging of a Case of Balò's Concentric Sclerosis: Description of a Case and Literature Review

Stecco, A.·Ripellino, P.·Leone, M.·Cantello, R.·Perchinunno, M.·Carriero, A.
ASU Maggiore della Carità
Novara, ITALY.

Purpose
Balo's concentric sclerosis is a rare variant of multiple sclerosis which can mimic tumor or stroke lesions.
Case Report
We report the case of a 51-year-old woman who was admitted to our department in January 2012 for a slowly increasing right hemiparesis with right brisk deep tendon reflexes. She suffered from Sjogren syndrome and HBV hepatitis (healthy carrier). At patient's admittance the brain MRI showed a concentric ring lesion in the FLAIR sequence and in the T2-weighted image. The lesion was surrounded by a wide vasogenic edema and appeared hypointense in sagittal T1-weighted image, without gadolinium enhancement. We then performed, on a 1.5 T magnet with an 8-channel sense head coil, an advanced MRI study of the lesion which included spectroscopical and perfusional analysis. Single voxel spectroscopy detected a high ratio of Cho/NAA and a double pick of lactate lipids.
Imaging Findings
Perfusion with DSCE technique and calculation of CBV, CBF, MTT maps, showed, after post-processing by arterial input fraction, a central layer (red box) more perfused compared to the surrounding areas, confirming the hypothesis that Balò's lesions usually surround a vessel.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Cerebrospinal fluid analysis detected oligoclonal bands, without anti-aquaporin-4 antibodies. High-dose iv methylprednisolone was started (1g/day for 10 days) and followed by oral prednisone (1mg/kg/day for two months, then slowly tapered) with concomitant lamivudine as antiviral prophylaxis. The right hemiparesis fully recovered after two weeks and has not relapse after six months, as also documented by follow-up MR scans.



Summary

Balo's concentric sclerosis is a rare variant of multiple sclerosis which can mimic tumor or stroke. It has a well known aspect on MR conventional images, although with advanced techniques is possible to retrieve more structural features.

KEYWORDS: MR spectrocopy, MR perfusion-weighted imaging, multiple sclerosis

EE-19

Amyloid Angitis: Spectrum of Imaging Findings

Kalra, V. B.·Rao, B.·Gibson, J.·Malhotra, A.
Yale University
New Haven, CT.

Purpose

Amyloid angitis is an uncommon entity separate from amyloid angiopathy, and acts as a clinical subset of primary central nervous system vasculitis, responsive to immunosuppression. We present three biopsy-proven cases spanning the spectrum of imaging findings - extensive leukoencephalopathy, focal nonenhancing tumefactive mass lesion, and lobar hemorrhage.

Case Report

Patient #1. A 78-year-old male with one year history of abnormal hand movements, unusual behaviors, and personality changes. MR demonstrated confluent areas of leukoencephalopathy in the right parietal, occipital, and temporal lobes with associated punctate cerebral microhemmorahges. Clinically, there was suspicion for gliomatosis cerebri. MR spectroscopy was not done and there was no immediate response to dexamethasone. Biopsy was performed and showed granulomatous angitis with transmural vasculitis at sites of amyloid deposition - findings consistent with amyloid angitis. Patient #2. A 48-year-old male with new onset generalized seizures. MR demonstrated a right occiptotemporal mass-like lesion. The patient received dexamethasone and phenytoin which decreased the size of the mass. Biopsy showed granulomatous angitis with transmural vasculitis at sites of amyloid deposition - findings consistent with amyloid angitis. Patient #3. A 72-year-old female with history of endometrial carcinoma had two episodes of altered vision two days prior to acute onset left-sided numbness and right-sided headache. The patient underwent CT and MR which demonstrated an isolated posterior right temporal lobar intraparenchymal hemorrhage. CT angiography was normal. Resection was performed secondary to concern for an underlying mass lesion. Pathology showed granulomatous angitis with transmural vasculitis at sites of amyloid deposition - findings consistent with amyloid angitis.

Imaging Findings

Patient #1. MR demonstrates confluent areas of T2/FLAIR hyperintensity in the right parietal, occipital, and temporal lobes with associated regional punctate microhemmorhages and sulcal effacement. These areas had no postcontrast enhancement. MR spectroscopy was not performed and there was no significant change in imaging findings on an MR done four days later while the patient was on dexamethasone. Patient #2. MR demonstrates a right occipitotemporal mass-like area of T2/FLAIR signal abnormality that measured 2.5 x 2.1 cm. There was no postcontrast enhancement or abnormality on spectroscopy. Three months following biopsy, the lesion had markedly decreased in size, measuring 0.8 x 0.8 cm. Patient #3. MR demonstrates an isolated posterior right temporal lobar intraparenchymal hemorrhage. No significant postcontrast enhancement was seen. No punctate areas of microhemmorhage were seen. MR spectroscopy and perfusion showed no abnormalities. No vascular lesions were seen on CT angiography.

Summary

We present three cases reflecting the spectrum of findings seen in amyloid angitis ranging from confluent multilobar

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

T2 signal abnormalities resembling gliomatosis cerebri to nonenhancing tumefactive lesions to nonspecific appearing lobar hemorrhages. Lesions resembling gliomatosis cerebri can be distinguished by presence of punctate foci of susceptibility and normal spectroscopy findings and lesions resembling tumefactive lesions can be distinguished from amyloidomas and malignancy by lack of enhancement and normal MR spectroscopy findings. When supportive imaging findings are seen, it is important to suggest the diagnosis as these patients can respond to immunosuppression and biopsy can be avoided.

KEYWORDS: Amyloid, Arteriopathy

EE-20

Confounding Clinical Presentation of Acute Hemorrhagic Leukoencephalitis in Adulthood

Chakraborty, A. K.·Keiper, M. D.·White, M. L.·Helvey, J. T.·Poage, D. P.
University of Nebraska Medical Center
Omaha, NE.

Purpose
Acute hemorrhagic leukoencephalitis (AHL) is a rapidly progressive form of acute disseminating encephalomyelitis (ADEM) generally affecting children and young adults. Acute hemorrhagic leukoencephalitis is relatively rare in middle age and later adulthood and can be a difficult diagnosis based on its protean radiographic findings and radiographic overlap with many more common diseases of adulthood. The neuroradiologist has the unique opportunity to suggest this diagnosis in the appropriate clinical and radiographic setting and provide early potential treatment options for an extremely aggressive and typically fulminant disease process.
Case Report
A 55-year-old gentleman presented to the Emergency Department with rapid onset altered mental status, left-sided weakness and malignant hypertension. MR imaging demonstrated posterior fossa and bihemispheric findings suggestive of somewhat atypical PRES, although additional diagnoses were entertained. Following successful treatment of malignant hypertension, the patient's clinical status did not improve prompting a repeat MR examination demonstrating progressive findings in a radiographic pattern more suggestive of hemorrhagic ADEM (AHL) or other hemorrhagic viral encephalitis. Despite high-dose steroid therapy, the patient deteriorated on hospital day 10 due to progressive development of cerebral swelling and herniation and ultimately expired. An autopsy was performed and confirmed severe cerebral edema, extensive white matter abnormality and scattered petechial hemorrhage most consistent with hemorrhagic leukoencephalitis.
Imaging Findings
Admission brain MRI demonstrated bilateral predominately subcortical hemispheric white matter T2 signal intensity abnormality with additional bilateral signal intensity abnormality and somewhat restricted diffusion in the deep gray nuclei. Additional T2 signal intensity abnormality was noted in the brainstem and cerebellum. Brain MRI on hospital day #5 demonstrated progressive T2 signal abnormality and mass effect in the brain stem, brachium pontis, internal capsules, deep gray nuclei and hemispheric white matter in a pattern suggestive of demyelination. Scattered regions of mildly restricted diffusion and petechial hemorrhage involving the brainstem and internal capsules were noted. Brain MRI hospital day #10 demonstrated marked progression of edema, cerebral swelling, mass effect and herniation. Autopsy demonstrated severe cerebral edema and petechial hemorrhage in the midbrain, pons and medulla.

Summary
Acute hemorrhagic leukoencephalitis is a rare entity particularly in middle aged and elderly adults. Knowledge of the radiographic pattern and presenting findings of AHL allows the neuroradiologist to consider this rare diagnosis over more common diseases of adulthood and potentially provide early therapy for a typically fulminating disease process.

KEYWORDS: Hemorrhage, Leukoencephalopathy

EE-21

Chordoid Glioma Involving Posterior Body of Corpus Callosum

Wang, B.·Ketonen, L.
M. D. Anderson Cancer Center
Houston, TX.

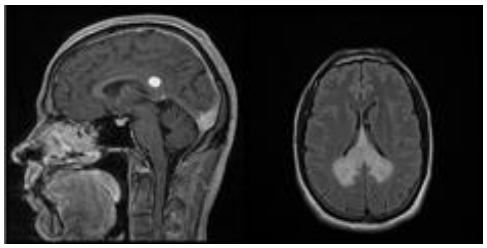
Purpose
To illustrate the imaging findings of a case of chordoid glioma involving the posterior body of corpus callosum, which to our knowledge has not been reported in the literature. Our purpose is to raise awareness of the neuroradiology community concerning this extremely unusual location of a rare tumor that typically occurs in the region of the hypothalamus/anterior third ventricle.
Case Report
A 55-year-old right-handed man developed seizure-like episodes on 2/21/2010 and was evaluated at an outside ER where he underwent a CT followed by an MRI, which revealed an enhancing mass in the posterior corpus callosum. A very limited biopsy was performed, and

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

pathology was read as low grade glioma. The physicians at the outside facility felt clinically that the mass was behaving like a high grade glioma, so he was treated with chemoradiation. On followup MRI, there was progressive enhancement around the corpus callosum. Stereotactic biopsy of the lesion was performed at our institution which demonstrated chordoid glioma, perivascular mononuclear infiltrate, and gliosis.

Imaging Findings

On CT, there is low density involving the posterior corpus callosum extending into the bilateral periventricular white matter, suggestive of underlying tumor. On MRI, there is a homogeneously enhancing lesion in the posterior body and splenium of the corpus callosum. Extensive T2 FLAIR hyperintensity involves the posterior corpus callosum and adjacent brain parenchyma around the occipital horns and in the posterior centrum semiovale. Diffusion-weighted imaging demonstrates no restricted diffusion within the tumor.



Summary

Chordoid glioma is a rare pathologic entity that has been added to the World Health Organization glioma classification scheme. This neoplasm normally occurs in the region of the hypothalamus/anterior third ventricle. Distinctive imaging characteristics are its consistent location, ovoid shape, hyperdensity on CT scans, and uniform intense contrast enhancement. When present, mass effect causing vasogenic edema tends to be bilaterally symmetrical. We illustrate the imaging findings of a case of chordoid glioma involving posterior body of corpus callosum, which to our knowledge has not been reported in the literature. Despite its rarity, neuroradiologists should be aware of this extremely unusual location of this rare neoplasm and consider it in the differential diagnosis when the characteristic features are encountered.

KEYWORDS: Glioma, Corpus callosum, chordoid

Isolated Multi-Intraventricular Rosai-Dorfman Disease

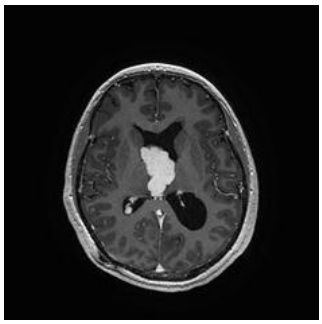
Palacios, W.[1]·Nidecker, A.[2]·Bobinski, M.[2]·Boggan, J.[2]·Shahlaie, K.[2]·Borys, E.[2]
[1]University of California Davis School of Medicine, Sacramento, CA, [2]University of California Davis Medical Center, Sacramento, CA.

Purpose

To report the first case of isolated multi-intraventricular Rosai-Dorfman disease.

Case Report

A 35-year-old woman was evaluated at a different institution in March 2011 for acute onset of persistent, severe headaches. Computed tomography (CT) of the head and subsequent magnetic resonance (MR) imaging of the brain revealed an intraventricular mass, most suspicious for tumor. Two concurrent tissue biopsies were nondiagnostic. She presented at our institution in February 2012 with worsening symptoms. MR imaging of the brain showed interval increase in size of the intraventricular mass. It was centered in the third ventricle extending into the lateral ventricles and was homogenously isointense on T1- and hyperintense on T2-weighted images. Additional lesions were identified in the right temporal horn and left foramen of Luschka. On CT of the brain, the mass was heterogeneous in attenuation with predominantly hyperdense components. A three-section tissue biopsy revealed benign histiocytic infiltrates by positive CD68 and S-100 staining with emperipolesis and a mixture of lymphocytes and plasma cells by positive CD20 and CD3 staining in a fibrotic background, most consistent with Rosai-Dorfman disease.



Summary

Rosai-Dorfman disease is also known as sinus histiocytosis with massive lymphadenopathy. It is a rare benign disorder. Isolated extranodal Rosai-Dorfman disease is more rare with isolated intracranial Rosai-Dorfman disease even more so. Only one case has been reported of isolated single intraventricular variant. We report the first case of isolated multi-intraventricular Rosai-Dorfman disease. Management for intracranial disease is low-dose radiotherapy. The disease is most often indistinguishable from a meningioma but has a wide radiographic differential ranging from metastasis to glioma, the management of each just as varied and very much different from treatment for Rosai-Dorfman disease. As such, the recognition and consideration of Rosai-Dorfman disease in all its various forms is essential to avoid improper and unnecessary invasive therapies.

KEYWORDS: Rosai-Dorfman disease, Histiocytosis

EE-23

MR Imaging Findings in an Extra-Axial Mass Mimicking a Meningioma in an HIV Positive Patient

Lopez, M.·Moonis, G.
Beth Israel Deaconness Medical Center
Boston, MA.

Purpose
Describe the MRI findings in an HIV positive patient with Epstein-Barr virus-related smooth muscle tumor (EBV-SMT) of the CNS which mimicked a meningioma.
Case Report
Our patient was a 50-year-old woman diagnosed with HIV in 10/1991 following a eye examination which revealed CMV retinitis. This patient also had history of a left occipital meningioma, stable for many years and developed rectal and vaginal carcinomas for which she was treated over the preceding years. In 08/2011, in one of her follow-up MRI examinations for her known left occipital meningioma, a new extra-axial mass in the right parietal lobe measuring 9 mm AP x 16 mm TR x 10 mm SI was seen and thought to be an additional meningioma. In the follow-up examination of 08/01/12, the lesion demonstrated rapid growth and measured 15 mm AP x 21 mm TR x 17 mm SI with increased surrounding parenchymal edema (images 1 and 2). Given its rapid growth and associated edema, the lesion was resected. The final pathology report was EBV-associated smooth muscle tumor.
Imaging Findings
This lesion demonstrated signal isointense to gray matter on T2-weighted images, with mild hypointensity on T1-weighted images, and diffuse homogeneous enhancement in the postcontrast images.

Summary
Patients with HIV are known to develop Epstein-Barr virus-related smooth muscle tumor in any organ. However, the most common location is in the CNS. Epstein-Barr virus-related smooth muscle tumor also occurs in immunosuppressed patients (post-transplantation, common variable immunodeficiency syndrome). Pathogenesis appears to be related to infection and transformation of smooth muscle cells by EBV. The mechanism by which EBV enters into the smooth muscle cell is not clear. However, once the tumor is present, they have shown to have different degrees of aggressiveness and thus clinical outcomes, as in some cases these tumors can be fatal. Therefore, when presented with a mass like CNS lesion in a patient with HIV, one must consider EBV-related smooth muscle tumor in the differential.

KEYWORDS: Extra-axial, Masses, meningioma mimicker

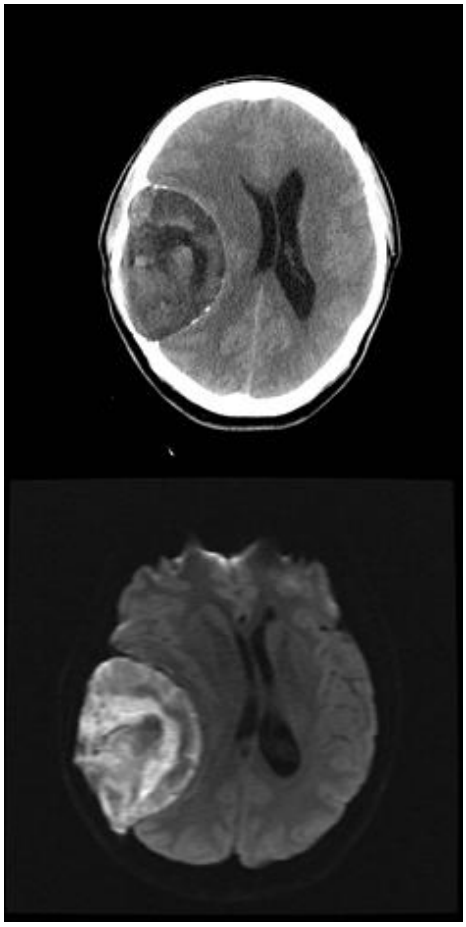
EE-24

Giant Intradiploic Epidermoid Cyst of the Parietal Bone

Sundblad, A.·Ralston, M.·Livingston, B.·Florman, J.
Maine Medical Center
Portland, ME.

Purpose
Intracranial epidermoid cysts are rare congenital tumors of ectodermal origin representing 0.2-1.8% of all primary intracranial tumors. They grow slowly as the squamous epithelial lining sheds keratin and cholesterol debris. We report a giant intradiploic epidermoid cyst resulting in profound deformity of the brain without neurologic deficit.
Case Report
A 38-year-old Filipino male presented with intermittent headaches and no focal neurologic symptoms. Noncontrast head CT revealed a large, heterogeneous, extradural right parietal mass measuring 8.5 x 6.1 x 7.4 cm with resultant shift of midline structures by 1.5 cm and uncal herniation. MR imaging demonstrated heterogeneous signal on T1 and T2 with incomplete suppression on FLAIR and marked increased signal on DWI. Postgadolinium and perfusion imaging showed a thin rim of enhancement with absence of internal blood flow. Right parietal craniectomy revealed an extradural mass, soft and mixed in color. Histologically, the mass was lined with squamous epithelium and mostly composed of keratin debris. Areas of ruptured wall were present with foreign body giant cell reaction.
Imaging Findings
On CT, epidermoid cysts typically are well defined hypoattenuating masses that do not enhance. On MR, most epidermoid cysts are isointense or slightly hyperintense to CSF on T1 and T2. Often, they are distinguished from arachnoid cysts by incomplete suppression on FLAIR and high signal intensity on diffusion-weighted images. The characteristic diffusion-weighted appearance is thought to be on the basis of high 2D planar anisotropy, which could be attributed to the well structured orientation of keratin filaments.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Summary
Extradural epidermoid cysts are slow growing tumors that may cause profound deformity of the brain without significant neurologic impairment. While high signal on DWI and incomplete suppression on FLAIR are the most relevant MR imaging features, absence of blood flow on MR perfusion increases diagnostic confidence.

KEYWORDS: Epidermoid

Isolated Cystic Schwannoma of the Hypoglossal Nerve

Marashi, K. B.·Nickell, L. T.·Coimbra, C.·Barnett, D.·Layton, K. F.·Opatowsky, M. J.
Baylor University Medical Center
Dallas, TX.

Purpose
We present an unusual case of a large hypoglossal nerve schwannoma.
Case Report
A 52-year-old man presented with a several month history of intermittent, progressively worsening dizziness and vertigo. He also described new onset headaches, fatigue, difficulty walking down stairs, and difficulty maintaining his lane while driving his car. Physical examination revealed impaired tandem walking. An MRI of the brain demonstrated a large, extra-axial cystic mass centered near the left foramen of Luschka with extension into the ipsilateral hypoglossal canal (Figures 1 and 2). Surgical resection confirmed that the lesion arose from the left hypoglossal nerve at the level of the hypoglossal canal. Pathologic analysis was consistent with a WHO Grade 1 schwannoma.
Imaging Findings

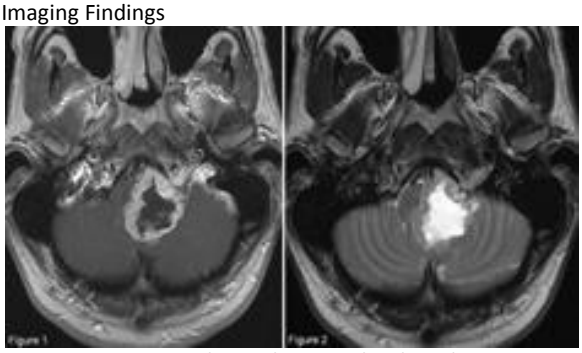

Figure 1: Contrast-enhanced T1-weighted axial MR image of the posterior fossa shows a mass within the left foramen magnum that exhibits thick and irregular enhancement. Figure 2: T2-weighted axial MR image through the same region reveals signal hyperintensity in a more cystic portion of the tumor.

Summary
Schwannomas account for six to eight percent of all intracranial neoplasms. Of these, vestibular schwannomas are the most common, followed by trigeminal and facial schwannomas. Even less frequent are schwannomas arising from the glossopharyngeal, vagus, and spinal accessory nerves. Schwannomas of the oculomotor, trochlear, abducens, and hypoglossal nerves are rare. We present this unusual case of a large, isolated schwannoma of the left hypoglossal nerve.

MR Imaging of Heavily Calcified Meningioma on 1.5 and 3T: Difference in T1 Signal and Degree of Contrast Enhancement

Wilms, G. E. R.·Demaerel, P.·Sunaert, S.
UZLeuven
Leuven, BELGIUM.

Purpose
To compare the T1-signal and the degree of contrast enhancement of heavily calcified meningioma on 1.5 and 3T magnets.
Case Report
We retrospectively studied the MRI of seven patients with 10 heavily calcified meningiomas in whom T1-weighted images before and after contrast administration were available both on a 1.5 and a 3T magnet.
Imaging Findings

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

On the 1.5T studies all calcified meningiomas displayed some degree of T1 hyperintensity. After contrast administration there was intense enhancement that was homogeneous in the majority of patients. On the 3T studies all calcified meningiomas were strongly T1 hypointense. After contrast administration the enhancement was definitely less pronounced. In all but one patient the calcified meningiomas were more strongly hypointense on T2-weighted sequences on the 3T than on the 1.5T study.

Summary

There is a clear difference between the T1-signal and the degree of contrast enhancement of heavily calcified meningioma on 1.5 and 3T magnets, with a more prononunced T1 hypointensity and a lesser degree of contrast enhancement on the 3T studies. We postulate that the T1 hypointensity and the lesser degree of enhancement on 3T are due to a T2 shine through effect. Changes in T1 signal or degree of contrast enhancement in a calcified meningioma between 1.5 and 3T do not reflect pathologicl changes or changes in the vascularity of the lesions, but are due to technical factors.

Pituicytoma: Case Report and Literature Review

Liu, H.·Sitton, C. W.·Papasozomenos, S.
University of Texas Health Science Center at Houston
Houston, TX.

Purpose

To present a case of pituicytoma, a rare primary tumor of the neurohypophysis, of which to date only 32 cases have been reported in the literature, along with its imaging features with pathologic correlation.

Case Report

A 44-year-old male with headache, fatigue, vision changes, and decreased libido presented to an endocrinologist where he was found to have bitemporal hemianopsia on exam. Endocrine studies were normal except for a low testosterone level.

Imaging Findings

MR imaging showed a well circumscribed, ovoid, suprasellar mass centered about the pituitary stalk that was slightly hypointense on T1, hyperintense on T2, with peripheral flow voids and marked homogenous enhancement following intravenous administration of Gd-DTPA. The mass displaced the optic chiasm anteriorly and splayed the optic tracts laterally, contacting but not encasing the internal carotid arteries.

Summary

Pituicytoma, although rare, has characteristic MR findings, and inclusion within a preoperative differential diagnosis may help the neurosurgeons manage the highly vascular nature of this tumor with prior embolization.

KEYWORDS: Pituitary gland, Neoplasm, pituicytoma

Role of Prone CT in the Diagnosis of Silicone Oil Intraventricular Migration after Intraocular Tamponade: Case Report

Carneiro, F.[1]·Carneiro, F.[2]·Daher Vaz, N.[3]
[1]University of Cincinnati, Cincinnati, OH, [2]Universidade de São Paulo, São Paulo, BRAZIL, [3]Hospital Santa Marcelina - Cidade Tiradentes, São Paulo, BRAZIL.

Purpose

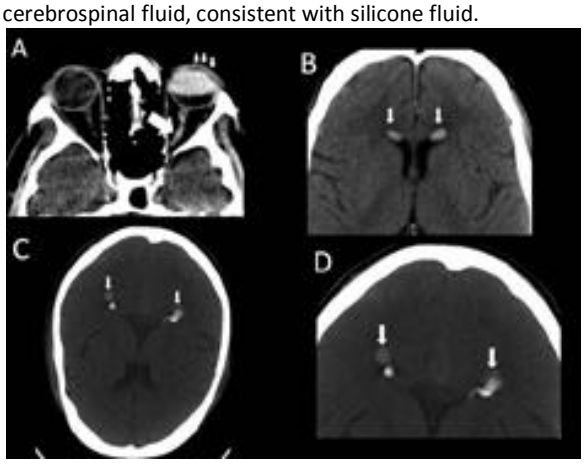
To present the imaging findings of intraventricular silicone oil and emphasize the role of prone imaging as an important diagnostic tool.

Case Report

A 54-year-old man with history of hepatic insufficiency was admitted due to disorientation. A diagnosis of hepatic encephalopathy was suggested, and noncontrast head computed tomography (NCCT) was performed to rule out other causes. A previous history of left eye vitrectomy with silicone oil tamponed to treat retinal detachment was obtained.

Image Findings

Noncontrast head computed tomography demonstrated hyperattenuating material filling the left eye vitreous space, within the optic nerve sheath, and within the frontal horns of the lateral ventricles (Figure A,B). Magnetic resonance imaging (MRI) demonstrated hyperintensity in T1-weighted images (T1WI) and hypointensity in T2-weighted images (T2WI). Both T1WI and T2WI depicted crescent-shaped bands in the silicone oil-aqueous interface representing chemical shift artifact. No diffusion restriction or contrast enhancement was demonstrated. On Prone NCCT, the hyperattenuating material previously located in the frontal horns migrated to the occipital horns (Figure C,D) confirming the low specific gravity of the material in comparison to the cerebrospinal fluid, consistent with silicone fluid.



Summary

Silicone oil is a popular agent used to treat retinal

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

detachment. Intraventricular migration is rare, but recently has been reported in the medical literature. The mechanism is not totally clear, but some authors have suggested that atrophy of the optic disk associated with elevated intraocular pressure could lead to migration of the silicone oil through the optic nerve sheath that communicates with the subarachnoid space. Silicone oil has been described as hyperattenuating on NCCT with Hounsfield units in the range of blood. Jabbour et al described a case where the NCCT was misdiagnosed as intraventricular hemorrhage. Our MRI findings are in according to the ones described previously. Specific silicone MRI and MR spectroscopy for silicone oil also have been described. Reported MRI and MRS findings likely help assure definitive diagnosis, and might prove highly specific if further investigated. Nondependent, intraventricular CT hyperattenuation likely will not be misdiagnosed as hemorrhagic lesions, particularly if we note the orbital findings and patient history. Prone CT is able to depict the low specific gravity of the oil agent. Due to its low cost and less complexity when compared to MRI and MRS techniques, supine and prone NCCT is the first option in order to confirm the presence of silicone oil in the ventricular system.

Pitfalls in the Diagnosis of Superior Sagittal Sinus Thrombosis: The *Anterior* Delta Sign

Venkatesh, R. M.·Hasso, A. N.·Handwerker, J.
University of California Irvine Medical Center
Orange, CA.

Purpose
Although the "delta" sign is commonly associated with superior sagittal thrombosis, attention often is placed primarily on the posterior superior sagittal sinus on axial CT head images. Anterior "delta" signs are more neglected, particularly near the vertex, and vigilance to this particular area is needed to identify subtle thrombosis. Appropriate imaging protocols are essential for diagnostic accuracy. MR imaging sequences optimally include SWI with phase imaging and GRE sequences as well as thin cut sagittal T1 pre and postcontrast sequences. Computed tomography head optimally should include the vertex as well as additional imaging in the coronal and sagittal planes.
Case Report
This is a 37-year-old right-handed female with no significant past medical history who presents with complaints of worsening headache to an outside hospital. After initial workup with noncontrast CT head, the patient worsened and developed right arm weakness. MR imaging without and with contrast of the brain (axial and sagittal T1 and T2, postcontrast axial T1) consequently was obtained at the outside facility and interpreted as presumed left posterior parietal brain mass. Patient was transferred to our hospital for workup and possible resection of “brain mass”.
Imaging Findings
In retrospect, the initial outside hospital CT (single axial plane, vertex not completely imaged), shows a hyperdense anterior superior sagittal sinus near the vertex and incompletely seen hyperdense vertex cortical veins. Additional small focus of subtle edema is present in the adjacent high right frontal lobe. Subsequently, repeat imaging at our institution (including MRI without and with contrast of the brain and MRV) show anterior superior sagittal sinus thrombosis as well as dilated vertex cortical veins with right supplementary motor area and left posterior parietal lobar hemorrhage, most prominently identified on SWI sequence.

Summary
Although classically superior sagittal sinus thrombosis is associated with the “empty delta sign” on contrast-enhanced CT or contrast-enhanced MR T1WI, radiologists tend to focus primarily on the posterior aspect of the sinus on axial images. Attention should be made to the anterior aspect of the superior sagittal sinus on axial images, especially near the vertex, as potential blind spots in the evaluation for dural sinus thrombosis. Additionally, appropriate imaging protocols are necessary to help confirm the presence of associated venous infarction.

Multifocal Intracranial Arterial Stenoses - A Challenging Diagnosis: Case Report and Review of the Literature

McNeill, G. J.·Scott, C. J.·Heran, M. K. S.
Vancouver General Hospital
Vancouver, BC, CANADA.

Purpose
The etiology of multifocal intracranial arterial stenosis is often straightforward based on patient demographics, clinical presentation and typical imaging features. A subset

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

of patients exists in whom the etiology of such a finding is not readily apparent. In this scenario, the diagnosis often is difficult. This exhibit will discuss the clinical presentation and imaging findings of the possible etiologies of multifocal intracranial arterial stenosis, using a case discussion as a framework. Entities such as atherosclerosis, reversible cerebral vasoconstriction syndrome, arteritis and vasospasm as well as rare causes will be discussed.
Case Report
A 45-year-old male nonsmoker presented with headache and right hemiplegia. His neurologic symptoms took a fluctuating course with persistent headache but a constellation of different localizing signs. He showed no improvement with anticoagulation or intra-arterial vasodilators but slow improvement following the instigation of immunosuppressive therapy. As a consequence, a diagnosis of central nervous system arteritis was reached.
Imaging Findings
Initial noncontrast CT brain showed no changes of acute ischemia. Computed tomography angiogram performed at presentation showed multifocal large and small vessel stenoses. A severe stenosis of the left M1 segment of his middle cerebral artery was considered responsible for his initial neurologic deficit. These stenoses were confirmed at catheter angiography at which time they proved resistant to intra-arterial vasodilators. Serial imaging demonstrated persistence of intracranial stenoses as well as development of multi-territory infarcts demonstrated at MRI by diffusion-weighted imaging.
Summary
The etiology of multifocal intracranial arterial stenoses can be difficult to ascertain. Using a case presentation as a framework, this exhibit has reviewed the imaging features of both common and rare diagnoses, with emphasis placed on the helpful discriminatory features.

Isolated Thrombosis of the Deep Medullary Cerebral Veins

San Millan, D.[1]·Bonvin, C.[1]·Gailloud, P.[2]
[1]Hospital of Sion, Sion, SWITZERLAND, [2]The Johns Hopkins Hospital, Baltimore, MD.

Purpose
To report two cases of isolated cerebral deep medullary venous thrombosis.
Case Report
Case 1. A 20 year-old normotensive female with no past medical history presented with an acute episode of left sided hemiparesis and dysarthria in a setting of thunder clap headache. Hemiparesis and dysarthria resolved after 30 minutes. Cardiovascular risk factors included active smoking and oral contraception. The patient was discharged with no persistent neurologic deficit and persistent headache, which resolved over the following weeks. Thrombophilia workup was negative. Noncontrast CT demonstrated linear hyperintensities oriented along the perivascular spaces from the right putamen through the deep white matter to the supero-external angle of the lateral ventricle, suggesting thrombosis of the superior striated veins. Contrast CT did not disclose deep venous system, cortical or dural venous sinus thrombosis. On initial MRI, these linear hyperintensities showed restricted diffusion and susceptibility artifact on SWI. There was locoregional hyperintensity on FLAIR without restricted diffusion consistent with vasogenic edema and several foci of punctate susceptibility artifact consistent with parenchymal hemorrhage in the right putamen and deep white matter. No intraparenchymal or meningeal enhancement was disclosed. Gadolinium-enhanced 3D T1 and phlebography sequences and catheter angiography failed to reveal intracranial thrombosis, particularly of the deep venous system. Follow-up MRI at one and five months demonstrated progressive decrease of the white matter edema with persistence of several foci of FLAIR hyperintensity on the last MRI consistent with gliosis. The linear susceptibility artifacts consistent with superior striated vein thrombosis were found on all follow-up MRIs though restricted diffusion had disappeared. Case 2. A 39-year-old normotensive female with no past medical history presented with severe acute headache, transient dysarthria, lower extremity weakness, left facial paralysis and left upper extremity paresthesia. Cardiovascular risk factors included active smoking, oral contraception and dyslipidemia. The patient was discharged after three days with no persistent neurologic deficit or headache. Aside from a 3 mm putaminal hemorrhage on initial noncontrast CT and MRI, imaging findings were identical to those described in case 1. MR imaging performed three days after the initial imaging workup demonstrated T1-weighted hyperintensity consistent with methemoglobin within the signal changes thought to represent superior striated vein thrombosis.
Imaging Findings
Findings on follow-up MRI performed two years after the initial episode were identical to those in case 1.
Summary
The two cases described above are thought to be consistent with isolated cerebral deep medullary venous thrombosis (superior striated veins) presenting with acute headache (thunderclap headache in case 1) and transient neurologic deficit occurring in two young female smokers under oral contraception. Diagnosis was based on CT and MRI findings consistent with acute clot in the trajectory of the superior striated veins along with locoregional deep white matter edema and punctate hemorrhages, in a setting of predisposing factors for venous thrombosis. Conservative treatment without anticoagulation was opted in both cases. Clinical evolution was favorable with resolution of neurologic symptoms including headache. To the best of our knowledge isolated cerebral deep

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

medullary venous thrombosis has not been reported previously in adults.

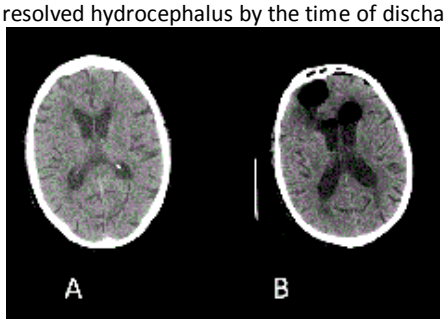
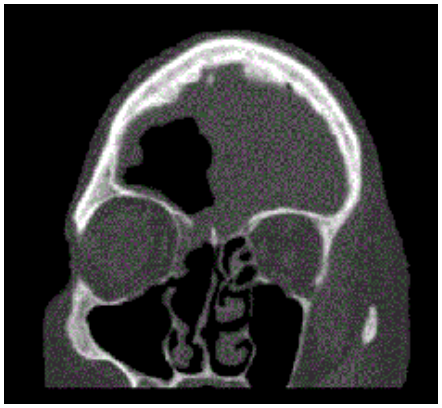
Why Is This Patient Such an Air Head?

Urdaneta-Moncada, A. R.·Helmer, E.·Wong, A.
Kaiser Permanente Los Angeles Medical Center
Los Angeles, CA.

Purpose
To illustrate an unusual case of direct barotrauma to the brain, from inappropriate CPAP use, causing tension hydropneumocephalus.
Case Report
An 88-year-old male with history of obstructive sleep apnea (OSA) presents with worsening headaches and three days of altered mental status. Patient was afebrile and without any focal motor or sensory deficits. Head CT demonstrated extensive pneumocephalus with intraventricular extension and moderate hydrocephalus (Figure 1), initially of unclear cause. Five weeks earlier, the patient had undergone transnasal surgical biopsy of a right sphenoid bone lesion, complicated by CSF leakage that subsequently was repaired (Figure 2). It was later revealed that, after surgery, the patient had used CPAP at home for his OSA against medical advice. It then became clear that the tension hydropneumocephalus seen on our admission reflected direct barotrauma to the brain as a result of positive pressure ventilation into a postsurgical skull base defect which had not yet healed. The dissection of gas through the brain parenchyma into the ventricular system was felt to be due to postsurgical adhesions between the skullbase defect and the overlying brain surface. As the patient was not clinically infected, he was treated conservatively and followed with serial head CTs, which showed marked decrease in pneumocephalus and resolved hydrocephalus by the time of discharge.





Imaging Findings
1. A: Axial image presurgery, demonstrating normal ventricular size. B: Axial image at admission, demonstrating tension hydropneumocephalus. 2. Coronal reformat, demonstrating surgical defect through the right cribriform plate and pneumocephalus.
Summary
Pneumocephalus is a known consequence of skullbase surgery or trauma. Several cases of positive pressure-induced tension pneumocephalus are reported in the literature. However, to our knowledge, no case of tension pneumocephalus with intraventricular extension and hydrocephalus is documented before. This case illustrates the dangers of using positive pressure ventilation soon after skullbase surgery.

Evaluation of Isodense Subdural Hemorrhages

Kohler, N.·Felsberg, G.
Florida Hospital
Orlando, FL.

Purpose
The purpose of this case report is to review the CT and MRI findings in patients with isodense subdural hemorrhages (SDH) on initial CT examination.
Case Report
A 66-year-old male with a past medical history of hypertension, hyperlipidemia and bipolar disorder presented with a history of worsening headaches. On review, the patient denied a history of speech, visual or balance disturbances. He denied vertigo or neurologic deficits. He stated he had a history of fall two weeks previously.
Imaging Findings
The initial scan demonstrates bilateral ill-defined fluid collections which were isodense to cortical gray matter. Follow-up MR imaging demonstrates hypointense subdural fluid collections on T2-weighted imaging.
Summary
Isodense SDH remain a problem for clinicians and

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

radiologists in the initial screening evaluation for hemorrhage. Patients with SDH may present initially with a headache and a benign neurologic exam but may quickly deteriorate. Timely diagnosis and treatment is important. In particular, this patient initially underwent a diagnostic MRI and was determined to be neurologically stable. Shortly after he suffered a neurologic decline and underwent emergency decompression. Subdural hemorrhages on CT evaluation have been categorized based on the age of the hematoma, namely, acute (0-7 days), subacute (8-22 days), and chronic (>22 days). A previous study of 429 patients with SDHs found that 98.6% of patients with acute hemorrhages were hyperdense. In patients with subacute hemorrhages, 45.7% were hypodense, 42.9% were isodense and 11.4% were hyperdense. The majority of chronic SDHs were isodense, 73.2% with the remainder hypodense, 21.1%. The large percentage of patients presenting with isodense SDHs remain a diagnostic quandary for radiologists. Diagnosis on plain CT can be difficult due to hemorrhage isodensity to cortex. CT scanning with contrast has been proposed for rapid diagnosis of SDH as subacute or chronic subdural hematomas result in blood-brain barrier breakdown with enhancing margins easily detected. When the diagnosis of SDH is unclear, MRI may be performed in lieu of CT with contrast as was the case for this patient. A retrospective study classified the imaging findings of SDH in 1.5T scanners. Subdural hemorrhages were categorized as acute (one week and two weeks and <one month) and chronic (>one month). Acute SDHs were characterized by hypointensity on long TR/TE images. Early subacute SDHs were noted to have a rim of high signal intensity with a surrounding center of low intensity on long TR/TE images. In late subacute SDHs, there was high signal intensity on all pulse sequences. Chronic SDHs were found to have variable intensity ranging from hypointense to isointense to relative gray matter on short TR/TE imaging.

Remote Cerebellar Hemorrhage after Lumbar Drain Placement: Review of a Case

Koohi, Y.·Mukherjee, S.·Matsumoto, J.
University of Virginia Health System
Charlottesville, VA.

Purpose
Intracerebral hemorrhage remote from the site of surgery is an infrequent complication, which has been described after neurosurgical procedures. Remote cerebellar hemorrhage (RCH) has been described following supratentorial and spinal surgery. The most accepted explanation for the occurrence of RCH is the development of cerebrospinal fluid (CSF) hypotension, which in turn leads to sagging of the cerebellum and stretching of the cerebellar veins with subsequent bleeding. Whether stretching leads to occlusion or rupture of bridging cerebellar veins, with resultant hemorrhagic venous infarction or direct hemorrhage remains unclear. Remote cerebellar hemorrhage usually occurs in the superior aspect of the cerebellum following the cerebellar folia in a pattern that has been termed the “zebra sign”. We present a case of RCH in a patient following lumbar drain placement, an uncommon etiology for this rare entity.
Case Report
The patient is a 61-year-old male who was admitted to the hospital for elective open repair of a type III thoracoabdominal aortic aneurysm. The patient underwent intraoperative placement of a lumbar drain. On postoperative day (POD)1, the patient was weaned off sedation and extubated. Upon awakening, the patient was noted to have paraplegia of his lower extremities. The patient was reintubated shortly after extubation due to respiratory distress. MR imaging of the thoracolumbar spine revealed cord infarct extending from T8 to the conus. The patient was started on corticosteroids and lumbar drain remained in place to maintain intracranial pressure (ICP) at 0-5 mm Hg. On POD2, the patient’s lumbar drain was removed without incident. On POD 3, the patient failed to recover his neurologic exam after sedation was weaned. There was concern for an acute intracranial process. Stat head CT revealed hemorrhage in the bilateral cerebellar hemispheres, in a peculiar linear pattern extending across the superior cerebellum and vermis. Blood products appeared to have both an intra- and extra-axial component. This pattern was thought to be most consistent with remote cerebellar hemorrhage following CSF loss related to lumbar drain. Unfortunately, the patient suffered hypoxic ischemic failure and continued to deteriorate neurologically. The patient was extubated and transitioned to comfort care only. He expired on POD 11.
Imaging Findings
Noncontrasted CT of the brain revealed hyperdensity extending in a linear and streaky pattern across the bilateral superior cerebellar hemispheres, compatible with acute hemorrhage. MR imaging, MRA and MRV of the brain was performed shortly after, and ruled out an underlying vascular malformation or dural venous sinus thrombosis as the etiology of the hemorrhage. There was hypointense T2 signal extending across the cerebellar hemispheres with mild adjacent parenchymal edema and mass effect upon the fourth ventricle. There was no hydrocephalus. Several follow-up head CTs did not demonstrate any new hemorrhage.
Summary
Remote cerebellar hemorrhage has been described with supratentorial craniotomy and spinal surgery complicated by dural tear. Intraoperative or postoperative loss of CSF has been proposed as the etiology of this complication. We present a case of RCH following large volume CSF drainage as a result of lumbar drain placement, an unusual etiology of this entity.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Cerebral Fat Embolism in a Patient with Sickle Cell Anemia/Beta Thalassemia in the Setting of Acute Chest Syndrome and Active Parvovirus B19 Infection

Witkosky, M.·Mossa-Basha, M.
University of Washington
Seattle, WA.

Purpose
We describe the MRI findings in a case of pathology proven cerebral fat embolism in the setting of sickle cell anemia/beta thalassemia and active parvovirus (PV) B19 infection. This is followed by a discussion of relevant pathophysiology.
Case Report
A 27-year-old male patient with sickle cell anemia/beta thalassemia initially presented to the ER with back and chest pain, typical of his prior episodes of acute chest syndrome. Over two days, the patient's consciousness slowly decreased to the point of unresponsiveness. Initial MRI of the brain is described below. The patient's mental status continued to deteriorate, and eight days later repeat MRI brain showed the findings described below. Prognosis was made of a vegetative state and the decision was made to extubate the patient, shortly after which he expired. Post mortem evaluation demonstrated multiple intravascular lesions (consistent with fat) within the brain parenchyma, lungs, and renal glomeruli. Serum PVB19 PCR was positive.
Imaging Findings
Initial MRI brain two days after initial presentation: multiple foci of restricted diffusion involving the striatocapsular region and thalami. Follow-up MRI: diffuse leukoencephalopathy, involving the supratentorial and infratentorial white matter. Susceptibility-weighted imaging shows innumerable foci of susceptibility throughout the white matter, representing tiny hemorrhages. Findings are highly suggestive of cerebral fat embolism syndrome.
Summary
Clinical presentation of cerebral fat embolism is variable including lethargy, delirium, seizures, and coma. In the setting of sickle cell anemia/beta thalassemia, the origin of fat emboli is thought to be the result of vaso-occlusive marrow necrosis, with fat emboli then released into the bloodstream. PVB19 infection can cause an aplastic crisis in patients with chronic hemolytic anemia. This process may be complicated by severe acute lung injury and death in individuals with thalassemia, through the mechanism of fat embolism syndrome associated with bone marrow necrosis. An association of PV B19 infection with marrow necrosis has been recognized, although it is unknown if the virus results in primary marrow necrosis or whether viral injury to the lung results in systemic hypoxemia with resultant increased sickling and subsequent increased marrow necrosis. Petechial hemorrhages throughout the cerebral white matter are the classic histologic lesions suggestive of cerebral fat embolism; however, these are nonspecific and also can be seen in carbon monoxide poisoning, air embolism, and head trauma.The petechial hemorrhages are thought to represent small hemorrhagic embolic infarcts with occlusive fat embolus resulting in vessel wall rupture. Typical MRI findings in cerebral fat embolism include multiple micro-infarcts with punctuate hyperintense foci on T2 and DWI images in the cerebral white matter, basal ganglia, thalami, brainstem, and cerebellum. More confluent hyperinetense T2 and DWI lesions can be seen. Numerous petechial hemorrhages can be seen on heme-sensitive sequences. These microhemorrhages are better depicted on SWI as opposed to GRE images. In conclusion, early diagnosis of hemoglobinopathies and a better understanding of prevention and transmission of PV B19, may result in decreased morbidity and mortality associated with the neurologic sequelae of cerebral fat embolism syndrome.

Angiographic Characterization of a Duplicated Posterior Communicating Artery Variant Associated with a Persistent Primitive Fetal Posterior Cerebral Artery

Honarmand, A. R.·Seth, R.·Hurley, M. C.·Shaibani, A.·Ansari, S. A.
Northwestern University Feinberg School of Medicine
Chicago, IL.

Purpose
Anatomical knowledge is essential for the detection of important neurovascular variants such as duplications, persistent fetal arteries, and fenestrations that may be

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

crucial in the pre-operative angiographic evaluation of neurovascular disease. We describe and angiographically elucidate a unique duplication variant of the posterior communicating artery (PcomA) associated with a persistent primitive fetal posterior cerebral artery (PCA) using 3D DSA.

Case Report

A 67-year-old male with a history of fall was diagnosed with prepotine and interpeduncular SAH on CT head study. Digital subtraction angiography (DSA) was performed for further evaluation to exclude underlying neurovascular pathology.

Imaging Findings

Standard AP/lateral and 3D rotational DSA images of the anterior intracranial circulation revealed a duplicated right fetal PCA superior to the right PcomA, providing isolated supply to the posterior temporal branch. The anterior choroidal artery also arose separately from a common origin of the duplicated fetal posterior cerebral artery. Additionally, right vertebral artery DSA images demonstrated minimal opacification of the hypoplastic, but patent right P1 segment contributing to the right PCA distribution in addition to the dominant collateral supply from the right PcomA. However, there was no communication from either the PcomA or P1 segment to the duplicated fetal PCA or its isolated supply to the posterior temporal branch.

Summary

The PcomA, also referred to as “caudal ramus” of the internal carotid artery (ICA), embryogically belongs to the anterior circulation. PcomA variants have been described with several types of anomalies and morphologies including hypoplasia, aplasia/atresia, different lengths and courses, fetal configuration of the PCA branching directly from the ICA, vessels originating from the PcomA (e.g., anterior choroidal artery), fenestration, and partial or complete duplication. A vessel arising independently from ICA distal to the PcomA is termed duplicated PcomAs or duplicated PCAs by different authors. It is exceedingly rare (0.2% at surgical dissection) and has been reported in association with bilateral fetal PCAs and PcomA aneurysm. A few surgical cases of a PcomA duplication variant associated with a persistent primitive PCA have been described, in which one of the arteries arises from the ICA and courses as an isolated temporal artery without joining the PCA. To the best of our knowledge, angiographic characterization of this duplicated PcomA variant (with a persistent primitive PCA) has never been shown. Isolated posterior temporal supply from a persistent primitive PCA versus the native PCA distribution may be an important finding to recognize prior to surgical and endovascular interventions.

KEYWORDS: Anatomical variation, 3D DSA, duplicated posterior communicating artery

EE-37

Fenestration of the Cervical Internal Carotid Artery: Rare Anatomical Variant or Uncommon Presentation of a Common Disorder?

Berberian, G. H.·Federer, G. E.·Burd, D. A.
St. Vincent Hospital
Worcester, MA.

Purpose

We report a case of cervical segment internal carotid artery (ICA) fenestration with contralateral persistent trigeminal artery (PTA) in a 47-year-old female during a workup of transient ischemic attack with ipsilateral weakness and numbness. Fenestration of the cervical ICA is thought to be an extremely rare anatomical variant with only few previously reported cases. Previous authors have even questioned the validity of some true cervical ICA fenestrations, citing a lack of sufficient underlying embryologic explanation. They felt reported angiographic findings instead represented acquired pseudofenetration of dissecting aneurysm, a common cause of stroke in young and middle-aged patients. Our patient presented with symptoms supporting a diagnosis of ICA dissection. Her imaging findings, however, lacked expected supporting pathologic details such as irregular contours, asymmetric limb caliber, intramural hematoma or wall thickening. We describe both the potential congenital and pathologic origins of cervical ICA true and

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

pseudofenestrations, present viewpoints both in support of and opposition to true ICA fenestrations with discussion of the expected clinical symptoms and imaging findings, and review the potential imaging pitfalls and mimics of these two discordant diagnoses. Additionally, PTA is an uncommon but well described persistent communication between the carotid artery and vertebrobasilar circulation due to failure of regression of the embryologic trigeminal artery. This is seen in 0.02-0.6% of cerebral angiograms. While PTA is associated with other vascular anomalies such as intracranial aneurysm and vascular malformations, we find no previous report associating it with an ICA fenestration.

Case Report

A 47-year-old female presented with mild occipital headache and left-sided paresthesias of her leg, arm, and face. A left-sided facial droop was reported by the patient's colleagues. She recalled a single episode of lower extremity tingling and weakness with subsequent resolution three years prior. On examination, facial droop had resolved and strength was normal.

Imaging Findings

3D time-of-flight MRA images with maximum intensity projection revealed a 9 mm length fenestration of the left distal cervical ICA with symmetric and smooth 2.5 mm dual channels without wall thickening or intramural hematoma. The bilateral cervical ICAs were dysplastic cephalad to this anomaly. Additionally, an anomalous artery was identified arising from the cavernous C4 segment of the right ICA, extending posteriorly to the basilar artery as a Saltzman type 1 persistent trigeminal artery.

Summary

We report a case of two contralateral anatomical variants. Persistent trigeminal artery is an uncommon but well described finding. Cervical segment ICA true fenestration is, however, quite rare and controversial. The origin of this debate is discussed, both supporting and opposing views are presented, and the potential imaging pitfalls are reviewed.

KEYWORDS: Carotid artery, Fenestration

What Defines Persistent Primitive Ophthalmic Arteries?: A Report of Five Anatomical Variants

Gregg, L.[1]·San Millán, D.[2]·Tamargo, R. J.[1]·Gailloud, P.[1]
[1]Johns Hopkins University School of Medicine, Baltimore, MD, [2]Hospital of Sion, Sion, Valais, Switzerland, SWITZERLAND.

Purpose

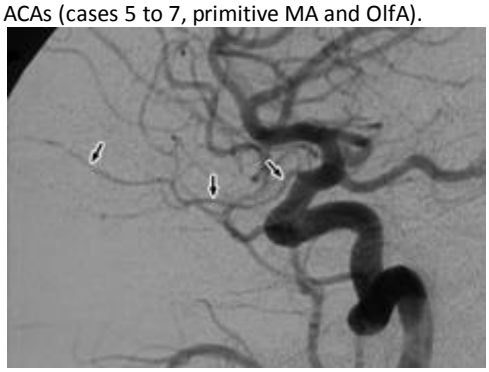
Understanding anomalous ophthalmic artery (OA) origins is essential in preventing inadvertent passage of embolic material into important ophthalmic branches during endovascular procedures. We report four observations of OA origin variants and three cases of infraoptic anterior cerebral arteries (ACA). The vessels involved in these variations include the primitive ventral and dorsal OA, the primitive maxillary artery (MA), and the primitive olfactory artery (OlfA). The criteria allowing the identification of these embryonic vessels are discussed.

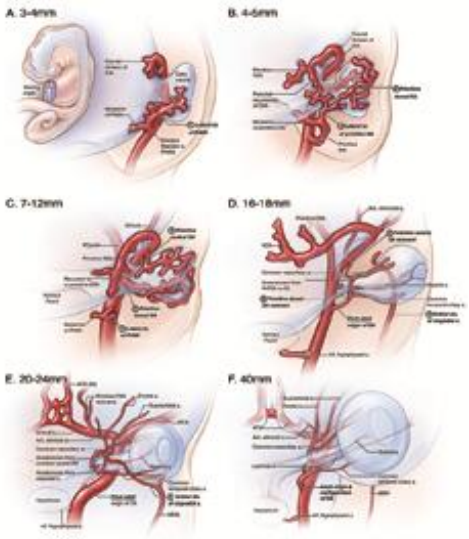
Case Report

Seven observations of anatomical anomalies derived from variations of four embryonic arteries involved in the formation of the OA are reported.

Imaging Findings

Four types of variants are described: (i) OA from the cavernous segment of the internal carotid artery (ICA) (case 1, primitive MA), (ii) OAs from the distal supraclinoid ICA (cases 2 and 3, primitive ventral or dorsal OA), (iii) OA from the ACA (case 4, primitive OlfA), and (iv) infraoptic ACAs (cases 5 to 7, primitive MA and OlfA).





Figures

1. OA (arrows) originating from the distal supraclinoid ICA
2. Development of the OA

Summary

Prior to the formation of the adult OA, the primitive MA, primitive dorsal and ventral OAs, and primitive OlfA contribute to the capillary network surrounding the developing eye. Four types of anomalies derived from these vessels are described. Previously reported OA origin variants and the development of the orbital vasculature are reviewed. Erroneous criteria currently used to identify

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

persistent primitive OAs are discussed. An OA arising from the cavernous segment of the ICA likely derives from the primitive MA, while an OA arising from the ACA represents the persistence of a branch of the primitive OlfA. The confusion between these variants and a persistent primitive ventral or dorsal OA appears to result from misinterpretation of the literature concerning the development of the cranial arteries.

Venous Invasion of a Salivary Gland Mass as the First Presentation of Metastatic Renal Cell Carcinoma

Maralani, P. J.·Mohan, S.·Loevner, L. A.·Jhala, N. C.
University of Pennsylvania
Philadelphia, PA.

Purpose
We review the imaging findings of a 64-year-old otherwise healthy female who presented with left facial swelling. Imaging findings demonstrated multiple salivary gland masses. The mass in the left parotid gland was associated with venous invasion into the retro-mandibular and facial veins and into the left internal jugular vein (IJV). Based on the venous invasion, the diagnosis of metastatic renal cell carcinoma was suggested on imaging, which subsequently was confirmed on systemic workup and pathology.
Case Report
Our patient is a 64-year-old female with a history of hypertension controlled by thiazide diuretics who presented to an outside physician with swelling in the left side of the face of unknown duration. There was no sign of facial nerve deficit or other significant past medical or surgical history. Outside institution contrast-enhanced neck CT scan demonstrated multiple masses in bilateral parotid glands, left submandibular gland and in the right lobe of the thyroid gland. The patient then was referred to our institution for further management.
Imaging Findings
Contrast-enhanced MRI of the neck demonstrated a 2.8 cm mass involving the superficial and deep lobes of the left parotid gland, a 1.0 cm mass in the right parotid gland, several masses in the left submandibular gland the largest one measuring 2.0 cm and a 3.0 cm mass in the right lobe of the thyroid gland. The masses were slightly hyperintense compared to skeletal muscle on T1- and T2-weighted images with mild restricted diffusion and showed avid postcontrast enhancement. There was no pathologic neck lymphadenopathy. The mass in the left parotid demonstrated invasion and extension to the left retro-mandibular and facial veins extending to the left IJV. Based on this finding and multiplicity of the masses imaging diagnosis of metastatic renal cell carcinoma was proposed. The patient subsequently underwent contrast-enhanced CT of the abdomen and pelvis which demonstrated a 9 x 7 x 6 cm vascular enhancing mass in the right kidney with no extension to the right renal vein. Biopsy of the salivary gland masses and nephrectomy specimen both confirmed clear cell renal cell carcinoma.
Summary
This case signifies two important imaging findings. Firstly, multiplicity of masses should raise suspicion for metastatic disease with the renal cell carcinoma being the most common source for distant metastasis to the thyroid. Secondly, venous invasion of a mass is a known characteristic of the renal cell carcinoma. Although venous invasion can occur in other neoplasms such as hepatocellular carcinoma, renal cell carcinoma is the most common to present in this fashion with remote metastasis.

Rare Submandibular Bronchopulmonary Foregut Cystic Malformation Mimicking a Lymphatic Malformation

Gross Kelly, T. C.[1,2]·Subramanian, S.[1]·Moe, D.[1,2]·North, P. E.[3,2]·Chun, R. H.[1,2]
[1]Children's Hospital of Wisconsin, Milwaukee, WI, [2]Medical College of Wisconsin, Milwaukee, WI, [3]Wisconsin Children's Hospital, Milwaukee, WI.

Purpose
Bronchopulmonary foregut cystic malformation (BFCM) is an uncommon cause of a cystic neck mass, as they usually are found in chest and abdomen. The imaging features are nonspecific and preoperative diagnosis is usually difficult. We present an unusual case of BPFCM that presented as a multiseptated cystic lesion in the submandibular and sublingual space mimicking a lymphatic malformation.
Case Report
A 31/2-year-old girl presented with recurrent swelling of the left submandibular gland region. When she was one

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

year old a lump was noted in the same area, but it spontaneously decompressed. Based upon the current MRI findings, a lymphatic malformation was suspected. A ranula was felt to be less likely as no lesion could be palpated along the floor of the mouth. She underwent three sclerotherapy attempts but the lesion persisted and swelling increased. Therefore, the lesion finally was surgically excised. Surgical pathology results revealed that the lesion was a rare bronchopulmonary foregut cystic malformation (BPFCM).

Imaging Findings

MR imaging examination revealed a septated cystic lesion within the left submandibular space extending into the left sublingual space. The left submandibular gland was displaced laterally. Ultrasound revealed a cystic mass without solid components. Using Picibanil and ultrasound guidance three sclerotherapy attempts were made.

Summary

Given the findings in this case, we suggest that BPFCM should be added to the list of diagnostic possibilities when encountering a mulitseptated cystic lesion in the submandibular space.

KEYWORDS: Masses, Cystic neck mass, submandibular space

EE-40

Hypervascular Mass at the Carotid Bifurcation: Not Always a Carotid Body Tumor

Ibrahim, H.·Sepahdari, A.
University of California Los Angeles
Los Angeles, CA.

Purpose

We present a series of three cases of hypervascular carotid bifurcation-region masses mimicking carotid paraganglioma [i.e., carotid body tumor (CBT)], and a companion case of a true CBT. Relevant anatomy of the carotid space is reviewed, including position of traversing cranial nerves, the sympathetic chain, vessels, and paraganglia. The imaging features of CBT are reviewed, and the phenomena of hypervascular schwannomas and low vagal paragangliomas (i.e., those occurring below the typical location of the inferior nodose ganglion) are discussed.

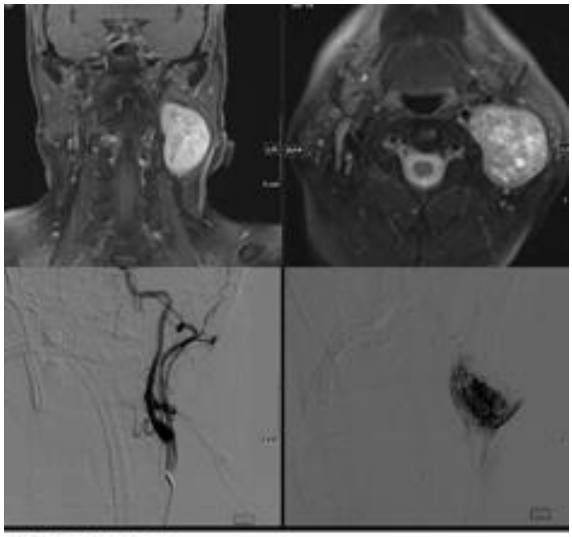
Case Report

Three adult patients with hypervascular neck masses were referred to our hospital with presumptive diagnoses of CBT. These lesions were surgically proven to be a sympathetic chain schwannoma, vagal schwannoma and vagal paraganglioma. In each case, a careful review of the images was able to suggest sympathetic chain or vagal origin of these lesions.

Imaging Findings

Characteristic imaging features of CBTs are well established on noncontrast and contrast-enhanced MRI, and also on conventional angiography. These include avid contrast enhancement, a “salt-and-pepper” appearance on MRI, and splaying of the internal and external carotid arteries at the carotid bifurcation. Catheter angiography is able to demonstrate a vascular blush, and tumor supply by enlarged branches of the external carotid artery, which are amenable to preoperative embolization. The hypervascular carotid bifurcation region masses in our case series showed the typical signal characteristics described, and also separated the internal and external carotid arteries, but were not centered at the carotid bifurcation. The sympathetic chain lesion displaced both the internal and carotid arteries laterally, while the vagal lesions anteriorly displaced the internal and external carotid arteries while posteriorly displacing the internal jugular vein.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Vagal schwannoma.
Fig 1a. T2-weighted coronal and axial MR images of the neck at the level of the carotid bifurcation demonstrating a heterogenously hyperintense mass.
Fig 1b. Angiography (AP view) of the left CCA and selective ECA branch injection demonstrates a hypervascular mass displacing the ECA medially, but absence of splaying of the ICA/ECA that is seen with carotid body tumors.

Summary
Carotid body tumors classically present as hypervascular masses at the carotid bifurcation. This well known feature may cause a reflexive diagnosis of any hypervascular mass in that region as a CBT. The therapeutic and prognostic implications of an erroneous imaging diagnosis are important. All neuroradiologists should be familiar with detailed anatomy of the carotid space, differential considerations of hypervascular tumors in that region, and how to distinguish them on imaging.

KEYWORDS: Glomus tumors, Neck masses

EE-41

Bilateral Inferior Alveolar Nerve Enlargement

Kumar, S.[1,2]·Ginsberg, L. E.[2]
[1]Baylor College of Medicine, Houston, TX, [2]The University of Texas M. D. Anderson Cancer Center, Houston, TX.

Purpose
We present an unusual case of bilateral inferior alveolar nerve enlargement.
Case Report
A 30-year-old, asymptomatic female presented to the dentist office for routine care. Bilateral enlarged mandibular canal was noticed in her routine panoramic radiograph and the patient was referred for imaging evaluation. There was no sensory neuropathy referable to the mandible, and no prior history of trauma.
Imaging Findings
MR imaging of the face with intravenous contrast was obtained to assess the extent of potential disease and for further characterization. There was bilateral widening of the mandibular canal (L>R) with an "onion- bulb" like configuration, presumably caused by enlarged inferior alveolar nerves. The enlarged nerves were isointense to muscle on T1 and markedly hyperintense on T2 without any enhancement. The mandibular and mental foramen were intact. Panoramic radiograph shows fusiform enlargement of both mandibular canals.

Summary
Bilateral enlargement of intramandibular inferior alveolar nerve without enhancement in an asymptomatic patient was presumed to be hypertrophic neuropathy. Nonenhancement is atypical for peripheral nerve sheath tumor with MR imaging. Hypertrophic neuropathy is a well known condition of the peripheral nerves. They rarely have involved cranial nerves including the trigeminal and vestibulocochlear nerves. There has been only one case of isolated unilateral hypertrophic neuropathy of inferior alveolar nerve reported in the literature. However, our case is unique because of bilateral inferior alveolar nerve enlargement. In localized hypertrophic neuropathy there is slow progressive loss of motor function and sensation in the distribution of a single nerve. Our patient is presently asymptomatic and an asymptomatic variant has not been described in the literature. Because of potential for development of neurologic symptoms in the future, a detailed neurologic workup and close observation are planned.

KEYWORDS: Hypertrophic neuropathy, Inferior alveolar nerve

EE-42

Intraneural Perineurioma of the Trigeminal Nerve Presenting as Recurrent Headache

DeLoia, S. P.·Branstetter, B. F.·Clark, K. H.
University of Pittsburgh Medical Center
Pittsburgh, PA.

Purpose
Perineurioma is a rare neoplasm of the nerve sheath that most commonly is associated with peripheral nerves of the extremities. We present a rare case of the intraneural variant of this lesion arising from the trigeminal nerve.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Case Report
A 36-year-old Caucasian male with no significant past medical history presented with two years intermittent left-sided headaches. When the headaches progressed in frequency and intensity, the patient underwent unsuccessful medical therapy for presumed migraines, after which MRI of the brain was performed. MR imaging revealed a complex lesion centered in the cisternal segment of the left trigeminal nerve, and a presumptive diagnosis of trigeminal schwannoma was rendered. The patient was referred to neurosurgery for endoscopic transsphenoidal debulking, with final pathology revealing intraneural perineuroma. Incomplete symptomatic relief was reported following surgery. Stereotactic radiosurgery is planned to control residual tumor.
Imaging Findings
Multiple MR examinations reveal a lobular, heterogenous lesion extending from the cisternal segment of the left trigeminal nerve through Meckel's cave and into the left cavernous sinus. There were regions of high T2 signal with minimal enhancement, and other regions with intermediate T2 signal and moderate enhancement. Involvement of the second and third branches of the fifth cranial nerve also was demonstrated, as tumor spread through the foramen ovale and foramen rotundum. A largely cystic component extended into the left pterygopalatine fossa.
Summary
A rare case of intraneural perineurioma of the trigeminal nerve is presented, with symptoms of trigeminal neuralgia correlated to tumor involvement of the second and third branches. The imaging findings and pathologic characteristics are described to illustrate the nature of this unique neoplasm. We also review the pathologic classification of nerve sheath tumors with attention to their different radiologic appearances.

KEYWORDS: Perineural, Trigeminal nerve

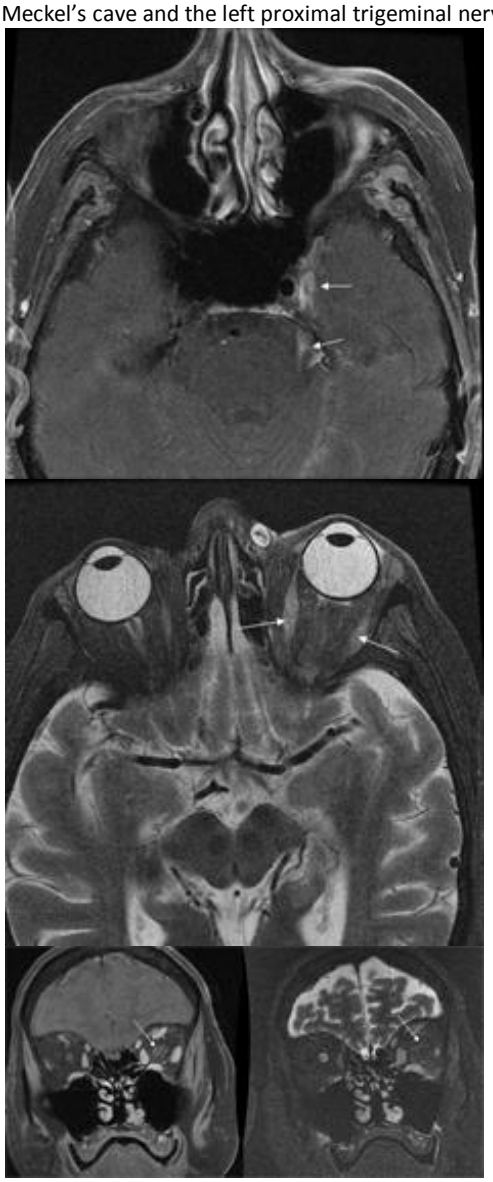
Review of MR Imaging Features of Herpes Zoster Opthalmicus

Rehmani, R.·Gandhi, S.
North Shore University Medical Center
Manhasset, NY.

Purpose
To illustrate subtle and often overlooked imaging features of herpes zoster opthalmicus on MRI.
Case Report
A 69-year-old female presented with intractable left eye pain and ocular migraines for one week. She went on to develop vesicular rash along the left medial canthus. Clinical diagnosis of herpetic neuralgia was made. Initial orbit and brain MRI were normal. However, she returned two weeks later with worsening left ocular pain with new onset ptosis, opthalmoplegia and photophobia. However, a repeat follow-up brain MRI demonstrated multitude of intracranial and left orbital findings.
Imaging Findings
MR imaging findings showed loss of normal hyperintense T2 CSF signal within the left optic nerve sheath and evidence of retrobulbar perioptic enhancement. Left orbit also demonstrated extraocular myositis, stranding of the retrobulbar fat and proptosis. Postcontrast intracranial transneural enhancement also was noted in the left Meckel's cave and the left proximal trigeminal nerve.



Summary
Herpes zoster opthalmicus is a rare entity and can progress to complications such as acute retinal necrosis which can drastically alter the clinical outcome and patient management. This case outlines the key orbital and intracranial imaging checklist for herpes zoster infection.

KEYWORDS: Orbits, Optic nerve, orbital myositis

EE-44

Isolated Rheumatoid Arthritis of the Atlanto-Occipital Joint Confused with Migraine

Kozic, D.·Bjelan, M.·Njagulj, V.·Lucic, M.·Koprivsek, K.
University of Novi Sad School of Medicine
Novi Sad, SERBIA.

Purpose
The aim of this report is to demonstrate imaging findings of isolated rheumatoid arthritis (RA) of atlanto-occipital joint that was presented clinically as atypical migraine.
Case Report
Magnetic resonance imaging (MRI) was performed in a 52-year-old woman with a several years long history of the left hemicranial pain, most compatible with migraine. The pain was accompanied with left eye "tunnel vision". The duration of pain was between 48-72 hours, approximately three times per month. No positive response to treatment was evident. The patient also complained of chronic muscle stiffness and tightness in the left suboccipital region. The presence of synovial effusion without erosions of the joint's facets was revealed on MRI most consistent with RA (Figure a,b). No lesions within the brain parenchyma were evident. Laboratory screening was ordered. Rheumatoid factor was significantly positive, >80 IU/ml (normal range 0-20 IU/ml). Clinical examination, performed after MRI study, detected no involvement of other joints.

Summary
Isolated RA of atlanto-occipital or atlantoaxial joints easily could be associated with misdiagnosis and mistreatment. MR imaging became important imaging tool that has had the ability to assess simultaneously all relevant structures in inflammatory joint disease - the synovium, cartilage, bone, ligaments, tendons, tendon sheaths and the presence of synovial fluid.

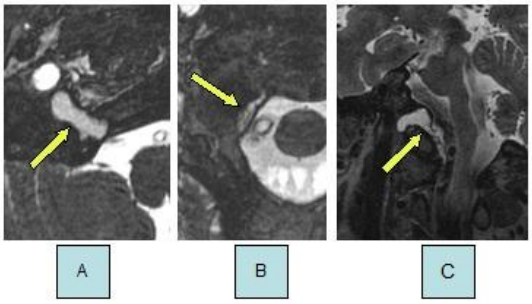
KEYWORDS: Rheumatoid arthritis, MR imaging

EE-45

Optimized Imaging of Atlantooccipital Synovial Cysts Compressing the Hypoglossal Nerve

Rydberg, C. H.·Lane, J. I.
Mayo Clinic
Rochester, MN.

Purpose
Isolated unilateral hypoglossal nerve palsy is a rare condition. When imaging reveals a cystic mass in the hypoglossal canal, a synovial cyst arising from the atlanto-occipital joint may be misdiagnosed as the more common cystic schwannoma. We offer suggestions for detecting and correctly diagnosing this rare lesion.
Case Report
A 64-year-old man presents with a one-year history of progressive dysarthria, dysphagia, and right tongue hemiatrophy. Electromyography confirmed denervation of the genioglossus muscle.
Imaging Findings
CT and MRI demonstrate expansion of the right hypoglossal canal by a cystic mass with minimial peripheral enhancement suggesting a hypoglossal schwannoma with cystic degeneration. Axial 3D gradient (FIESTA) sequence shows the cystic mass within the hypoglossal canal (Image A) and the continuity of the cyst with the atlanto-occipital joint (Image B). A 3D FSET2 (Cube) sequence parallel to the hypoglossal canal confirms the cyst as arising from the atlanto-occipital joint and extending cephalad to exit through the hypoglossal canal (Image C).



Summary
Isolated unilateral hypoglossal nerve palsy is a rare condition. Differential diagnosis includes hypoglossal schwannoma, meningioma, metastasis, epidermoid, jugulotympanic paraganglioma, dural AVF, solitary fibrous tumor, and synovial cyst arising from either the atlanto-occipital or atlanto-axial joint. If a cystic mass with minimal or no periperal enhancement is discovered, a cystic schwannoma or synovial cyst is the most likely diagnosis. To differentiate, an axial 3D gradient (FIESTA) sequence and 3D FSET2 (Cube) images obtained/reformatted parallel to the hypoglossal canal can demonstrate the origin of the synovial cyst from a joint space. Correct diagnosis allows correct treatment - stabilization, rather than an unnecessary intradural exploratory surgery.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

KEYWORDS: Cyst, Cranio-cervical junction, hypoglossal nerve palsy

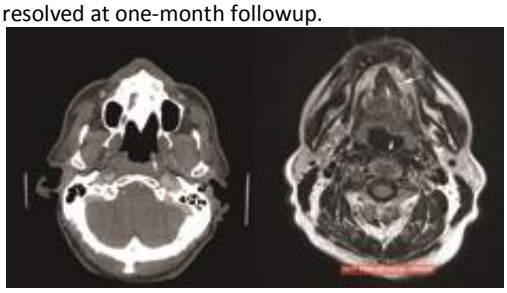
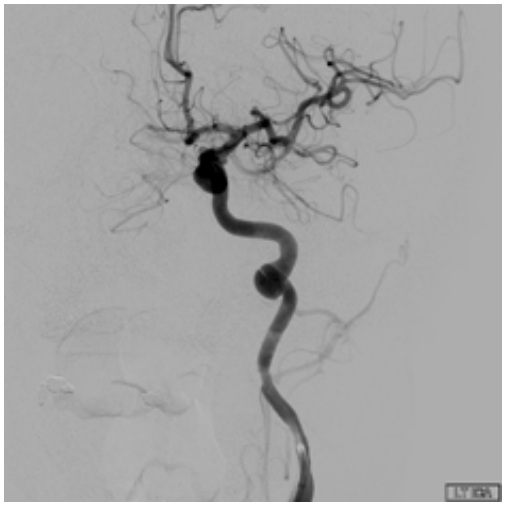
Tongue Twisted

Darflinger, R. J.·Wong, A.
Kaiser Permanente Los Angeles Medical College
Los Angeles, CA.

Purpose
Illustrate a rarely seen etiology for cranial nerve XII palsy: dissection of the internal carotid artery with pseudoaneurysm formation at the level of the hypoglossal canal.
Case Report
A 61-year-old male with history of hypertension presents with 10 days of left occipital headaches radiating to the neck, and dysphagia, initially treated unsuccessfully for muscle spasm. Subsequent evaluation showed leftward tongue and uvular deviation, and left tongue hemiatrophy with fasciculations.
Imaging Findings
Brain MRI showed asymmetry of the left genioglossus muscle (Figure 1). Laryngoscopy confirmed left tongue atrophy, ipsilateral deviation, and left palate asymmetry; however, no mass was seen. Subsequent CTA demonstrated a left ICA dissection at the craniocervical junction with a 10 mm tortuous dissecting pseudoaneurysm at the level of the hypoglossal canal, effacing the soft tissue planes in the area of the exiting hypoglossal nerve (Figure 1). The aneurysm was confirmed with cerebral angiography (Figure 2) and treated with stent placement. The patient's tongue deviation was resolved at one-month followup.





Summary
Hypoglossal (CN XII) palsies can be due to a variety of conditions, with more common etiologies including ischemia, CNS neoplasm, demyelination disease, nasopharyngeal carcinoma, and metastases. Lesions causing this deficit can be located anywhere from the level of the CN XII nucleus at the medullary tectum to the base of the tongue. Dissection and pseudoaneurysm of the ICA is a rarely reported etiology. This case illustrates the importance of considering vascular causes when interpreting imaging studies, including MR imaging, for CN XII palsy.

KEYWORDS: Dissecting aneurysm, Carotid artery, hypoglossal nerve

EE-47

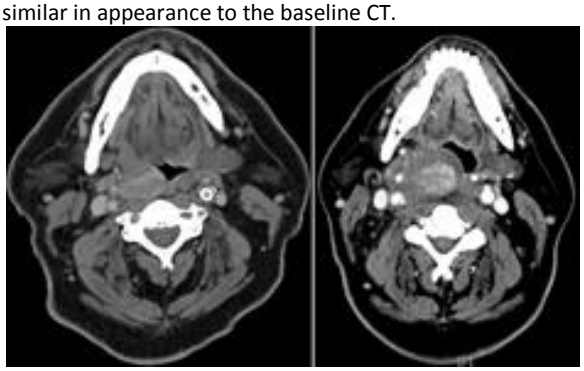
Patient with Incidental Ectopic Retropharyngeal Thyroid Tissue Found to Have Hashimoto's Thyroiditis

Wrubel, G. L.[1]·Juliano, A. F.[2]
[1]Brigham and Women's Hospital, Boston, MA,
[2]Massachusetts Eye and Ear Infirmary, Boston, MA.

Purpose
Ectopic thyroid tissue should be considered in the differential diagnosis of a neck mass which is similar density to thyroid gland on noncontrast CT. This case report highlights that the spectrum of pathology affecting the thyroid gland (e.g., infection, auto-immune disease, neoplasm, etc.) also can affect ectopic thyroid.
Case Report
This 56-year-old male was incidentally found to have a retropharyngeal mass on MRI while being worked up for a musculoskeletal complaint. Initial neck imaging showed a large enhancing right-sided retropharyngeal mass. A fine needle aspiration revealed normal thyroid tissue. The patient returned one month later with odynophagia. Repeat imaging demonstrated an interval increase in size of the retropharyneal mass which exhibited new heterogeneity concerning for infection or less likely

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

malignancy. Following empiric antibiotic therapy, the patients symptoms resolved and the mass returned to its baseline appearance on CT. For definitive diagnosis, the patient was taken to the OR for resection. Chronic lymphocytic thyroiditis was diagnosed on pathology.
Imaging Findings
This patients' initial contrast-enhanced neck CT showed a homogeneously enhancing right-sided retropharyngeal mass that minimally extended into the right parapharyngeal space. Normal-appearing thyroid was identified within the infrahyoid visceral space. Repeat imaging when the patient acutely presented with odynophagia showed an interval increase in size of the mass which exhibited new heterogeneous enhancement and resulted in mass effect on the oropharynx. There was adjacent lymphadenopathy and oropharyngeal mucosal thickening and enhancement. Multiple new foci of hypoattenuation throughout the mass and surrounding the mass were suggestive of phlegmon or developing abscess. A follow-up CT after the patients empiric antibiotic course showed the retropharyngeal mass to be similar in appearance to the baseline CT.



Summary
Ectopic thyroid tissue is reported in seven percent of adults. The majority of ectopic thyroid tissue occurs along the course of the thyroglossal duct or along the 4th brachial pouches. Rarely, ectopic thyroid tissue may occur in unusual locations such as the retropharyngeal space, mediastinum, pericardium, etc. A few case reports of Hashimoto's thyroiditis involving struma ovarii and multinodular goiters extending into the retropharyngeal space have been described in the literature with no previously described case involving incidental ectopic retropharyngeal thyroid tissue. This case report demonstrates that ectopic thyroid tissue should be considered in the differential diagnosis of a neck mass that has thyroid tissue characteristics on CT and that ectopic thyroid tissue can harbor the same pathology affecting normal thyroid gland.

KEYWORDS: Ectopic thyroid, Hashimoto's

EE-48

Youngest Reported Case of Anaplastic Thyroid Cancer

Morozova, L.·Gibson, T.·LaFranchi, S.·Shindo, M.·Sauer, D.·Stork, L.·Pollock, J.
Oregon Health and Science University
Portland, OR.

Purpose
Describe the history, clinical presentation, and imaging findings of the youngest reported female with anaplastic thyroid cancer (ATC).
Case Report
A previously healthy 13-year-old girl was brought to medical attention after discovering a rapidly enlarging right neck mass. The patient reported recent development of "breathy" voice and occasional cough while drinking liquids. There was no hemoptysis, dyspnea, wheezing, or dysphagia. On physical examination, there was a 4 cm minimally mobile hard right neck mass, extending from the right thyroid. The patient also had enlarged right deep cervical lymph nodes and right vocal cord paralysis. FNA of the lesion yielded poorly differentiated carcinoma. The patient underwent CECT scan of the neck and PET scan which demonstrated large right thyroid mass with multiple FDG avid, enlarged, hypodense cervical, mediastinal, and hilar lymph nodes. The patient underwent total thyroidectomy and bilateral modified radical neck dissection. The pathology revealed poorly differentiated thyroid carcinoma with extensive lymphatic and vascular invasion. Metastatic deposits were found in 14/70 regional lymph nodes. The patient proceeded to systemic chemotherapy and subsequently to palliative radiation therapy, but continued to decline. Follow-up imaging demonstrated development of osseous and rapid progression of pulmonary metastasis and hospice referral was made.
Imaging Findings
CECT neck: enlarged and heterogeneous thyroid gland with multiple hypodense and enlarged lymph nodes in the cervical, mediastinal and hilar regions. PET/CT: increased FDG metabolism in both thyroid lobes with extensive metastasis to bilateral cervical, mediastinal, and hylar lymph nodes. Multiple pulmonary nodules were seen on low dose CT scan but only the largest pulmonary nodule in the left lower lobe demonstrates increased metabolic activity.
Summary
Anaplastic thyroid cancer is a very aggressive and deadly cancer that is typically seen in the elderly. This entity should be considered in any patient who presents with a rapidly enlarging neck mass.

KEYWORDS: Thyroid, Neoplasm, anaplastic

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Two Cases with Ulcerative Colitis Presenting Acute, Localized Myositis in the Neck

Nakatsuka, T.·KItamura, N.·Inaoka, T.·Terada, H.
Toho University
Sakura, JAPAN.

Purpose
We recently encountered two cases with ulcerative colitis presenting acute, localized myositis in the neck under an immunosuppressive therapy. To our knowledge there is no previous report describing inflammatory bowel disease (IBD)-related myositis in the neck. We report these cases.
Case Report
Cases were a female patient in her 30s with four-year history of ulcerative colitis and a male patient in his 10s with six-month history of ulcerative colitis. Both of them presented with neck pain and fever. CT scan and MRI revealed swelling and T2-prolongation of neck muscles in both cases. Infliximab therapy in the first case and steroid therapy in the second case for ulcerative colitis resolved their neck symptoms.
Summary
From 25 to 40 percent of cases with IBDs, including ulcerative colitis and Crohn's disease, may be associated with extraintestinal manifestations, of which musculoskeletal manifestations are the most common. Arthritis is common in patients with IBDs, but myositis is quite rare.

KEYWORDS: Inflammatory

Anaplastic Lymphoma Kinase-Positive Anaplastic Large Cell Lymphoma of the Anterior Skull Base

Jamshidi, P.[1]·Chen, J. Y.[2,3]·Wang, H.[2]·Chen, C. C.[2]
[1]University of California at San Diego, La Jolla, CA,
[2]University of California San Diego Health System, La Jolla, CA, [3]San Diego Veterans Adminstration, La Jolla, CA.

Purpose
To describe an unusual case of an anaplastic lymphoma kinase (ALK)-positive anaplastic large cell lymphoma (ALCL) and highlight its multimodal imaging features and interdisciplinary approach to diagnosis and management. ALK(+) ALCL is a rare peripheral T-cell lymphoma, accounting for approximately 3% of adult nonHodgkin lymphomas (NHL). To the best of our knowledge, this is the first report in which the presentation was an aggressive mass involving upper nasal cavity and anterior skull base.
Case Report
A 28-year-old Asian female presented with a three-month history of nasal congestion culminating in epistaxis. Physical examination was notable for a tissue mass obstructing nasal cavity and the sphenoid sinus. CT and MR imaging revealed a lesion primarily involving the upper nasal cavity extending intracranially through the cribriform plates into the anterior cranial fossa. Preoperative biopsy of the mass proved to be an ALK(+) ALCL based on histological and immunohistochemical profiles, thus obviating need for invasive surgical resection. The tumor mass shrank significantly after two cycles of chemotherapy supplemented with radiation therapy. The patient achieved clinical remission and remained neurologically stable throughout the treatment.
Imaging Findings
MR imaging of the orbital and nasal region demonstrated a homogenous and well-defined mass, with mild homogenous enhancement and mild restricted diffusion, expanding and filling both nasal cavities and extending intracranially through the cribriform plates, with thick dural enhancement, as well as extension through the clivus into the prepontine cistern. The mass encased the right cavernous carotid artery in the cavernous sinus. There was expansile remodeling of the nasal cavity, with lateral deviation of the medial orbital walls with mass effect on the lateral rectus muscles and compression of the orbital apices and intra-orbital optic nerves, likely contributing to the patient's lack of vision in the left eye. Pathologically enlarged right retropharyngeal lymph node with conspicuous left retropharyngeal lymph nodes as well as upper level IB/II lymph nodes, were compatible with either a typical pattern of esthesioneuroblastoma nodal metastases or lymphoma. Maxillofacial CT scan confirmed the MR imaging findings and bony erosion of the anterior clivus, bilateral medial sphenoid bones, and left clinoid process. Although the constellation of tumor location, characteristics of radiologic findings as well as the pattern of bony and regional lymph node involvement is helpful in narrowing down the differential diagnosis to lymphoma or ethesioblastoma, the clinical management of these entities is dramatically different, and biopsy is required for definitive diagnosis to guide management.
Summary
To our best knowledge, this is the first case of an ALK(+) ALCL that presented as an aggressive upper nasal cavity and anterior skull base lesion. This case highlights the importance of multimodality approaches including preoperative imaging and tissue biopsy for definitive diagnosis in order to optimize treatment options and achieve best clinical outcome.

Inflammatory Pseudotumors of the Head and Neck: A Pictorial Review

Koohi, Y.·Raghavan, P.
University of Virginia Health System
Charlottesville, VA.

Purpose
Inflammatory pseudotumor (IPT) is a nonneoplastic process, consisting of inflammatory cells with a variable fibrous response, and can arise in almost any organ, most frequently involving the lungs, abdominal organs and orbits. Inflammatory pseudotumors can mimic a malignant tumor both radiologically and clinically. Inflammatory pseudotumors in the head and neck region most frequently involve the orbit, with sinonasal involvement being relatively rare. The purpose of this exhibit is to present the imaging findings of inflammatory pseudotumors of the head and neck on CT and MRI, utilizing a variety of cases from our institution. Several of the presented cases involve the maxillary sinus, where we have noted distinct bony changes of the maxillary antrum. Pathologic findings in several of these cases demonstrate borderline increased IgG4 positive plasma cells, and these lesions may in fact represent IgG4-related sclerosing lesions.
Case Report
A number of cases will be presented, including a 20-year-old male with left medial orbital mass and left maxillary sinus mass, with biopsy of both lesions revealing fibrosis and chronic inflammation with borderline increased IgG4 positive plasma cells in the orbital lesion. A 45-year-old female presented with a right medial orbital mass and right maxillary sinus mass. Biopsy of the maxillary sinus mass revealed sclerosing inflammatory lesion with question of IgG4-related sclerosing lesion. A 35-year-old female presented with a left maxillary and left buccal space lesion. Biopsy of the maxillary lesion showed tumefactive fibroinflammatory lesion. A 10-year-old female presented with left nasal cavity and left orbital mass. Pathology revealed inflammatory myofibroblastic tumor.
Imaging Findings
The presented cases with maxillary sinus involvement all show distinct bony changes of the maxillary antrum, with thickened, sclerotic bone on CT. MR imaging followup in several patients showed hypointense T2 signal of the soft tissue components, characteristic for fibrous-type tumors. Interestingly, one of the presented patients with maxillary sinus involvement also had unilateral pachymeningeal enhancement, thought to be related to idiopathic hypertrophic pachymeningitis. This entity may in fact represent central nervous system involvement with IgG4-related sclerosing disease.
Summary
Inflammatory pseudotumor is still a poorly understood entity and has many synonyms. Recently it has been proposed that IgG4-related sclerosing lesions may have been described previously as inflammatory pseudotumors. Treatment with corticosteroids represents first line treatment for inflammatory pseudotumors.

Is That Just a Nasal Polyp? Or Is That a Meningoencephalocele Extending Through the Frontal Sinus?

Krishnan, A.·Al-Jaber, A.·Zakalik, K.·Rontal, D.
William Beaumont Hospital
Royal Oak, MI.

Purpose
Nasal polyps are common findings both clinically and on imaging. The predominant fluid nature of these lesions can be well seen on both MRI and on CT. Anterior skull-based cephaloceles can rarely present as intranasal masses. It is even rarer to find a meningocele traversing the frontal sinus drainage pathway into the nasal cavity and then proceeding into the nasopharynx, thereby mimicking a frontal sinonasal polyp.
Case Report
A 60-year-old female patient with a prolonged history of nasal stuffiness and sinusitis was scheduled for an endoscopic sinus surgery. Outside sinus CT had demonstrated a long polypoid structure in the nasal cavity extending into the nasopharynx. Fortunately, in the preoperative area, the images were reviewed with radiology and concern was raised for an intracranial abnormality. The surgery was rescheduled. After review of multiple head MRIs, a diagnosis was made and a combined approach by ENT and neurosurgery to extract both the nasal mass and repair the frontal sinus and frontal lobe abnormality was adopted. Intraoperative pictures documenting the surgery also were obtained.
Imaging Findings
Prior head MRI images demonstrated an irregular inferior frontal lobe indenting the frontal sinus through a defect in the posterior wall of the sinus. Subsequent studies revealed gradual increase in the size of the frontal sinus encephalocele that extended further inferiorly in the frontal sinus. At its distal aspect, a fluid-filled structure was seen exiting the sinus into the nasal cavity. The final MRI and CT obtained before surgery demonstrated a long fluid-filled structure in the nasal cavity extending from the frontal sinus into the posterior choana and finally into the nasopharynx. As the encephalocele portion itself was small and restricted to the frontal sinus, it was this meningocele portion that initially had been thought to represent a long sinonasal polyp.
Summary
Herniation of brain, meninges, and CSF via skull base defects can lead to masses that mimic nasal and sinus lesions. Accurate cross-sectional imaging, particularly

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

coronal MR images help separate intracranial lesions from primary nasal lesions by assessing for skull base defects. However, this particular case illustrates that the abnormality can occur even via the frontal sinus drainage pathway. In this case, the cephalocele gained access into the frontal sinus through a defect in the posterior wall of the sinus and then utilized the natural frontal sinus drainage pathway to extend into the nasal cavity and progressively grow. The sinusitis that the patient suffered may have been a post-obstructive process to this condition or even unrelated to this condition. In either case, a serious complication may have resulted if the large nasal lesion had not been tied to the frontal lobe abnormality. The value of closely evaluating the adjacent intracranial contents on sinus CT is critical to both the neuroradiologist and to the clinician and is depicted in this case.

Organized Hematoma of the Maxillary Sinus: 2.5-Year Followup

Fujita, A.[1]·Fujii, H.[1]·Sung, E.[2]·Sakai, O.[2]·Sugimoto, H.[1]
[1]Jichi Medical University, School of Medicine, Shimotsuke, JAPAN, [2]Boston University, Boston Medical Center, Boston, MA.

Purpose
Treatment for nasopharyngeal carcinoma.
Case Report
A 72-year-old male presented with nasal obstruction and pharyngeal pain. He was diagnosed with a large nasopharyngeal carcinoma, and initial CT and MR imaging incidentally found a mass-like lesion in the right maxillary. Treatment for nasopharyngeal carcinoma was prioritized and the patient underwent chemoradiation therapy, without intervention to the right maxillary sinus lesion. After completion of the treatment for nasopharyngeal carcinoma, he was imaged by MRI periodically for surveillance. The maxillary sinus lesion showed gradual increase in size, and the patient suffered from epistaxis. He underwent endoscopic sinus surgery 2.5 years after the initial diagnosis of the maxillary sinus lesion, and the histopathologic diagnosis of organized hematoma of the maxillary sinus was obtained.
Imaging Findings
The mass-like lesion of the right maxillary sinus showed heterogeneous signal with peripheral low signal rim on T2-weighted images. Postcontrast T1-weighted images showed multinodular marked enhancement within the lesion corresponding to areas of high signal intensity on T2-weighted images. The surveillance MR studies demonstrated gradual increase in size of the lesion, and CT demonstrated progressive osseous erosion/destruction of the sinus wall, as well as calcifications. Histopathologic specimen confirmed an organized hematoma, and demonstrated vascular rich components which corresponded to areas of high T2 signal and avid enhancement.
Summary
Organized hematoma of the maxillary sinus is a rare benign condition, which is often difficult to differentiate from malignancies. Our case report demonstrates the natural progression of the organized hematoma over the course of 2.5 years, where it was seen to gradually increase in size and result in osseous destruction. Given this progression of disease when left untreated, elective surgery should be considered for definitive management of organized hematoma of the maxillary sinus.

KEYWORDS: CT, MR imaging, organized hematoma

Extramedullary Hematopoiesis of the Paranasal Sinuses Associated with Moyamoya Syndrome in Sickle Cell Disease

Ozgür, A.·Kara, E.·Çabuk, G.·Unal, S.·Nass Duce, M.
Mersin University
Mersin, TURKEY.

Purpose
To present magnetic resonance imaging (MRI) and diffusion-weighted imaging (DWI) findings of extramedullary hematopoiesis (EMH) of the paranasal sinuses in a patient with sickle cell disease who has concomitant moyamoya syndrome.
Case Report
A 10-year-old male with known sickle cell disease was evaluated for headache with cerebral MRI and DWI.
Imaging Findings
Cerebral MRI revealed findings consistent with moyamoya such as tapering of both distal internal carotid arteries, collateral vessels within the ambient cisterns and engorged pial vessels causing typical "ivy sign". In addition; homogeneous soft tissue masses filling the entire cavities of both maxillary and sphenoidal sinuses were detected. The masses demonstrated signal intensity similiar to those of red marrow within the craniofacial bony structures on all pulse sequences. Diffusion-weighted imaging showed restricted diffusion within the masses and craniofacial bone marrow with similiar signal intensity and ADC values. Extramedullary hematopoiesis was the final diagnosis on the basis of these imaging findings.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Summary
Extramedullary hematopoiesis occurs in chronic anemic conditions as a result of increased need for blood production. It commonly is seen in spleen, liver and lymph nodes. Involvement of paranasal sinuses is a rare entity with only a few case reports in the literature. To our knowledge this is the first report of EMH of the paranasal sinuses associated with moyamoya syndrome in sickle cell disease although it seems to be a coincidental finding. Diagnosis of EMH should be considered in the presence of a homogeneous soft tissue mass arising from the paranasal sinus if the mass and the intramedullary red marrow have similiar signal intensity and enhancement pattern.

Pressurized Rapid Sequence Digital Subtraction Sialography for Characterizing Salivary Ductal Injury and Sialocele Formation

Horsburgh, A.[1,2]·Antoun, N.[1]·Massoud, T. F.[1,3]
[1]Addenbrooke's Hospital, Cambridge, UNITED KINGDOM,
[2]Queen's Hospital, Romford, UNITED KINGDOM,
[3]University of Cambridge, Cambridge, UNITED KINGDOM.

Purpose
A sialocele is a subcutaneous cavity with an inflammatory pseudo capsule, containing saliva that accumulates following continuous secretion with no adequate drainage. Sialoceles occur secondary to trauma, infection or as iatrogenic complications in up to 10% of partial superficial parotidectomies. Van Sickles classified ductal injuries into three types: Type A: Intraglandular (proximal to masseter). Type B: Ductal injury (over masseter). Type C: Ductal injury (distal to masseter). Failure to distinguish between these different subtypes of parotid ductal injuries can lead to inappropriate management and increased risk of long-term complications. The imaging of sialoceles and the accurate localization of ductal injuries can be complex, and includes the use of sialography, ultrasonography, CT and MRI. We present a patient who suffered damage to Stenson's duct following a partial parotidectomy. This case is unusual as iatrogenic injuries to Stensen's duct after parotidectomy are much less common than those occurring to intraglandular ducts. We found that by using a modified digital subtraction sialography technique we were able to accurately demonstrate the location of the salivary duct injury.
Case Report
A 26-year-old male underwent an apparently uneventful superficial parotidectomy for a benign myoepithelial adenoma of the left accessory parotid gland. Following surgery he noticed a recurrent postprandial painless and fluctuant swelling at the left angle of mandible region. A sialogram at this time using a pressurized rapid sequence digital subtraction showed significant extravasation of contrast medium due to a lacerated proximal main parotid duct into a large sialocele confirming the presence of an iatrogenic Van Sickles type B injury. This was managed conservatively by regular aspirations and pressure bandages every few days for a month, at the end of which the swelling subsided.
Imaging Findings
An initial attempted parotid sialogram using a standard gentle injection of contrast medium was unhelpful in that there was an arrest of the column of contrast in mid-duct. A slightly more forceful injection revealed a slow extra-luminal trickle of contrast medium in the immediate vicinity of the duct occlusion, which suggested a likely ductal injury, but its relation to the mandibular swelling was still not apparent. A more pressurized injection concurrent with digital subtraction images at 3 frames/second demonstrated a significant extravasation of contrast medium due to a postsurgical lacerated main parotid duct. The contrast medium jetted into a large multiloculated sialocele consisting of two locules, each measuring 6 cm in size, extending laterally into the subcutaneous tissues at the left angle of the mandible.
Summary
Failure to distinguish different subtypes of parotid ductal injuries can lead to suboptimal clinical management. Sialography is best used in cases where the ductal injury may have been overlooked resulting in sialocele formation. Sialographic technique normally requires gentle injection of contrast medium so as not to cause ductal injury or excessive acinarization of the salivary gland. However, this case illustrates the use of pressurized sialography as a useful method for locating and characterizing the site of duct injury, which may not be appreciated easily on conventional sialography or cross-sectional imaging.

Endovascular Treatment of an Iatrogenic Carotid-Cavernous Fistula with Pseudoaneurysm after Trans-Sphenoidal Pituitary Resection

Murph, D.·Lankford, D.·Chaljub, G.·von Ritschl, R.
University of Texas Medical Branch
Galveston, TX.

Purpose
Endovascular stent-assisted coil embolization utilizing Neuroform stent and Guglielmi detachable coils provided a safe and effective treatment of an iatrogenic carotid-cavernous fistula with pseudoaneurysm after trans-sphenoidal pituitary resection.
Case Report
A 35-year-old female with pituitary macroadenoma presented with excessive bleeding during trans-sphenoidal surgery at the lateral resection margin. Right cavernous internal carotid artery injury was suspected. Subsequent neuroangiography revealed a medial 6 mm pseudoaneurysm and early filling of the superior opthalmic vein suggestive of a carotid-cavernous fistula. A Neuroform stent was placed across the pseudoaneurysm neck with subsequent Guglielmi detachable coil embolization. Follow-up carotid angiography demonstrated successful pseudoaneurysm embolization.
Imaging Findings
Digital subtraction angiography, right ICA (Day 1): A focal irregularity was present at the anterior and medial aspect of the right internal carotid artery at its cavernous portion. This may have represented mild vasospasm or intimal injury at this portion of the artery that lay in close proximity to the surgical area. No active bleeding was seen at this time. Digital subtraction angiography, right ICA (Day 2): The right internal carotid artery was patent with expected branching intracranially. A medial 6 mm pseudoaneurysm had developed since the previous exam. In addition, early filling of the superior opthalmic vein suggested a carotid-cavernous fistula. Neurointervention: A 6 French guiding catheter was placed into the proximal right internal carotid artery. A 4.5 x 20 mm Neuroform stent then was placed across the pseudoaneurysm neck. A microwire was left in place, over which an SL-10 angled microcatheter was advanced into the pseudoaneurysm. Guglielmi detachable coils (1-3 x 6; 1-2 x 3; 2-2 x 1) were placed into the pseudoaneurysm. Subsequent angiographic runs showed minimal residual lumen and significant improvement of the carotid-cavernous fistula with only trace filling. Digital subtraction angiography, Right ICA, follow up: Successful right internal carotid artery pseudoaneurysm embolization without significant residual lumen was noted. The right ICA stent remained patent with minimal narrowing of the lumen. No residual carotid-cavernous fistula was identified.

Summary
Pseudoaneurysm formation in the cavernous portion of the ICA during trans-sphenoidal pituitary resection is a rarely reported complication with significant morbidity and mortality. With stent-assisted coil embolization using Neuroform stent and Guglielmi detachable coils, complete obliteration of an iatrogenic pseudoaneurysm was attained as well as complete resolution of its associated carotid-cavernous fistula.

Endovascular Treatment of a Symptomatic Dissecting Vertebral Artery Pseudoaneurysm after Chiropractic Manipulation

Murph, D.·Tran, B.·Lankford, D.·Chaljub, G.·von Ritschl, R.
University of Texas Medical Branch
Galveston, TX.

Purpose
Dissecting pseudoaneurysm of the extracranial vertebral

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

artery is an injury that can be sustained by trauma to the cervical spine. Endovascular techniques such as stent-assisted coil embolization can be utilized to treat these traumatic injuries in symptomatic patients.
Case Report
History: A 25-year-old female presented after chiropractic manipulation with severe neck pain. She was later found to be aphasic and unable to move extremities. She was admitted to the trauma service and was given methylprednisolone 30mg/kg. Physical exam: Responsive, alert and oriented X3 with GCS of 15, Pupils equal, round, reactive to light, Nystagmus and left lateral gaze, 2/5 strength in BLE, 4/5 strength in BUE, Absent Babinski sign, Sensation was intact throughout, Rectal tone was normal.
Imaging Findings
MR imaging brain with and with contrast: Multiple small lesions were scattered throughout the cerebellum (more prominent on the left), including the cerebellar gray matter, and also are present within the left pons and left medulla. The lesions had increased intensity on T2-weighted and FLAIR, and were hypointense on T1 with no enhancement on the postcontrast images. These lesions were hyperintense on diffusion-weighted imaging and hypointense on the ADC map. Digital subtraction angiography: A dissection involving the distal extracranial segment of the left vertebral artery resulted in severe flow-limiting stenosis of this artery. This extended from C3 to C1 level. A 6 mm pseudoaneurysm was present at C1/C2 level in relation to this dissection.
Neurointervention: GDC embolization of left vertebral artery dissecting pseudoaneurysm: Two 4.5 x 30 mm Neuroform stents were deployed across the neck of the pseudoaneurysm with jailed-microcatheter technique. The aneurysm was subsequently GDC embolized. Follow-up angiography showed good flow and expected intracranial branching of the left vertebral artery. Digital subtraction angiography, 2-year followup: The left vertebral artery demonstrated expected flow intracranially with good filling of the posterior circulation. The pseudoaneurysm at the level of C1/C2 remained coiled and the (2) stents remained patent. A trivial amount of residual was noted in the proximal neck of the pseudoaneurysm; however, this was markedly improved since previous study. There were no major branch vessel occlusion or significant stenosis.

Summary
Dissecting pseudoaneurysm of the extracranial vertebral artery is a well described injury that can be complicated by significant stenosis as well embolic infarcts. We present the case of a symptomatic patient after chiropractic manipulation, complicated by findings of multiple posterior fossa infarcts, that was amenable to endovascular therapy by stent-assisted coiling.

Staged Endovascular Management of a Complex Intraorbital Arteriovenous Malformation

Metwalli, Z. A.·Yevich, S. M.·Lee, S. R.·Benndorf, G.
Baylor College of Medicine
Houston, TX.

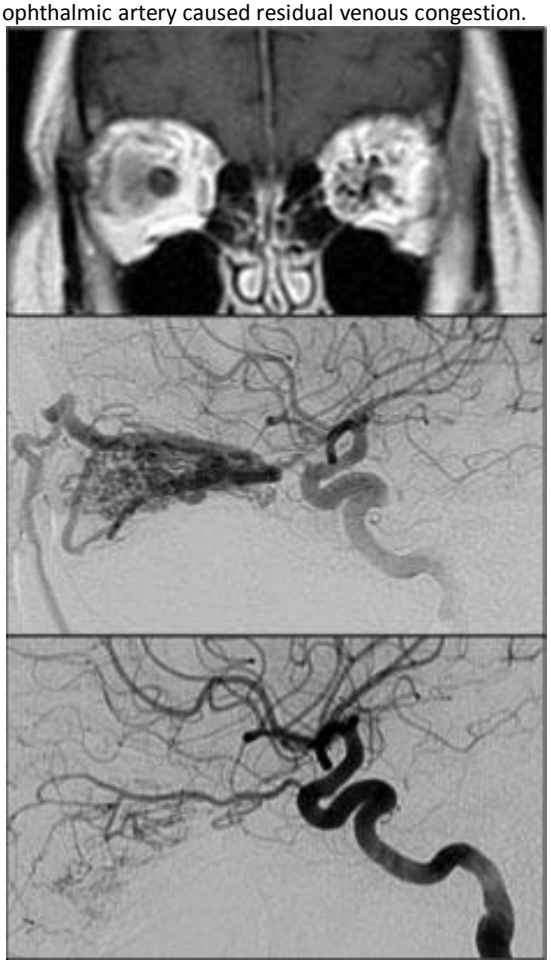
Purpose
Orbital arteriovenous malformations (AVM) are often part of more extensive intracranial or facial vascular malformations. They can cause exophthalmos, conjunctival injection, visual problems, and rarely intraorbital hemorrhage. Management can be challenging and consists of surgical removal, endovascular treatment, or a combination thereof. We report our experience with a patient that presented with a complex intraorbital AVM successfully treated with staged transarterial embolization.
Case Report
A 56-year-old woman with a past medical history of smoking, alcoholic cirrhosis, and thrombocytopenia presented with progressive left exophthalmos and conjunctival injection of several months duration. Imaging revealed a high-flow intraorbital AVM. Over the next year, the patient reported subjective worsening in diplopia, exophthalmos and conjunctival injection. On clinical exam, there was mild proptosis, mild afferent pupillary defect, mild hyperemia, normal vision, and elevated intraocular pressure (25 mmHg). Staged embolization procedures over

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

the course of two years were performed and resulted in successful endovascular occlusion of the AVM. Intraocular pressure normalized (14mmHg) and conjunctival injection and exophthalmos improved. Two weeks after initial treatment, the patient developed progressive vision loss due to central retinal vein occlusion. Residual acuity was 20/100 and remained unchanged during post-treatment period.

Imaging Findings

MR imaging and CTA revealed an intraconal orbital vascular mass adjacent to the region of the medial rectus muscle. Digital subtraction angiography revealed a high-flow intraorbital AVM with a nidus supplied by muscular branches of the ophthalmic artery and drained primarily via the superior ophthalmic vein (SOV). Initial intranidal glue (NBCA) injections resulted in 40% occlusion with subsequent progressive occlusion to 80%. Decrease of the arteriovenous shunting lead to unexpected thrombosis of the SOV necessitating heparinization, and shrinkage of two flow-related intraorbital aneurysms. Two additional selective embolization procedures within a 12-month period resulted in complete occlusion of the AVM. An additional small dural AV shunt arising from the proximal ophthalmic artery caused residual venous congestion.



Summary

Orbital AVMs are rare lesions and pose a challenge for treatment. Although surgical resection by fronto-ortibal craniotomy is the conventional treatment, a more comprehensive multidisciplinary approach, which involves ophthalmology, neurosurgery, and neurointerventional radiology allows for optimal management of these complex and rare lesions. Endovascular treatment of intraorbital AVMs can be performed successfully in selected patients either preoperatively or as a primary therapy. We suggest a staged approach to endovascular occlusion of the AVM. However, patients must be counseled regarding the risks of SOV thrombosis worsening of their vision. Concomitant anticoagulation is advised.

Glue Embolization of Pelvic Varices in a Patient with Iliac Vein Compression Syndrome Prior to Sacral Chordoma Resection

Scott, C. J.·Heran, M. K. S.·Dea, N.·McNeill, G. J.
Vancouver General Hospital
Vancouver, BC, CANADA.

Purpose

To present a unique case of successful glue embolization of pelvic varices prior to en bloc sacral chordoma resection.

Case Report

A 69-year-old male with sacral chordoma. The patient had a co-existing right common iliac artery aneurysm with compression of the left common iliac vein leading to extensive presacral venous collaterals. These varices significantly increased perioperative bleeding risk and threatened the ability to perform an en bloc resection.

Imaging Findings

Transvenous N-butyl-2-cyanoacrylate (Histocryl) embolization of presacral varices was performed successfully via right common femoral venous approach. Surgical excision subsequently was achieved with minimal intraoperative blood loss and without further complications.

Summary

Preoperative venous embolization is a novel treatment option in patients with presacral varices prior to sacral tumor resection.

KEYWORDS: Chordoma, Venous obstruction, Embolization

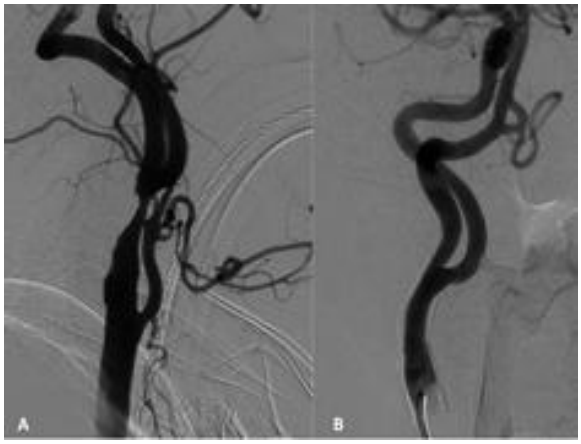
Double Embolic Protection during Carotid Artery Stenting with Persistent Hypoglossal Artery

Hou, S.·Silva, C. F.·Kuhn, A. L.·Wakhloo, A. K.
University of Masschusetts Medical Center
Worcester, MA.

Purpose
A persistent hypoglossal artery (PHA) is an extremely rare embryonic carotid-basilar artery anastomosis. Although its presence is usually asymptomatic, it may complicate surgical and interventional procedures used in the treatment of carotid disease. Here we present a highly unique case of carotid artery stenosis with extension into a PHA. Additionally, a novel approach in treating this lesion was employed by stenting and angioplasty while protecting both the anterior and posterior cerebral circulations.
Case Report
A 63-year-old woman presented with a 13-year history of intermittent numbness and weakness involving the left upper extremities and a seven-year history of right-sided pulsatile tinnitus, but her symptoms had increased in frequency prior to her hospitalization. The patient was neurologically intact upon admission. Carotid artery stenting was seen as more technically feasible and safer because it allowed for protection of the anterior and posterior circulations using distal protection devices. The patient tolerated the procedure well, and the hospital course was uneventful. All symptoms of left upper extremity paresthesia and auditory pulsations had resolved completely postprocedure, and the patient was discharged home the next day.
Imaging Findings
Computed tomography angiograms (CTA) of the head and neck and digital subtraction angiography (DSA) (Figure 1A) showed a calcified atherosclerotic plaque involving the proximal right ICA leading to 75% stenosis. The stenosis was just proximal to the origin of the PHA, which arose from the ICA at C2 vertebral body level and continued to the intracranial cavity anterior to the right occipital condyle. The PHA then merged with the left vertebral artery to form the basilar artery, and was the dominant supply to the posterior circulation. At 6-month followup DSA (Figure 1B) the stented vessel segment remained patent without any significant intimal hyperplasia. The patient has been asymptomatic and has not experienced any auditory bruit since the intervention.



Summary
Carotid artery stenting involving the ICA and origin of the PHA presents a challenge for distal embolic protection (i.e., treatment can be complicated by the necessity to protect both the PHA and the ICA during the intervention). We suggest jailing of one of the protection devices during stent placement enabling simultaneous protection of both the anterior and posterior cerebral circulations.

Retrieval of a Fractured Coil Using the Solitaire FR Revascularization Device

Saad, A. F.[1]·Winters, R. R.[2]·Haithcock, J. A.[1]·Layton, K. F.[1]
[1]Baylor University Medical Center, Dallas, TX, [2]Texas Tech University Health Sciences Center, Lubbock, TX.

Purpose
The purpose of this excerpta is to describe the novel use of the Solitaire FR revascularization device (Ev3, Irvine, CA, USA) in the retrieval of a fractured coil.
Case Report
A 52-year-old woman with multiple incidentally discovered cerebral aneurysms was referred for endovascular treatment. During the coiling of a right middle cerebral artery (MCA) bifurcation aneurysm a coil was partially deployed with unsatisfactory placement. During subsequent retraction of the coil for repositioning the coil fractured and was unable to be withdrawn, lodging in the M1 segment of the MCA (Figure 1). Attempts were made to retrieve the coil fragment using a microsnare device without success. A Solitaire FR revascularization device then was deployed in the distal M1 segment with successful engagement of the coil fragment and subsequent successful retrieval. The patient's additional right posterior communicating artery origin aneurysm was coiled successfully, and she awoke without neurologic deficit and was discharged home the next day.
Imaging Findings

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

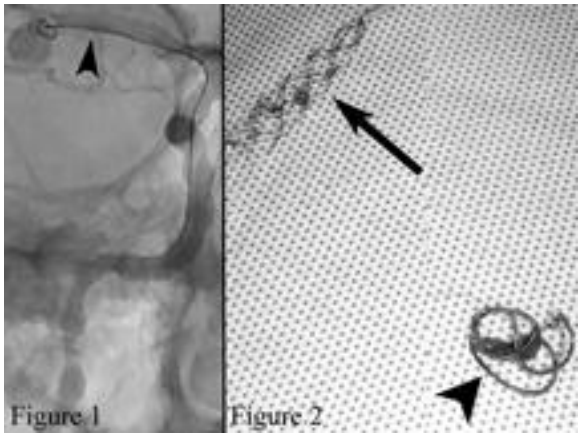

Figure 1: Unsubtracted right internal carotid artery (ICA) injection demonstrates fractured coil (arrowhead) with tip situated within the MCA bifurcation aneurysm in addition to diffuse catheter induced spasm. Figure 2: Coil fragment (arrowhead) is seen following successful retrieval with the Solitaire device (arrow).

Summary

The displacement or less frequent fracture of coils used in the treatment of cerebral aneurysms is an uncommon complication that can have potentially dire results. The use of snare devices has been advocated with favorable results; however in cases of technical failure alternative methods are limited. Reports have shown efficacy of additional devices such as the Alligator retriever (Ev3, Irvine, CA, USA) and MERCI retrieval device (Concentric Medical, Mountain View, CA, USA). We present a case of coil fracture with failure of subsequent microsnare retrieval attempts, followed by successful retrieval using the Solitaire FR revascularization device. The Solitaire stent-retriever, although designed for clot retrieval, may be an additional viable option in the retrieval of fractured or displaced coils. Further experience will be necessary to demonstrate consistent efficacy and safety.

Neuroradiologic Findings in a Patient with Wolfram Syndrome: A Case Report

Leake, D. R.
Austin Radiological Association
Austin, TX.

Purpose

Wolfram syndrome is a rare autosomal recessive disorder first described in 1938 by Wolfram and Wagener. The disease consists of diabetes insipidus, diabetes mellitus, optic atrophy, and deafness (acronym DIDMOAD). Wolfram syndrome is caused by WFS1 gene mutation leading to dysfunction of homeostasis of the endoplasmic reticulum. Only a few cases have been described in the radiology literature. Neuroradiologic findings include optic nerve/chiasm atrophy, absent or reduced normal pituitary bright spot on T1, cerebellar and brainstem atrophy, and abnormal T2 hyperintensity in the pons, peritrigonal white matter, and frontal/occipital cortex.

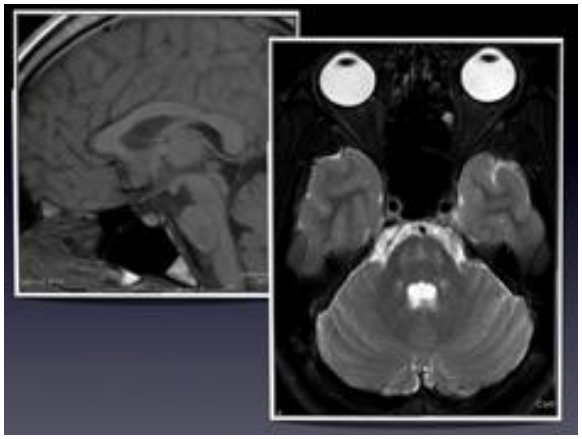
Case Report

The patient is an 18-year-old male diagnosed with optic atrophy and diabetes mellitus at age four. He presented with a large midline pelvic mass. Ultrasound exam demonstrated bladder distension and bilateral hydronephrosis. Subsequently, patient was admitted to the hospital, and workup revealed polyuria/diabetes insipidus in addition to the patient's known diabetes mellitus/optic atrophy. No deafness was noted. Genetic Testing of Wolfram Syndrome 1/Wolframin, WFS1 Sequencing was confirmatory for Wolfram syndrome.

Image Findings

Neuroradiologic findings include bilateral optic nerve and chiasm atrophy, absence of posterior pituitary bright spot on T1, and abnormal T2 hyperintensity of the pons. Septum pellucidum was present.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Summary
The purpose of this report was to describe the neuroradiologic findings of a rare case of Wolfram syndrome. Knowledge of the clinical and neuroradiologic findings may lead to earlier diagnosis and treatment of this disease.

KEYWORDS: Metabolic, Optic chiasm, Wolfram Syndrome

EE-62

An Unusual Case of Progressive Multifocal Leukoencephalopathy in a Child with Acute Lymphocytic Leukemia

Mair, Y. H.·Adas, R. A. A.·Almehdar, A. S.
King Abdul-Aziz Medical City
Jeddah, SAUDI ARABIA.

Purpose
To present a case of progressive multifocal leukoencephalopathy (PML) in a child diagnosed with acute lymphocytic leukemia (ALL) five months prior.
Case Report
A three-year-old girl with a known case of ALL presented to the clinic three days after intrathecal injection of methotrexate with right-sided clonic jerks and mouth twitching. A CT scan and an MRI of the brain were performed. The imaging differential diagnosis suggested changes of chemotherapy toxicity versus encephalitis. During her first few days in the hospital, the patient continued to have repeated attacks of seizure with deterioration in the level of consciousness dropping her GCS from 15/15 to 3/15 within a course of three days. She was intubated and shifted to the PICU. During her PICU admission, she developed left-sided seizures and was put on combined antiepileptic medications. She also developed severe hyponatremia which gradually was corrected. Initial CSF analysis was negative and blood and urine cultures were unremarkable. Attempts to treat methotrexate toxicity were ineffective and another MRI was requested. The second MRI showed progression of the lesions with interval development of bilateral abnormalities. The diagnosis of PML was suspected by the neuroradiologist and a CD4 count was requested. A second CSF sample was acquired for JC virus PCR analysis. The CD4 count was < 80 cells/mm3. Although the CSF JC virus PCR was negative, the diagnosis of PML was made. During the following weeks the patient continued to decline demonstrating uncontrollable seizures and enlarging lesions on serial MR studies. She died in the PICU 54 days after admission.
Imaging Findings
The initial CT scan of the brain demonstrated a large left basal ganglia and subinsular hypodensity, with no significant mass effect. The MRI done afterwards showed an ill-defined hyperintense FLAIR change in the left basal ganglia with no diffusion restriction or enhancement. The MRI performed six days later showed marked enlargement of the central gray and white matter lesions without mass effect, enhancement or diffusion restriction. Spectroscopy demonstrated low NAA levels within the lesions compared to unaffected areas. Newer lesions in the brain stem, cerebellum and subcortical white matter were developing over the course of her hospital stay.
Summary
Progressive multifocal leukoencephalopathy is a severe lethal form of demyelinating disease caused by reactivation of the JC virus due to severe immunodeficiency. Very few cases have been reported in children and often were associated with HIV. MR imaging typically shows areas of asymmetric high signal intensity in the periventricular and subcortical white matter. The lack of mass effect, enhancement and diffusion restriction is often a helpful imaging clue. The clinical picture along with the imaging and immunologic findings are often enough to diagnose PML. Knowledge of this entity and its possible occurrence in children is very important since early diagnosis may impact patient survival.

KEYWORDS: Leukemia, PML

Concurrent Spontaneous High-Flow Vertebral Arteriovenous Fistula and Reversal of Basilar Artery Flow in a Pediatric Patient: An Extremely Rare Entity

Honarmand, A. R.[1]·Soltanolkoltabi, M.[1]·Ansari, S. A.[1]·Rahman, O.[1]·Schoeneman, S. E.[2]·Hurley, M. C.[1]·Alden, T. D.[2]·Shaibani, A.[1]
[1]Northwestern University Feinberg School of Medicine, Chicago, IL, [2]Ann & Robert H. Lurie Children's Hospital of Chicago, Chicago, IL.

Purpose
High-flow vertebral artery arteriovenous fistula (VAVF) and concurrent steal from intracranial arteries or contralateral vertebral artery is a well known phenomenon; however, to the best of our knowledge, association with basilar artery (BA) steal in the pediatric population has not been reported. Our purpose is to describe a unique

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

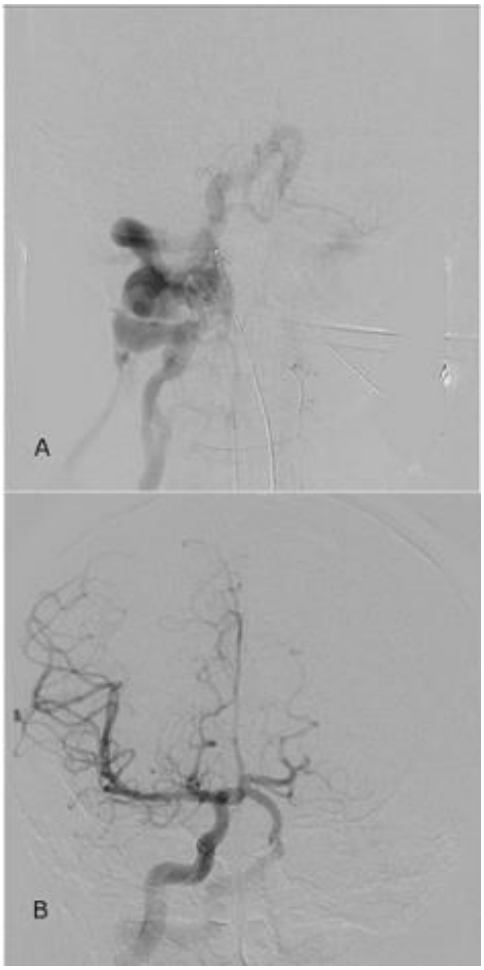
asymptomatic presentation of a spontaneous high-flow VAVF in a child associated with flow reversal in the BA treated with endovascular coil embolization.

Case Report

An 8-year-old boy presented to the emergency department with fever and lethargy. No relevant clinical signs or symptoms were noted except for a prominent palpable pulse on the right side of the neck. There was no history of trauma to the head and neck or connective tissue disorders.

Imaging Findings

Following primary MR imaging, digital subtraction angiography (DSA) demonstrated a high-flow AVF between the distal portion of the right cervical VA at the level of the proximal transverse foramen of C2, draining into a very large recipient paraspinous venous pouch. Significant enlargement of the right VA was observed at and above the level of the shunt with retrograde supply across the hypertrophied left VA and vertebrobasilar junction into the right VA V4 segment. Selective DSA also demonstrated an enlarged right deep cervical artery supplying the AVF and an enlarged left costocervical trunk augmenting collateral supply to the left VA (Figure A). There was no antegrade visualization of the BA from either the vertebral or costocervical/thyrocervical injections, due to the significant steal towards the AVF. Right internal carotid DSA demonstrated reversal of flow in the BA via a large right posterior communicating artery (Figures B).



Summary

Reversal of BA flow is an uncommonly described entity and has been described in rare complicated cases of intracranial VA dissections, vertebrobasilar occlusions, giant cell arteritis, and bilateral subclavian steal phenomenon. It indicates both very high-flow arteriovenous shunting and patent posterior communicating arteries to compensate for vertebrobasilar insufficiency. Although reversed basilar flow has been associated with significant neurologic symptoms in patients suffering from subclavian steal phenomenon, it may be asymptomatic as in our case and emphasizes the robust collateral network often present in children. Understanding of complex AVF anatomy, controlled complete obliteration of the VAVF while preserving the parent VA, restoration of antegrade flow in the vertebrobasilar circulation, and strict hemodynamic and blood pressure monitoring are essential in order to obtain technical success and minimize complications.

Absence of a Cervical Nerve Root Mimicking Erb's Palsy in a Two-Month-Old Girl

Chung, M.[1]·Park, J.[1]·Valencia, H.[2]·Lefton, D.[1]·Grossman, J. A.[2]
[1]St. Luke's Roosevelt Hospital, New York, NY, [2]Miami Children's Hospital, Miami, FL.

Purpose
To report the importance of MRI techniques in the evaluation of an infant with a presumed upper brachial plexus injury that actually demonstrated congenital absence of a ventral cervical nerve root.
Case Report
A 4-month-old girl was seen to evaluate an upper plexus birth palsy. Noncontrast MRI at 10 months was performed and the standard T1- and T2-weighted sequences were obtained in multiple planes. Additionally, thin-section fast imaging employing steady state acquisition (FIESTA) T2-weighted images were acquired. The MRI demonstrated nonvisualization of the left C5 nerve root within the cal sac(Figure 1). There was no evidence of trauma, as evidenced by the absence of a pseudomeningocele, granulation tissue, or reparative neuroma formation. Additionally, there was no evidence of cervical disk herniation, spinal stenosis, or subluxation/dislocation of the humeral heads. Electrodiagnostic studies at 11 months of age failed to demonstrate evidence of a cervical root trauma lesion, but instead revealed lack of both denervation and reinnervation of C5 muscles with a lack of muscle fibers, consistent with the absence of ventral motor neurons. Surgical exploration at 15 months of age demonstrated no evidence of trauma and severe hypoplasia of C5 with minor underdevelopment of C6. Cortical sensory responses were absent with C5 stimulation but present with C6 stimulation. Since the surgery, limited recovery of upper trunk(C5-C6) motor function has occurred.

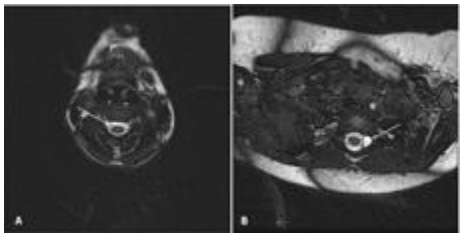

Figure. A. FIESTA sequence demonstrating nonvisualization of the ventral left C5 nerve root; arrow indicates normal ventral right C5 nerve root. B: FIESTA sequence demonstrating pseudomeningocele at the level of brachial plexus injury (arrow).
Imaging Findings
This case demonstrates a rare congenital abnormality that mimicked Erb's palsy clinically. The absence of the left C5 nerve root could be secondary to nerve root avulsion from birth trauma, but there was no associated pseudomeningocele, visible scar tissue, or reparative neuroma formation to corroborate this connection. The root absence was confirmed with electrodiagnostic studies and surgical exploration. Review of the literature shows no recorded cases demonstrating this type of congenital absence.
Summary
The case also demonstrates the importance of MRI in the preoperative workup. The FIESTA sequence is extremely useful in visualizing the individual cervical nerve roots and the pseudomeningocele, which is a key diagnostic feature of brachial plexus injury. The standard T1- and T2-weighted sequences are useful in detecting abnormal periscalene soft tissues on the side of injury. This tissue has been proven to correlate histologically with scar tissue and reparative neuromas.

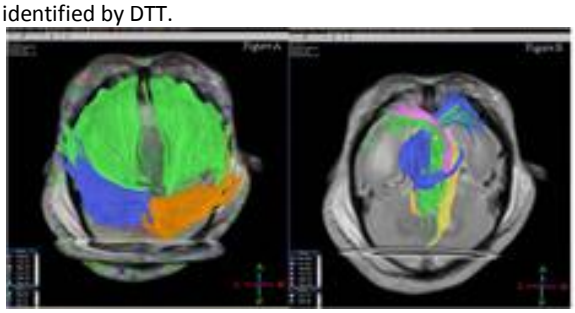
Diffusion Tensor Tractography for Understanding Complex Brain Fiber Connectivity in Holoprosencephaly: A Unique Case Presentation

Adapa, P.·White, M. L.·Keiper, M. D.·Zhang, Y.
University of Nebraska Medical Center
Omaha, NE.

Purpose
Holoprosencephaly is a disorder of abnormal or noncleavage of the cerebral hemispheres accompanied by midline structural abnormalities. We present a case of severe holoprosencephaly without a dorsal cyst. Diffusion tensor tractography (DTT) was performed and demonstrates marked white matter tract abnormalities in the brainstem, basal ganglia and cerebral hemispheres.
Case Report
A two-day-old full-term female neonate underwent conventional MRI of the brain along with diffusion tensor imaging due to intrauterine diagnosis of Sonic Hedgehog gene mutation, holoprosencephaly and facial anomalies. Family history was also positive for Sonic Hedgehog gene mutation and holoprosencephaly. Multiple intracranial abnormalities were identified on the MRI.
Imaging Findings
There was alobar holoprosencephaly with diffuse lissencephaly, large monoventricle, no dorsal cyst and minimal posterior midline cleavage. Fused midline deep gray nuclei without a third ventricle were seen. Deformed brainstem was present. Cerebellar hemispheres and fourth ventricle were grossly unremarkable. A single optic nerve originating from the brain bifurcated into two globes that were grossly malformed. Diffusion tensor tractography was performed which revealed abnormal anteroposterior hemispheric white matter fibers in anterior cerebral hemisphere with no evidence of crossing fibers (Figure A, green). In the posterior cerebral hemisphere the fibers were oriented more right to left and mostly terminated at the midline with a few posterior crossing fibers (Figure A,

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

orange and blue). In the brain stem (Figure B) no fibers extending cranial-caudal were identified. No definite corticospinal tracts were identified. Laterally in the fused brainstem and basal ganglia there were fibers running AP (Figure B, pink and blue) that demonstrated crossing which are of unknown origin but potentially represent corticospinal tracts. There was a midline group of fibers that might be the medial lemnisci running predominantly AP with some crossing identified (Figure B, green). Yellow fibers (Figure B) originated from the mono-optic nerve. Rudimentary middle cerebellar peduncles also were identified by DTT.



Summary
Diffusion tensor tractography helps in evaluating the complex brain fiber connectivity in subjects with holoprosencephaly. These findings may help with neurodevelopment assessment and prognostication that may otherwise not be available with conventional neuroimaging.

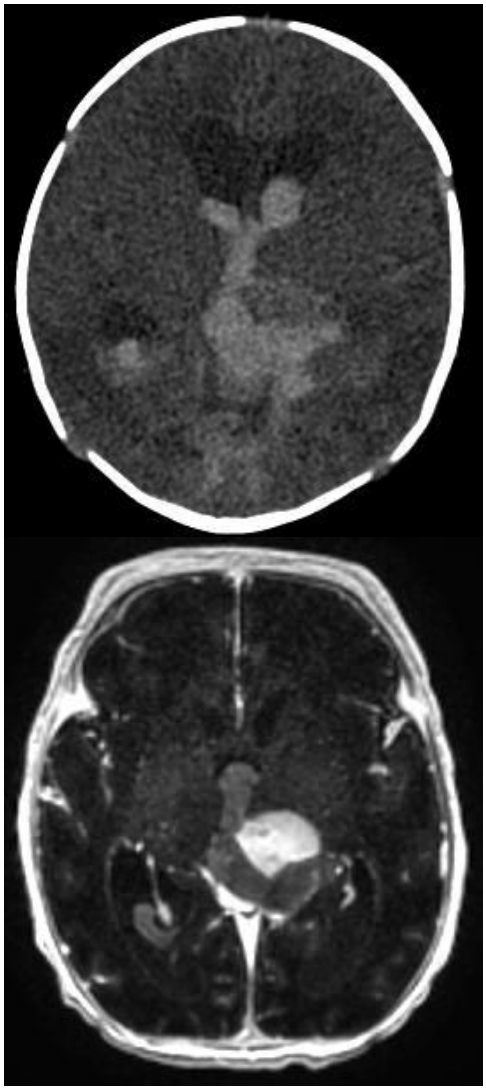
Term Newborn Found to Have Intraventricular Hemorrhage

Trinh, V.·Fong, C. L.
Kaiser Permanente Los Angeles Medical Center
Los Angeles, CA.

Purpose
Discuss the differential diagnosis of brain tumors found in the neonatal period. We present a rare case of neonatal atypical teratoid rhabdoid tumor (ATRT).
Case Report
One-day-old term newborn found to have intraventricular hemorrhage on ultrasound. A CT and MRI were ordered to evaluate for possible arteriovenous malformation.
Imaging Findings
Left thalamic enhancing mass with evidence of intraventricular hemorrhage and hydrocephalus. No calcifications noted on CT.



DDx of Neonatal Brain Tumors

Neuroepithelial	PNET and Glial tumors including Astrocytoma, GBM, Choroid plexus papilloma (atrium lateral ventricle), ependymoma
Germ Cell Tumor	Teratoma (coarse calcifications), germinoma
Others (less than 6%)	ATRT, ganglioglioma, medulloepithelioma, angioblastic meningioma

Summary
Neonatal brain tumors are described as tumors found in the first two months of life. The differential diagnosis of neonatal brain tumors primarily includes neuroepithelial

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

tumors and germ cell tumors. Atypical teratoid rhabdoid tumors (ATRT) generally have been described in infancy and young children with one case series showing a typical age range from four months to 15 years. We present a neonatal case of ATRT to be included in the differential diagnosis of a neonatal brain tumor. Most neonatal tumors will be difficult to differentiate on imaging alone; however certain tumors such as the potentially resectable choroid plexus papilloma typically seen in the atrium of the lateral ventricle or teratoma with coarse calcifications should be mentioned. Atypical teratoid rhabdoid tumor cannot be differentiated from other locally aggressive lesions such as PNET on imaging and the determination is made by specific immunohistochemical markers and by detection of genetic deletions and/or mutations.

Alveolar Soft Part Sarcoma: Adolescent Presenting with Headache and New Mediastinal Bruit

Schenning, R. C.·Vajtai, P. L.·Troxell, M. L.·Pollock, J. M.·Hopkins, K. L.
Oregon Health and Science University
Portland, OR.

Purpose
Alveolar soft part sarcoma (ASPS) is a rare soft tissue sarcoma occurring primarily in the second and third decades of life. Almost all cases arise in or adjacent to skeletal muscle, most often in the thigh and buttocks, and commonly have symptomatic metastasis in brain, lung, and bone at presentation. The purpose of this abstract is to illustrate the typical intracranial imaging features of ASPS metastases to the brain with a very unusual primary neoplasm arising in the mediastinum.
Case Report
A previously healthy 13-year-old girl presented with five-day history of headache unresponsive to nonsteroidal anti-inflammatory drugs. Physical exam was unremarkable except for a new mediastinal bruit on auscultation. Initial chest radiograph revealed a large left mediastinal mass, which on contrast-enhanced chest CT was seen to be hypervascular with large peripheral vessels and central necrosis. Numerous pulmonary nodules were present, which were pathology-proven metastatic ASPS. Subsequent neuroimaging workup consisted of a contrast-enhanced head CT and brain MRI with DSC perfusion and spectroscopy.
Imaging Findings
Contrast-enhanced head CT revealed a homogeneously enhancing left parietal mass measuring 3.3 cm x 3.0 cm x 3.7 cm, with large feeding arteries from the left middle cerebral artery. Circumferential vasogenic edema and mass effect on the left lateral ventricle were present. On MRI, the well circumscribed left parietal mass was minimally T1 hyperintense, T2 hyperintense, and homogeneously enhancing, with no evidence of necrosis, hemorrhage, or diffusion restriction. Large flow voids were present within the mass and radiating from its lateral margin. The mass demonstrated increased peripheral tumor blood volume and flow on DSC perfusion imaging. Single voxel MR spectroscopy revealed a highly elevated choline-to-creatine ratio, no lactate peak, and an undetectable NAA peak, consistent with a non-neuronal, non-necrotic neoplasm with high cell turnover.
Summary
The imaging appearance of both primary and metastatic ASPS reflects rich vascularity, with large intra and peritumoral vessels being a characteristic feature, regardless of imaging modality or anatomical location. Despite ASPS being rare, the diagnosis should be considered in adolescents and young adults when typical imaging features are present. In this case we present the typical intracranial imaging findings arising from an unreported primary mediastinal origin.

Pilomyxoid Astrocytoma: An Uncommon Tumor in an Atypical Location

Garger, A. V.·Anderson, R. C. E.·Needle, M.·Feldstein, N. A.·Garvin, J.·Filippi, C. G.·Millar, W. S.
Columbia University/New York Presbyterian Medical Center
New York, NY.

Purpose
To demonstrate the unusual MRI features of an exophytic pilomyxoid astrocytoma (PMA) arising from the medulla.
Case Report
A 4-year-old previously healthy girl was brought to a neurologist with a four-week history of increasing right-sided extremity weakness, tongue rolling when speaking, and left eyelid ptosis without headache or visual changes. She had experienced several episodes of emesis three weeks prior, which resolved. An MRI exam demonstrated a heterogeneous, exophytic, partly solid mass with significant cystic components emanating from the medulla. The initial differential based on MRI signal characteristics included pilocytic astrocytoma, ependymoma, hemangioblastoma, medulloblastoma, brainstem glioma or an atypical infection, since she recently had been exposed to a relative with tuberculosis. A PPD was placed, which was subsequently negative. Additional imaging of the spine demonstrated no evidence of metastatic dissemination. Biopsy/partial resection results demonstrated a low-grade glial neoplasm with features consistent with pilomyxoid astrocytoma. Further treatment with multiple cycles of chemotherapy resulted in a progressive decrease in the size of the mass and subjective improvement of right-sided weakness.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Imaging Findings

A well delineated, exophytic mass with solid and cystic components in the anterior medulla produced circumferential compression of the surrounding parenchyma, partial effacement of the 4th ventricle and posterior displacement of the brainstem and inferior vermis. After administration of gadolinium, the solid component demonstrated heterogeneous enhancement. There was no evidence of satellite or metastatic lesions.

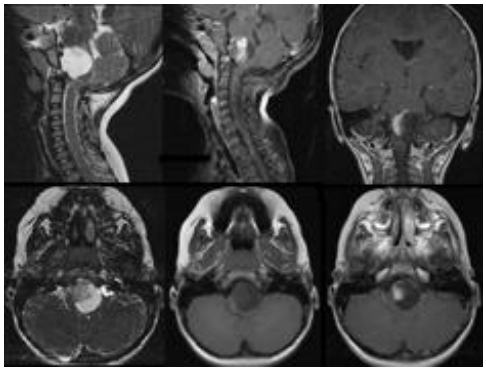

Figure 1: From left upper corner clockwise; sagittal T2; fat-sat sagittal T1C+; coronal T1 C+; axial T1 C+; axial T1 C-; axial T2

Summary

Pilomyxoid astrocytoma (PMA) was described initially as a variant of pilocytic astrocytoma in 1999, and subsequently recognized by the WHO as a distinct grade II tumor in 2007. Most reported cases of PMA are in the hypothalamus/optic chiasm or cerebellum. Less typical locations include the cerebrum , spinal cord and 4th ventricle. This case appears to be the first biopsy-proven primary occurrence of PMA in the medulla. Secondary metastatic involvement of the medulla was reported in only two prior cases. Pilomyxoid astrocytoma should always be considered in the differential diagnosis of posterior fossa masses.

Uncrossed Sensori-Motor Tracts: Horizontal Gaze Palsy with Progressive Scoliosis with Diffusion Tensor Imaging and Functional MR Imaging Evaluation

Seshadri, R.[1]·PS, B.[2]·Kulkarni, G. B.[2]·Upadhyay, N.[2]
[1]Sri Ramachandra Medical College, Chennai, INDIA,
[2]National Institute of Mental Health and Neurosciences, Bangalore, INDIA.

Purpose

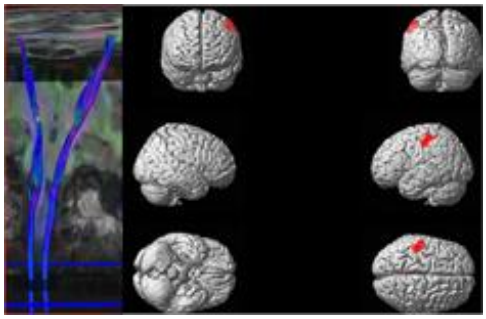
Contralateral control of the body by the cerebral hemispheres forms the basis of neurophysiologic functioning. Here we are presenting two unusual cases of defective neuronal wiring in the brainstem leading to ipsilateral control of the body by the cerebral hemispheres. Horizontal gaze palsy with progressive scoliosis (HGPPS) is a rare autosomal recessive disorder caused by defective ROBO-3 gene, leading to nondecussation of cortico-spinal tracts, posterior column-medial lemniscus tracts, medial longitudinal fasciculus and other commissural fibers in the rhombencephalon, causing congenital absence of conjugate horizontal eye movement and progressive scoliosis developing during childhood. Yet, neurologically, these patients are remarkably intact except for horizontal gaze palsy and progressive scoliosis. This suggests apparently normal sensori-motor integration although on the ipsilateral side of the body.

Case Reports

A 8-year-old boy born of consanguineous-marriage, presented with regression of language milestones following seizures for six months and right torticollis. A 14-year-old girl born of consanguineous marriage presented with delay in motor milestones and progressively increasing scoliosis. Both had horizontal gaze palsy, progressive scoliosis and right facial hemiatrophy. The boy also had torticollis.

Imaging Findings

MR imaging in both patients revealed brainstem hypoplasia, split pons, butterfly medulla, uncrossed sensori-motor axons on DTI (Figure A) and ipsilateral sensori-motor activation on fMRI studies (Figure B). On DTI, abnormalities were seen at the level of pons as well (absence of posterior strip of transverse pontine fibers). Differential diagnoses clinically include Duane syndrome and Mobius syndrome. In Duane's syndrome there will be selective absence of motor neurons in the abducent nuclei. Hence there will be absence of the abducens nerve on MRI (CISS3D). In Mobius syndrome, there will be absence of both the abducent and the facial nuclei. So the patient presents with facial diplegia associated with horizontal gaze palsy. MR imaging will demonstrate brainstem hypoplasia with straightening of the fourth ventricle floor due to absence of the facial colliculi and absence of the abducens nerves.



Summary

MR imaging may play a critical role on the precocious diagnosis of HGPPS by showing the maldevelopment of the brain stem, uncrossed sensorimotor tracts (DTI) and ipsilateral activations on fMRI. Early diagnosis of this congenital entity may be important to apply supportive therapies to prevent rapid progression of scoliosis and prevent unnecessary further investigations.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Imaging Evaluation of Meniere's Disease in Children

Vasani, D.·Malhotra, A.
Yale University School of Medicine
New Haven, CT.

Purpose
To identify and assess the reliability of an imaging finding associated with Meniere's disease in pediatric patients.
Case Report
We report a case of a 10-year-old boy with fluctuating hearing loss. Imaging evaluation with CT of temporal bones was performed, as requested by the patient's referring pediatric otolaryngologist.
Imaging Findings
Thin section axial CT imaging of the temporal bones with multiplanar reformatted images in our patient demonstrated nonvisualization of the vestibular aqueduct bilaterally. Previous studies have indicated that vestibular aqueduct size is smaller in patients with Meniere's disease in comparison to control patients and that in approximately 30% of patients with Meniere's disease the vestibular aqueduct is nonvisible. However, to our knowledge, the expected visibility of the vestibular aqueduct in pediatric patients had not been studied. To that end, we reviewed 10 randomly chosen "normal" CT examinations of the temporal bones performed between 2009-2012, of patients between the ages of eight-12 years old. This retrospective review confirmed that the vestibular aqueduct typically is well seen on thin section CT imaging of the temporal bones, even in pediatric patients.
Summary
We demonstrate the expected visibility of the vestibular aqueduct in pediatric patients. Thus, in patient's in whom Meneire's disease is clinically suspected, the absence of visualization of the vestibular aqueducts may reliably be used as supportive evidence towards that diagnosis.

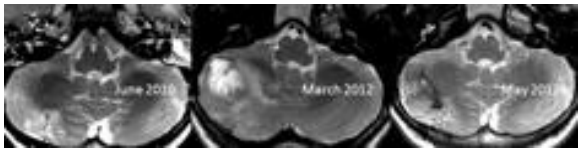
KEYWORDS: Meniere, Temporal bone, vestibular aqueduct

EE-72

Neovascularization and Hemorrhagic Transformation of Cerebellar Tubers in Tuberous Sclerosis Complex

Banker, P.·Rodrigues, D.·Salamon, N.
University of California Los Angeles
Los Angeles, CA.

Purpose
To describe a case of tuberous sclerosis complex (TSC) with cerebellar lesions that experienced changes in signal and morphology over time, including development of neovascularization and hemorrhage, suggesting an alternate pathogenesis of cerebellar tubers that differs from the natural course of cerebral tubers.
Case Report
A 14-year-old boy with history of TSC with right cerebellar tubers that demonstrated changes in size, signal, and content over time with eventual hemorrhagic transformation. He was diagnosed initially at one month of age when noted to have left-sided lip smacking and twitching of the left arm. Bleeding of the cerebellar tuber was discovered when the patient presented with ataxia. MR imaging over an 11-year period from ages two to 13 was reviewed for the patient. A retrospective review of MR imaging from 61 pediatric and young adult patients with TSC found 15 patients with cerebellar lesions (24.6%). The UCLA cohort showed 17 total cerebellar tubers of which six underwent change over time, including our case of hemorrhage. Tuberous sclerosis complex is an inherited systemic disease with prominent CNS, cutaneous, and visceral manifestations. Cerebellar tubers are uncommon, occurring 24-28% of the time in TSC. While Vaughn et al. recently have described cerebellar tubers to evolve with time, the development of adjacent vascularity and propensity for bleeding has never been reported.
Imaging Findings
MR imaging of the brain in our patient at the time of presentation demonstrated at least 25 cerebral tubers, bilateral subependymal nodules, and a right cerebellar tuber. His right cerebellar tuber initially showed T1 hypointensity, T2/FLAIR hyperintensity, enhancement, but no calcification or prominent cortical vessels. Over time, this lesion developed a new cortical vessel, adjacent focal parenchymal atrophy, and calcification. This lesion was found to ultimately hemorrhage about 11 years after its discovery. The hemorrhage bed on follow-up MRI was smaller.



Summary
Tuberous sclerosis complex is a unique neurophakomatosis with diverse manifestations. We describe specific progressive changes in cerebellar tubers in TSC and propose that these changes may have prognostic importance, especially as seen in our case of neovascularization and hemorrhage. Unlike cerebral tubers, which tend to remain stable, the morphologic evolution and vascular development of cerebellar tubers suggests that an alternate pathogenesis may play a role in the progression of these lesions.

Safety and Efficacy of Onyx Embolization for Pediatric Spinal Perimedullary (Type IV) Fistula

Honarmand, A. R.[1]·Soltanolkoltabi, M.[1]·Ansari, S. A.[1]·Schoeneman, S. E.[2]·Patel, B.[1]·Hurley, M. C.[1]·Tadanori Tomita, T.[2]·Shaibani, A.[1]
[1]Northwestern University Feinberg School of Medicine, Chicago, IL, [2]Ann & Robert H. Lurie Children's Hospital of Chicago, Chicago, IL.

Purpose
Several endovascular embolic agents have been utilized for permanent obliteration of perimedullary spinal arteriovenous fistulas (sAVFs) in children; however, endovascular embolization using ethylene vinyl alcohol copolymer (Onyx) has not been widely described in treatment of this type of spinal lesion in the pediatric population. We describe the usefulness of Onyx in endovascular embolization of two pediatric high-flow perimedullary sAVFs.
Case Report
Case 1: During evaluation of a 7-year-old boy presenting with abdominal pain, incidental intraspinal vascular abnormalities were detected on a contrast-enhanced CT abdomen/pelvis study. Subsequent MRI revealed dilated vascular flow voids predominantly along the ventral surface of the spinal cord extending from the lower thoracic level to the cauda equina appearing to be intradural but extramedullary and suggestive of a perimedullary sAVF. The patient had been completely asymptomatic. Physical examination was normal except for an audible bruit in the lower back by auscultation. Case 2: A 17-year-old boy with a history of a cervico-spinal arteriovenous malformation presented with right lower extremity pain and progressive ambulatory disturbance. On physical examination he was noted to have considerable right lower extremity weakness associated with tactile and proprioception deficits [modified Rankin Scale (mRS) score: 4].
Imaging Findings
Case 1: Spinal digital subtraction angiography (DSA) demonstrated a high flow intradural AVF at the L3-4 level with multiple feeders (an extremely hypertrophied anterior spinal artery arising from the left T9 intercostal and two enlarged radiculomedullary arteries arising from each lateral sacral artery respectively), classified as a perimedullary AVF (subtype B). Using detachable platinum coils and Onyx 18, progressive embolization of the fistula was initiated in the efferent recipient vein with embolic reflux proximally across the fistulous site and into the distal afferent components of the three major feeding arteries for obliteration. Postembolization spinal DSA one week later revealed a second separate perimedullary AVF subtype A supplied by the PSA which was resected surgically due to the small caliber of the posterior spinal artery supplying this AVF. Case 2: Spinal DSA demonstrated a high-flow dorsal perimedullary sAVF (subtype C) at C7-T1 level with a large recipient venous varix invaginating into the substance of the cervical cord posteriorly. The lesion was supplied entirely from the PSA and the recipient varix drained superiorly into the dorsal longitudinal spinal veins exiting via the petrosal veins, superior petrosal sinuses, and sigmoid sinuses respectively. Embolization of the AVF was performed utilizing Onyx 34 to occlude the proximal venous efferent, with controlled reflux into the fistulous site and distal afferent of several arterial feeders. The patient achieved significant clinical improvement after one year (mRS score: 2).
Summary
To the best of our knowledge, Onyx has been applied in only one case of a perimedullary sAVF embolization in the pediatric population. Although the safety of Onyx in individuals less than 18 years of age has not yet been well established, we believe Onyx embolization could be performed with high degree of safety and efficacy in treatment of spinal perimedullary AVFs in the pediatric population.

Nonenhancing Diskitis and Epidural Abscess in an Immunocompromised Patient: A Case Report

Carr, C. M.·Diehn, F. E.·Kaufmann, T. J.
Mayo Clinic
Rochester, MN.

Purpose
To review an atypical, nonenhancing presentation of lumbar diskitis and epidural abscess in an immuncompromised patient.
Case Report

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

A 61-year-old male with Wegener's granulomatosis and ankylosing spondylitis, immunosuppressed with high-dose prednisone, rituximab, and plasma exchange, was hospitalized for staphylococcus aureus sepsis from a urinary tract source and worsening back pain. A lumbar spine MRI scan raised concern for diskitis with epidural and paraspinal abscess at the lower two lumbar levels, but there were atypical imaging features. Overnight, the patient developed urinary retention, fecal incontinence, and decreased rectal tone. Repeat lumbar spine MRI showed slight progression of the epidural fluid collection. The patient underwent lumbar decompressive surgery that day, and purulent material which cultured positive for S. aureus was evacuated from the epidural space. A S. aureus-positive psoas abscess also was identified and drained. The patient was ultimately discharged on IV antibiotics.

Imaging Findings

Lumbar spine MRI (Figure 1A: FSE T2-weighted; 1B: post-gadolinium T1-weighted with fat saturation) depicted epidural (arrows) and anterior paraspinal (arrowheads) fluid collections centered around L4-5, and abnormal T2 hyperintensity within the L4-5 and L5-S1 intervertebral disks, compatible with diskitis and abscess formation. There was minimal generalized edema-type signal in the L4 through S1 vertebral body marrow best seen on fat-saturated T2-weighted images (not shown). Sagittal fat-saturated T1-weighted post-gadolinium images (Figure 1B) depicted no significant enhancement around the epidural fluid collection, nor in the vertebral body marrow about the L4-L5 and L5-S1 discs, nor in these disc spaces themselves. Notably, a degenerative vacuum phenomenon was present within these discs on an abdominal CT scan from one month prior, but was no longer present on an abdominal CT scan at admission. Admission abdominal CT also showed a new right psoas abscess adjacent to the L4-L5 level.

Summary

We present a case of nonenhancing lumbar diskitis and epidural and paraspinal abscess. The diagnosis of diskitis and epidural abscess is typically supported by associated enhancement on gadolinium contrast-enhanced MRI but may be absent in patients who are substantially immunocompromised and may not be able to mount the inflammatory response necessary to produce such enhancement. It is important to look for other signs to suggest infection, such as intradiskal hyperintense signal on T2-weighted images, epidural and paraspinal fluid collections, and loss of degenerative disk vacuum phenomenon, so as not to delay the diagnosis.

Rare Case of IgG4-Related Hypertrophic Pachymeningitis Involving the Spine with Spinal Cord Compression

Patro, S. N.·Torres, C.·Zwicker, J.
The Ottawa Hospital
Ottawa, ON, CANADA.

Purpose

To present the clinical and imaging features of a patient with IgG4-related hypertrophic pachymeningitis in the thoracic spinal cord that led to spinal cord compression. To discuss the rare central nervous system manifestation of IgG4 related disease.

Case Report

A 58-year-old woman presented with pain in the periscapular region followed by numbness in the feet which extended up the torso over several days. An MRI with gadolinium demonstrated circumferential epidural-dural lesion from C7 toT7 causing spinal cord compression. This was felt to represent a dural-based process, probably inflammatory myofibroblastic tumor, lymphoma or metastases. A CT of the chest/abdomen and pelvis demonstrated no neoplasm. At followup two months later, the patient's symptoms persisted. Repeat MRI showed no change. Three months later, the patient reported a two-week history of leg weakness and profound spasticity in the lower extremities. MR imaging with gadolinium demonstrated circumferential thickening of the dura from C7-T7 which was hypointense on T1- and T2-weighted imaging and enhanced homogeneously. A decompressive T2-T4 laminectomy with excision of the hypertrophied dura was performed. On histopathology the epidural/dural tissue was negative for microorganisms, malignancy, and stromal reaction with the smooth muscle actin antibody and was consistent with idiopathic hypertrophic pachymeningitis. Special staining of the tissue with IgG4 showed positive result. She had no clinical or laboratory findings of active connective tissue disorder, except positive rheumatoid factor. Ten months postoperatively, she complained of increasing numbness in the legs. Repeat MRI demonstrated progression of the disease. She was treated with high dose prednisone and methotrexate. Within days her symptoms improved and follow-up MRI demonstrated significantly improved dural thickening.

Imaging Findings

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

The initial MRI with gadolinium showed concentric epidural-dural lesion from C7 to T7, causing spinal cord compression. Follow-up MRI at two months interval showed no change. Three months later with worsening of symptoms a repeat MRI showed hypointense circumferential dural thickening on T1- and T2-weighted images with postcontrast enhancement. Ten months following decompressive surgery she again developed increasing leg numbness. Repeat MRI showed progression of dural thickening and compression of spinal cord at T5 level. Following treatment with steroid and methotrexate the symptoms and MRI findings showed significant improvement.

Summary

Prominent dural thickening isolated to the spine may be a manifestation of a systemic infectious/inflammatory or neoplastic process. Rare cases will be diagnosed pathologically as inflammatory pseudotumor, inflammatory myofibroblastic tumor, or idiopathic hypertrophic pachymeningitis. IgG4-related pachymeningitis is a very rare condition with only few case reports in the literature. The pathophysiology and pathogenesis still are not understood completely to date; however the favorable response to steroids suggests a benign and treatable condition. Abundant IgG4 immunostaining of the pathologic tissue and increased serum IgG4 concentration, as in our case helps in clinching the diagnosis of this disease. We strongly suggest that the IgG4-related sclerosing disease should always be considered in the differential diagnosis of patients with pachymeningitis.

KEYWORDS: Pachymeningitis, MR imaging, idiopathic, IgG4

MR Imaging of Sporotrichosis Meningitis in a Nonimmunocompromised Adult

Lai, L.·Moritani, T.·Kirby, P.
University of Iowa Hospital and Clinics
Iowa City, IA.

Purpose

To demonstrate MRI findings of an unusual presentation of sporotrichosis as isolated nodular meningitis in a nonimmunocompromised adult.

Case Report

A 22-year-old male construction worker presented with headache, vomiting, and severe lower back pain several months after a motor vehicle accident where he sustained multiple fractures including facial, cervical vertebrae, and ankle fractures. Past medical history included intravenous drug use. Brain and lumbar spine MRI showed meningeal enhancement and enhancing nodules throughout the thoracolumbar spine. Lumbar puncture showed WBC 1980 cells (73% neutrophils, 27% lymphocytes), total protein 720 mg/dl, and glucose <20 mg/dl, negative CSF and AFB stains, and negative bacterial and fungal cultures. Multiple serologic studies for fungal, inflammatory, and viral etiologies were negative. The only positive CSF serologic study was sporothrix with a weakly positive 1:4 antibody titer. Dural biopsy performed at the T11-12 level showed acute and chronic inflammation with necrosis. Gomori Methenamine silver stain showed single septate fungal hypha. Patient initially was treated empirically for tuberculosis but returned one month later with worsening back pain, urinary retention, and lower extremity weakness. Given the positive sporothrix antibody titers, therapy was switched to sporotrichosis treatment with two weeks of amphotericin followed by voriconazole. The patient clinically improved back to baseline. Five months later, lumbar puncture was normal and MRI showed decreased meningeal enhancement.

Imaging Findings

Brain MRI showed meningeal enhancement of the prepontine cistern and right ambient cistern. T2 (Figure, left) and postcontrast (Figure, right) spine MRI showed enhancing intradural, extramedullary nodules with low peripheral T2 signal and central cystic components in the thoracolumbar spine. Differential was fungal or tuberculosis meningitis. Increased T2 cord signal from T8 to the conus was consistent with cord edema.

Summary

Sporotrichosis is a subacute-chronic fungal infection, usually caused by inoculation of soil/moss containing sporothrix schenckii fungi into the skin or subcutaneous lymphatics. Rarely, sporotrichosis can involve the meninges, usually in immunocompromised patients. Obtaining a positive CSF culture of sporothrix is difficult, which can result in delay in treatment. In this case, CSF cultures were negative for sporothrix, but the positive CSF antibody titer, fungal hypha on dural biopsy, and clinical improvement with amphotericin strongly suggested the diagnosis of sporotrichosis. The differential for nodular meningeal enhancement should include fungal meningitis like sporotrichosis. There has been no prior literature on MRI imaging of sporothrix spinal meningitis. We report the MRI features of a rare case of meningeal sporotrichosis in a nonimmunocompromised adult.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Osseous Metastasis of the Spine with Superimposed Osteomyelitis

Gandhe, A. R.·Mohiuddin, J.·Rao, N.·Patel, F.·Flanders, A. E.
Thomas Jefferson University Hospital
Philadelphia, PA.

Purpose
To review the rare occurrence of osteomyelitis and osseous metastasis occurring simultaneously in the spine and to discuss the imaging features. Very few cases of osseous metastasis with coexistent/superimposed infection have been reported in the literature. We report a unique case of osteomyelitis superimposed on vertebral metastasis with associated epidural abscess.
Case Report
A 57-year-old man presented with left-sided headache, neck pain and melanotic stools for three weeks. Imaging demonstrated a destructive enhancing lesion in the occipital bone with epidural extension and edema in the left occipital lobe. On metastatic workup, he was found to have carcinoma of the colon, lymphadenopathy and a lytic lesion in T6 vertebra. Biopsy of the colon demonstrated adenocarcinoma. He underwent resection of the occipital mass which represented metastatic disease. Three weeks later, he presented with abdominal pain. CT demonstrated a lytic lesion with new, innumerable foci of gas throughout T7 vertebral body. Lytic changes and foci of gas also were present in C7 and T5 vertebra and the right fifth rib. There were foci of gas in the epidural space at T6 and in the paraspinal soft tissues. Due to numerous, small foci of intraosseous gas, paraspinal soft tissue gas and gram negative bacteremia, osteomyelitis was considered more likely. Metastatic disease was considered less likely. MR imaging of the spine demonstrated a rim-enhancing epidural collection throughout the thoracic spine, causing mass effect on the spinal cord. Abnormal marrow replacement, enhancement and numerous foci of gas was present in T7 vertebra with a paraspinal soft tissue abscess. There were other scattered marrow replacing lesions in the spine. The patient underwent surgery for evacuation of the epidural abscess, T7 corpectomy and posterior fixation. Histopathology of T7 vertebra demonstrated adenocarcinoma metastasis from the colon with signet ring cells. Culture from T7 vertebra demonstrated Bacteroides fragilis. The patient declined further treatment and was sent to hospice.

Summary
Osseous metastasis with superimposed/coexistent osteomyelitis is extremely uncommon documented in only several published case reports. Both osteomyelitis and metastases show abnormal marrow replacement on MRI and can demonstrate lytic lesions on CT. Isolated foci of gas in primary or secondary bone tumors is extremely unusual. However, the presence of small foci of intraosseous gas strongly suggests osteomyelitis, particularly in the presence of gas in the surrounding soft tissues. In the case of known osseous metastases, the presence of this pattern of intraosseous gas should raise the possibility of coexistent infection.

CT-Guided Transforaminal Ventral Epidural Blood Patch for the Treatment of Intracranial Hypotension

Park, J.·Yoo, B.·Villablanca, J. P.
University of California Los Angeles
Los Angeles, CA.

Purpose
To illustrate the novel technique of treating a ventral cerebrospinal fluid (CSF) leak utilizing a transforaminal blood patch delivered directly into the ventral epidural CSF collection. To our best knowledge the application of this technique under CT guidance has not been reported previously.
Case Report
A 35-year-old male presented with debilitating headaches secondary to recurrent ventral CSF leak, which did not respond to dorsal blood patch. Prior imaging revealed evidence of intracranial hypotension and a large chronic ventral CSF collection. He underwent an exploratory multilevel laminotomy that was unsuccessful in identifying the precise location of patient's dural tear. The patient underwent an additional CT myelogram, which suggested

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

that the site of leakage was approximately at the mid-thoracic level. A decision was made to place a transforaminal epidural blood patch directly into the collection under CT guidance. The technique may be applied as follows: Spinal myelography is performed as usual under fluoroscopic guidance. The patient then is transferred to the CT gantry table and placed prone. Using intermittent low-dose CT guidance, the ventral epidural collection is accessed via transforaminal approach at site of maximal thickness. Following confirmation of needle tip position within the epidural CSF collection, the fluid contents within the fluid collection are aspirated and measured. Incremental, volume-matched, ventral epidural blood patching then is performed under direct intermittent CT visualization using sterile peripheral venous blood until the ventral chamber is completely filled. Twenty-four to 48 hours of supine lumbar drainage postprocedure may be performed. The advantages over fluoroscopically guided techniques include direct visualization of target collection in ventral epidural space, direct visualization of critical neurovascular structures to be avoided(vertebral artery, spinal cord, spinal nerves), and direct visualization of access into, and injection of blood into the ventral epidural collection, maximizing technical success and potential therapeutic benefit.

Imaging Findings

Image A: Intraprocedural prone axial CT images demonstrates spinal needle placed via right transforaminal posterior lateral approach at T6 with needle tip within ventral epidural CSF collection filled with contrast. VES indicates ventral epidural space; VSS, ventral subarachnoid space. Image B: Sagittal postprocedural CT demonstrates ventral epidural space now filled with isodense peripheral venous blood, previously filled with high density contrast. C indicates cord.

Summary

In properly selected patients, CT-guided transforaminal blood patching may serve as a safe and effective alternative to extensive multilevel corpectomy and surgical exploration for the treatment of symptomatic intracranial hypotension caused by ventral epidural CSF leak.

EE-79

Chordoma Mimicking the Imaging Appearance of a Neurofibroma Extending through the Neural Foramen

Mohiuddin, J.·Gandhe, A. R.·Flanders, A. E.
Thomas Jefferson University Hospital
Philadelphia, PA.

Purpose

To review the rare appearance of a chordoma presenting as an extradural mass exiting through an expanded neural foramen and mimicking the appearance of a nerve sheath tumor such as a neurofibroma. CT-guided biopsy confirmed the diagnosis of chordoma with tumor cells having a vacuolated, "physaliphorous" appearance and showed positive immunohistochemical staining. To our knowledge, this is the eleventh reported case of chordoma presenting as a mass expanding the neural foramen. Making the correct diagnosis prior to surgery is important as radical resection of chordoma is required to reduce the risk of local recurrence.

Case Report

A 24-year-old female presented with significant neck pain as well as a history of bilateral hand numbness and tingling and some mild weakness in the bilateral hands. She also complained of difficulty with fine motor activities. She denied any bowel or bladder dysfunction but was noted to be ataxic. The patient had no significant past medical history. No sensory deficit was found on physical examination. No motor deficits were found, apart from 3+ muscle strength involving the triceps, wrist extensors, and finger flexion on the right (compared to 4+ strength on the left). Hand intrinsics were 3+ bilaterally. Given the neck pain and upper extremity weakness, MRI of the cervical spine was performed. This showed a large epidural tumor extending from C3 to C6, exiting through the neural foramina and causing some bony destruction predominantly at C4.

Imaging Findings

The preliminary diagnosis by imaging was made of neurofibroma or lymphoma. In the absence of a history of neurofibromatosis, CT-guided biopsy was arranged. The core biopsy showed cords of cells with eosinophilic cytoplasm situated in a myxoid matrix. Many tumor cells had a vacuolated, "physaliphorous" appearance. Tumor cells showed positive immunohistochemical staining and the diagnosis of chordoma was made. The patient underwent radical resection with cervical decompression, including sacrificing the encased right vertebral artery. She tolerated the procedure well with no complications. To date, the patient has not had evidence of recurrence, although she still complains of pain.

Summary

Morbidity and mortality regarding chordoma usually is related to local recurrence rather than distant metastasis. Therefore, en-bloc resection is necessary to prevent residual tumor or seeding of the surgical tract, and this underscores the importance of a correct preoperative

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

diagnosis. Although the MRI findings in our case were felt to be characteristic of a plexiform neurofibroma, the absence of a history of neurofibromatosis and the ability to safely target the large paraspinal component of the mass led to a biopsy that better informed the type of surgical treatment. Thus, we report to our knowledge the eleventh reported case of a chordoma presenting as a mass expanding the neural foramen and mimicking the more characteristic appearance of a nerve sheath tumor.

Primary Intradural Extramedullary Anaplastic Ependymoma: Report of a Case and Review of the Literature

Koohi, Y.·Durst, C.·Raghavan, P.·Nicolas-Jilwan, M.
University of Virginia
Charlottesville, VA.

Purpose
Primary intradural extramedullary ependymomas are extremely rare and develop from ectopic ependymal cell nests. There are approximately 19 reported cases in the literature, the vast majority of which are low grade with very few reported primarily anaplastic tumors at presentation. Approximately 80% of affected patients are females. To the best of our knowledge, there is to date no reported case of an anaplastic intradural extramedullary ependymoma with diffuse leptomeningeal dissemination at the time of presentation. We present a unique case of a grade III intradural extramedullary ependymoma in a 23-year-old male with extensive leptomeningeal dissemination at the time of diagnosis.
Case Report
The patient is a 23-year-old male who presented with neck pain radiating to the left arm associated with left upper extremity weakness and paresthesias. A cervical spine MRI revealed an intradural extramedullary tumor in the ventral thecal sac at C4 to C7 levels with severe cord compression, mild cord edema, and associated diffuse leptomeningeal nodularity and enhancement. The patient was started on steroids but presented a few weeks later with left foot drop and urinary retention. Imaging of the remainder of the neural axis revealed diffuse leptomeningeal dissemination at the thoracolumbar levels without imaging evidence of intracranial spread. A C4-C7 laminoplasty and tumor debulking were performed. The tumor was very adherent to the nerve roots and resection was subtotal. No cord or dural invasion was present. Postoperatively, the patient's symptoms improved with only mild residual weakness and numbness in the left upper extremity.
Imaging Findings
Cervical spine MRI at presentation shows a mildly heterogeneous avidly enhancing intradural extramedullary tumor in the ventral thecal sac spanning the C4 through C7 levels, eccentrically situated on the left without extradural extension. The tumor had a wide base along the dura. It caused severe cord compression with only mild cord edema. There was diffuse associated leptemeningeal nodularity and enhancement at the cervical, thoracic, and lumbar levels. No intracranial leptomeningeal enhancement was noted. There was no evidence of lymphadenopathy in the included portions of the neck, chest, and abdomen or abnormal bone marrow signal to suggest metastatic disease. While the patient's age would strongly favor metastatic lymphoma, the discrete amount of cord edema, lack of other evidence of metastasis, and the broad dural base and location of the lesion suggested a preliminary diagnosis of an atypical meningioma.
Summary
Intradural extramedullary ependymomas are extremely rare and most commonly low grade (WHO grade II) tumors. They frequently are misdiagnosed as meningiomas on preoperative imaging. Very few cases of primarily anaplastic tumors have been described previously in the literature, the majority of higher grade tumors showing extradural components. Our case illustrates one of these primarily anaplastic tumors with the unique feature of associated leptomeningeal dissemination at the time of presentation and lack of extramedullary extension. Although very rare, anaplastic extramedullary ependymomas should be included in the differential diagnosis of intradural extramedullary tumors with unusual features.

Epidural Chondrosarcoma from the Intervertebral Disk without Osseous Abnormalities

Kalra, V. B.·Gibson, J.·Malhotra, A.
Yale University
New Haven, CT.

Purpose
Chondrosarcoma in the spine is an uncommon entity, and when present, usually demonstrates osseous findings of scalloping, cortical disruption, and periosteal reaction. We present two cases that appear as isolated epidural masses arising from the intervertebral disk level with intact adjacent vertebrae.
Case Reports
Patient #1 - 74-year-old woman with leg weakness and back pain underwent a T11-T12 decompressive laminectomy for a ventral epidural lesion thought to represent a meningioma. MR imaging showed that she had severe spinal canal stenosis from the ventral epidural mass with its epicenter at the T11-T12 disk space. The lesion was mildly hyperintense on T2, hypointense on T1, and had punctate foci of enhancement. A year later, she redeveloped leg weakness, had similar MR findings, and underwent subtotal tumor excision. Pathology showed pleomorphic multinucleate chondrocytes consistent with

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

low-grade chondrosarcoma. Two years later, she developed compression fractures with retropulsion and underwent T11 and T12 anterior corpectomy, five CyberKnife treatments, and vertebroplasty of lower thoracic spine with instrumented fusion from T8-L5. T11-T12 diskectomy demonstrated the same pathology - low-grade chondrosarcoma. Patient #2 - 64-year-old man with lower back and leg pain with a L4-L5 posterior decompression for a ventral epidural lesion. MR imaging showed a ventral epidural mass at the L4-L5 disk space level causing severe spinal canal stenosis. The lesion was hyperintense on T2 and hypointense on T1. Pathology showed pleomorphic multinucleate chondrocytes consistent with low-grade chondrosarcoma.The mass grew slowly over six years to extend to the one higher disk space with no significant change in degree of spinal canal stenosis. There was also extension through multiple adjacent neural foramina.

Imaging Findings

Patient #1 - MR imaging demonstrates a 3 cm T2 hyperintense and T1 hypointense lesion in the epidural space with the epicenter at the T11-T12 disk space. The lesion demonstrated multiple punctate foci of enhancement. There were no associated osseous abnormalities. The T11-T12 intervertebral disk was unremarkable. CT demonstrated vague calcifications within the lesion. No significant growth was seen over one year prior to tumor resection and no recurrence was seen as of four years after resection. Patient #2 - MR imaging demonstrates a 4.8 cm x 1.1 cm T2 hyperintense and T1 hypointense lesion in the epidural space with the epicenter at the L4-L5 disk space. There were no associated osseous abnormalities. The L4-L5 intervertebral disk demonstrated degenerative changes similar to those seen at adjacent levels. CT demonstrated vague calcifications within the lesion. Six years later, the lesion grew slightly, 1 cm cranially and through the adjacent neuroforamina.

Summary

We present two cases of previously unreported low-grade chondrosarcomas isolated to the epidural space with their epicenters at intervertebral disks and no osseous involvement. Chondrosarcoma should be included in the differential of epidural lesions even if there is no osseous involvement, especially if CT demonstrates matrix calcifications and the lesion has its epicenter at an intervertebral disk.

Intraosseous Glomus Tumor of the Thoracic Spine

Fong, C. L.·Ngo, M.
Kaiser Permanente Los Angeles
Los Angeles, CA.

Purpose

The purpose of this case report is to demonstrate the findings of an intraosseous spinal glomus tumor.

Case Report

Intraosseous spinal glomus tumors are extremely rare entities. This case is of an 89-year-old male who presented to the ER with worsening gait.

Imaging Findings

CT imaging demonstrates a lytic lesion. MR imaging demonstrates an avidly enhancing markedly T2 hyperintense mass with a salt and pepper appearance due to flow voids. The mass has epidural and paravertebral extension.

Summary

In summary, intraosseous glomus tumors of the spine are extremely rare neoplasms that have a classic MR appearance similar to glomus tumors of the head and neck.

KEYWORDS: Spinal neoplasm, CT, glomus

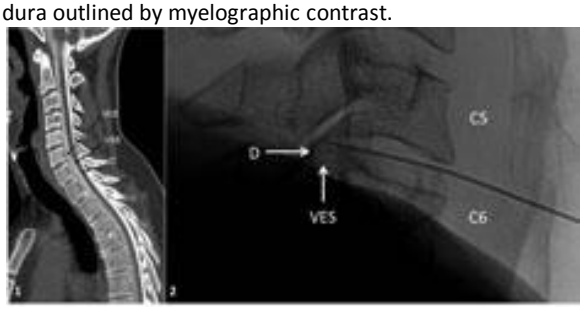
Feasibility of Placement of an Anterior Cervical Epidural Blood Patch for Spontaneous Intracranial Hypotension Secondary to a Ventral Dural Tear

Park, J. K.·Yoo, B.·Villablanca, J. P.
University of California Los Angeles
Los Angeles, CA.

Purpose
To illustrate a detailed guide for the novel technique of placing an anterior cervical blood patch for a large cervical ventral cerebrospinal fluid (CSF) leak.
Case Report
A 41-year-old man presented one year after onset of debilitating post-traumatic positional headaches with imaging evidence of intracranial hypotension. Before presentation at our center, he was treated unsuccessfully with multiple lumbar epidural blood patches (EBP) at outside hospitals. CT myelogram demonstrated a large ventral epidural contrast collection secondary to dural tear in the cervical spine. Given the large size of the collection and unknown exact location of dural injury it was thought that exploring the ventral spinal column would require morbid surgery and extensive vertebrectomies, and an anterior EBP approach was performed. Following supine placement on the fluoroscopy table, the C5-C6 disk space was identified and increasing digital pressure was applied in the right anterior neck to displace the carotid sheath laterally, and the esophagus and trachea medially. A spinal needle then was advanced through the target disk under fluoroscopy, with entry just right of midline. After confirmation of needle tip placement in the ventral epidural space with myelographic contrast and gentle CSF aspiration, fresh sterile peripheral blood was slowly injected into the collection without complication. Subsequently 72 hours of lumbar drainage was performed utilizing a lumbar drainage catheter. Our patient experienced marked symptomatic improvement and no complications.
Imaging Findings
Image 1 - Preprocedural sagittal CT myelogram demonstrates a large and continuous ventral epidural contrast collection extending from the C3-C4 through thoracic levels. While the exact site of communication with the ventral subarachnoid space (VSS) could not be identified, both a contrast-attenuation gradient and the largest cross-sectional area of the epidural collection were seen in the lower cervical region, suggesting cervical leakage site. VES indicates ventral epidural space; C, cord.
Image 2 - Lateral fluoroscopic image demonstrating the needle traversing the C5-6 disk space, with tip in the ventral epidural collection/space (VES). D indicates ventral

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

dura outlined by myelographic contrast.



Summary
We present, to our knowledge, the first case of the placement of an anterior EBP for the treatment of SIH from a cervical ventral dural tear. We suggest that in appropriately selected patients with refractory ventral cervical CSF leaks, the anterior technique can be performed safely.

KEYWORDS: Intracranial hypotension, Blood patch

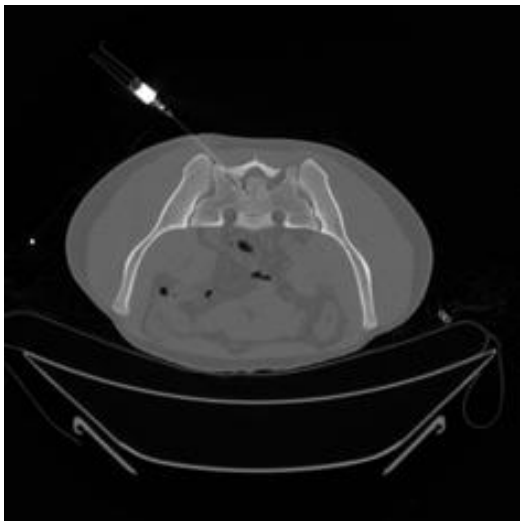
Rare Intraperitoneal Cerebrospinal Fluid Leak: A Unique Therapeutic Approach with Sacral Transforaminal Epidural Blood Patch

Fortes, M. C.·Jindal, G.·Miller, T.·Gandhi, D.
University of Maryland
Baltimore, MD.

Purpose
To report a case of severe intracranial hypotension secondary to Tarlov cyst intraperitoneal CSF leak, treated with CT-guided sacral transforaminal blood patch.
Case Report
A 41-years-old healthy male presented to the Emergency Department with a three weeks history of increasing headaches. Patient denied trauma, antiplatelets or anticoagulants. Normal laboratorial workup. Initial imaging evaluation of the head was performed with noncontrast CT and CT angiogram. A cerebral angiogram followed. A CT myelogram and MRI of the spine then were performed. A diagnosis of subdural hematoma secondary to intracranial hypotension was made. A CSF leak adjacent to a Tarlov cyst was identified. To avoid open surgery, a minimally invasive approach was chosen. A CT-guided right S2-3 transforaminal epidural blood patch was performed. After the procedure, patient's symptoms steadily improved and completely resolved in the following week. Follow-up nuclear imaging confirmed complete resolution of the CSF leak.
Imaging Findings
Noncontrast CT of the head demonstrated a subdural hematoma. CT angiogram of the head showed no vascular abnormalities. Cerebral angiography was also negative. MR imaging of the spine showed a 15 mm Tarlov cyst at the S2-3 level. Also seen was free fluid in the peritoneal cavity. CT myelogram demonstrated an area of CSF leakage, adjacent to the Tarlov cyst, at the level of the right S2 nerve root, extending inferiorly beyond the nerve sheath and towards the piriformis muscle and abdominal cavity. CT-guided epidural blood patch with injection of 0.5 ml of Ominipaque 180 contrast confirmed the leakage and again showed contrast along the right S2 nerve and into the right piriformis muscle. Indium-111 radiotracer was injected to the thecal sac 24 hours postepidural blood patch. Planar gamma camera imaging acquisition showed no residual CSF leak.



Summary
Cerebrospinal fluid leakage to the peritoneal cavity is a rare finding. Tarlov cyst rupture causing severe intracranial hypotension with subdural hematoma formation is managed more commonly with open surgical repair. We report our experience in a successful attempt of performing a less invasive CT-guided epidural blood patch as an alternative to open surgery.

Technique for CT Localization of Site of Leakage in Patients with Symptomatic Ventral Cerebrospinal Fluid Leaks

Yoo, B. Y.·Park, J. K.·Bentson, J.·Villablanca, J. P.
Ronald Reagan University of California Los Angeles Medical Center
Los Angeles, CA.

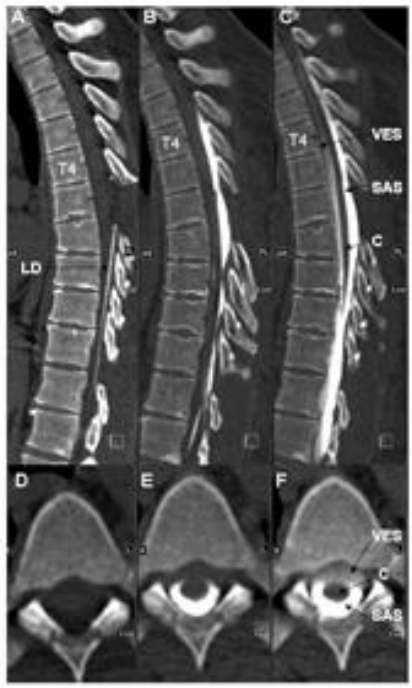
Purpose
To illustrate a novel technique for the detection of the site of leakage of cerebrospinal fluid (CSF) into the ventral epidural space utilizing the "chalice" technique.
Case Report
A 35-year-old male with debilitating headaches and imaging findings of intracranial hypotension secondary to

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

recurrent ventral CSF leak. Imaging revealed a large ventral CSF leak from C3 to L1. However, conventional and CT myelography, nuclear cisternography and surgical exploration did not localize the site of leakage. We utilized a novel “chalice” technique to localize the site of CSF leakage, as follows: A lumbar drain is placed into the CSF space using fluoroscopic guidance at the midpoint of the segment of interest. The patient then is placed in the supine position, utilizing the “chalice” technique [i.e., creation of an asymmetric kyphotic deformity at the mid thoracic spine (or appropriate spine segment) by using cervical and lumbar bolsters]. The subarachnoid space then is incrementally filled with small amounts of myelographic dye (Omnipaque-240) via the lumbar drain. Contrast begins to pool progressively in the dependent portion of the subarachnoid space. Intermittent, low dose CT scanning then is used to detect the vertebral level at which contrast opacification of the ventral epidural collection first occurs, as the dye “spills over” from the subarachnoid space into the ventral epidural collection, through the ventral dural defect. Once identified, a targeted surgical repair or blood patch of the dural defect can be performed.

Imaging Findings

Sagittal and axial CT images of the thoracic spine during intermittent injection of contrast through a lumbar drain into the subarachnoid space. Initial injection (B, E) demonstrates a column of dye in the SAS, without contrast filling of the VES. Subsequent injection of dye (C, F) demonstrates cephalad progression of contrast, with filling of the VES first noted when the dye in the SAS reached the T3 level, suggesting T3 as the level of the leak. VES = ventral epidural space; SAS = subarachnoid space; C = spinal cord; LD = lumbar drain.



Summary

When traditional methods have failed, the “Chalice" technique may be an effective method to identify the level of a ventral CSF by using low-dose CT monitoring of sequential filling of the subarachnoid space until the “spill-over” location is identified.

KEYWORDS: CSF leak, Myelography, intracranial hypotension

EE-87

Extradural Glioependymal Cyst: A Rare Cause of Spinal Cord Compression

Griffith, B.·Patel, S.·Abdulhak, M.·Gutierrez, J.
Henry Ford Hospital
Detroit, MI.

Purpose

Glioependymal cysts are rare congenital lesions of the central nervous system. While occurring in the spine, the lesions are typically intradural in location. This excerpta describes a rare case of an extradural glioependymal cyst causing compression of the thecal sac and cauda equina.

Case Report

We present a case of a 46-year-old man presenting with one to two-year history of bilateral lower extremity weakness and right foot drop. While the symptom onset was gradual, there had been noticeable worsening over the past year. The patient also complained of numbness, tingling, an a pressure sensation in the lower extremities.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

Electromyography demonstrated bilateral L1-S1 polyradiculopathies, worse on the right. The patient underwent a T11-L2 decompressive laminectomy at which time a thin, semitransparent epidural cyst was removed. Pathology demonstrated a cyst lined by flat cuboidal cells, which were strongly GFAP-positive with focal, intraluminal thick strands forming heaps of GFAP-positive tissue. The cells lining the cavity were EMA and CK negative. These findings are consistent with a glioependymal cyst. Following surgery and rehabilitation, the patient had mild persistent leg weakness.

Imaging Findings

Lumbar spine MR demonstrates a large T2 hyperintense/T1 hypointense extradural cystic lesion (Figure 1) along the posterior spinal canal extending from T12 to L3 with compression of the thecal sac and cauda equina. Bony remodeling and intraforaminal extension with foraminal widening also are present. CT myelogram redemonstrates the large extradural cystic lesion with slow filling of contrast on delayed images indicating communication with the thecal sac (Figure 2).

Summary

Glioependymal cysts are rare, congenital, non-neoplastic lesions of the CNS, lined by a single layer of cuboidal or columnar epithelium. Lesions are thought to be developmental in origin, arising from displaced ependymal cells that become isolated from the neural tube floor plate during embryogenesis. While rare, there are a number of case reports detailing both intra and extramedullary intradural lesions. To the best of our knowledge, this is only the second reported case of an extradural lesion, perhaps secondary to a dural defect permitting its extradural development. In conclusion, glioependymal cysts, while rare, should be considered in the differential diagnosis of extradural cystic spinal lesions.

KEYWORDS: Ependymal cyst, Extradural

Spinal Metastasis of Intracranial Primary Malignant Peripheral Nerve Sheath Tumor

Gandhe, A. R.·Mohiuddin, J.·Patel, F.·Talekar, K.·Flanders, A. E.
Thomas Jefferson University Hospital
Philadelphia, PA.

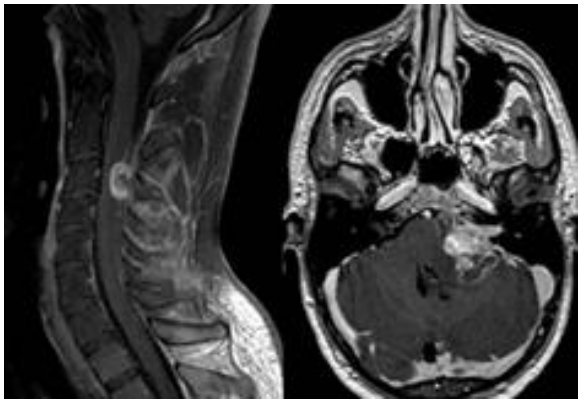
Purpose

To review the drop metastasis from intracranial malignant peripheral nerve sheath tumors (MPNST). Intracranial malignant peripheral nerve sheath tumors are extremely rare; less than 50 cases have been reported in the literature. Drop metastasis from intracranial MPNSTs had been described in only three prior reports. Two patients had a history of cranial radiation in childhood and one had malignant conversion of a vestibular schwannoma. We report the first case of de novo primary intracranial MPNSTs with drop metastasis to spine.

Case Report

A 27-year-old male presented with left facial weakness, hand numbness and severe headache for one week. His past medical history was significant for malignant rhabdomyosarcoma of the left thigh at the age of four, treated with chemotherapy and radiation. Though exact details of prior treatment were not available, there was no history of brain metastasis and radiation. CT scan and MRI of the brain demonstrated a left cerebellopontine angle hemorrhagic, enhancing, extra-axial mass lesion, causing compression on the 4th ventricle and obstructive hydrocephalus. Workup for metastasis was negative. Patient underwent uneventful resection with significant improvement in symptoms. Ventriculoperitoneal shunt also was placed for hydrocephalus. Pathology revealed a sarcoma most compatible with a malignant peripheral nerve sheath tumor. The patient then began a course of radiation therapy. Approximately three months later, he presented with neck and upper back pain with tingling in feet. An MRI of the spine demonstrated an intramedullary hemorrhagic enhancing mass lesion at C2 in the cervical spine and a smaller intramedullary enhancing lesion at T10 in the thoracic spine. The patient underwent immediate resection of the cervical lesion. Histopathology was consistent with MPNST, similar to the intracranial tumor. There was no residual tumor on immediate postoperative MRI. Three weeks later, he returned with a rapid onset of quadriparesis. MR imaging of the cervical spine demonstrated a recurrent hemorrhagic intramedullary mass at C3-C4. He underwent re-resection and was sent to rehabilitation.

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.



Summary
Intracranial MPNST is a very rare entity with a poor prognosis. It is a very aggressive tumor with a very high recurrence rate even after gross total resection. Only three cases of this kind have been reported previously, probably related to short life span after presentation. This is first case of de novo primary intracranial Malignant peripheral nerve sheath tumors with drop metastasis. Malignant peripheral nerve sheath tumors is a diagnostic consideration in the setting of a rapidly growing hemorrhagic extra-axial mass lesion.

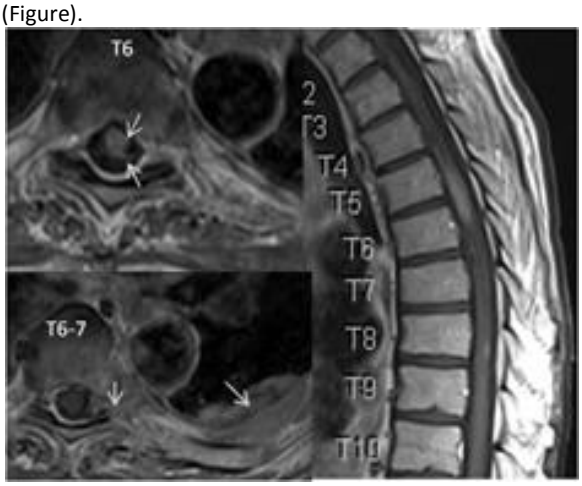
Perineural Spread of Malignant Mesothelioma with Spinal Cord Involvement

Newman, S. A.·Mohan, S.·Melhem, E. R.
Hospital of the University of Pennsylvania
Philadelphia, PA.

Purpose
We report a rare presentation of malignant mesothelioma with perineural spread of neoplasm along an intercostal nerve to invade the parenchyma of the spinal cord.
Case Report
Our patient is a 76-year-old man with previously biopsy-proven malignant mesothelioma who was undergoing palliative chemoradiation therapy. He presented with acute onset of urinary retention, bilateral lower extremity weakness and parasthesias with a new thoracic sensory level on neurologic examination. There were no pre-existent focal neurologic deficits. MR imaging scan of the thoracic spine demonstrated a pleural mass invading the left posterior chest wall with perineural spread along the left 6th intercostal nerve to involve the left T6 nerve root and parenchyma of the spinal cord. Based on the history and findings, the imaging diagnosis of malignant mesothelioma with extramedullary and intramedullary spinal cord involvement via perineural spread was proposed. The patient was started on steroids and underwent targeted proton therapy to the thoracic spine followed by fractionated daily radiation therapy, with improvement of bilateral lower extremity strength and sensation. Follow-up MRI performed one month later demonstrated decreased size of the enhancing intramedullary mass with decreased mass effect.
Imaging Findings
Contrast-enhanced MRI of the thoracic spine demonstrated a 5.8 cm pleural mass invading the left posterior chest wall, including the 6th, 7th, and 8th ribs and the left lateral paraspinous soft tissues, extending through the left T6-7 neural foramen contiguously involving the left lateral epidural space/dura mater, in continuity with enhancing intradural, extramedullary mass, with associated thickening and enhancement of the dorsal and ventral nerve roots. There was associated enhancing intramedullary mass in the thoracic cord, measuring 7 mm transverse by 7 mm anteroposterior by 38 mm craniocaudad, spanning the T5 and T6 levels, with extensive cord edema spanning from T4 through T9 (Figure).



Summary
This case demonstrates the rarely reported finding of intramedullary involvement of the spinal cord via perineural spread by malignant mesothelioma.

Synovial Osteochondromatosis of the Craniocervical Junction with Spinal Cord Compression

Garger, A. V.·Zacharia, B. E.·Bruce, J. N.·Ross, R. L.·Lignelli, A. A.
Columbia University New York Presbyterian Medical Center
New York, NY.

Purpose
To report a rare case of synovial osteochondromatosis resulting in cervical spinal cord compression.
Case Report

Note: Scanned images are included in the proceedings. Some submitted images were reduced during editing, thereby decreasing clarity. Also, refer to the Program Planner. Proceedings Content as of 3-29-2013.

An 82-year-old man presented with progressive right upper extremity weakness and diminished dexterity. MR imaging demonstrated a 2.1 x 1.5 cm, well circumscribed, nonenhancing, extramedullary mass at the level of the dens, markedly compressing the spinal cord. Magnetic susceptibility artifacts in the mass were suggestive of calcifications. Image-based differential included calcified meningioma, chordoma, synovial osteochondromatosis, chondrosarcoma, retro-odontoid psudotumor and dural metastasis. A right far lateral exposure was utilized to approach the lesion and grossly the tumor was avascular and soft. Pathology demonstrated dense fibrous and cartilaginous makeup with features consistent with synovial osteochondromatosis. Postoperative MRI demonstrated residual T2 signal abnormality of the spinal cord consistent with edema or myelomalacia. The patient underwent inpatient rehabilitation and has subjective improvement of his right arm deficits at two months followup.

Imaging Findings

A large mass was identified which demonstrated heterogeneous low T1 and T2 signal, as well as mild peripheral enhancement. The mass was severely compressing the spinal cord at the level of the dens (Figure 1: Axial and Sagittal T1 post contrast).
